EMERGENCY MEDICINE PROCEDURES

Eric F. Reichman

Second Edition

DVD INCLUDED
WITH ANIMATIONS OF KEY PROCEDURES!

Emergency Medicine Procedures

NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the editors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Emergency Medicine Procedures

Second Edition

Eric F. Reichman, PhD, MD, FAAEM, FACEP
Associate Professor of Emergency Medicine
Attending Physician, Department of Emergency Medicine
Medical Director, Surgical and Clinical Skills Center
University of Texas Health Science Center at Houston-Medical School
Attending Physician, Emergency Department
Memorial Hermann Hospital-Texas Medical Center
Attending Physician, Emergency Department
Lyndon Baines Johnson General Hospital
Houston, Texas

This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

To my wife, Kristi. Thanks for your patience with the semi-permanent card table and computer in the living room, and the mess with all the papers and files. Thanks for your support and understanding. Thanks to Joey, Jake, Rocky, and Phoebe for entertaining me each day.

Contents

Contributors . . . . . *xiii*
Preface . . . . . *xxiii*
Acknowledgments . . . . . *xxiv*

SECTION 1 Introductory Chapters 1

1 **Informed Consent for Procedures in the Emergency Department** 1
Eric Isaacs

2 **Aseptic Technique** 6
John S. Rose

3 **Basic Principles of Ultrasonography** 13
Gregory M. Press

4 **Ultrasound-Assisted Procedures** 24
Jehangir Meer, Sam Hsu, and Brian Euerle

5 **Trauma Ultrasound: The FAST Exam** 28
Wes Zeger

SECTION 2 Respiratory Procedures 35

6 **Essential Anatomy of the Airway** 35
Ned F. Nasr, Serge G. Tyler, Gennadiy Voronov, and Isam F. Nasr

7 **Basic Airway Management** 40
Christopher J. Russo and Zach Kassutto

8 **Pharmacologic Adjuncts to Intubation** 47
Ned F. Nasr, David W. Boldt, and Isam F. Nasr

9 **Endotracheal Medication Administration** 56
Shoma Desai

10 **Rapid Sequence Induction** 60
Piotr C. Aljindi, Ned F. Nasr, and Isam F. Nasr

11 **Orotracheal Intubation** 64
Eric F. Reichman and Joseph Cornett

12 **Confirmation of Endotracheal Intubation** 76
Tarlan Hedayati and Leonardo Rodriguez

13 **Video-Assisted Orotracheal Intubation Devices** 80
Pholaphat Charles Inboriboon

14 **Fiberoptic-Assisted Orotracheal Intubation Devices** 89
Michael Lutes and Olga Pawelek

15 **Endotracheal Tube Intubating Introducers and Bougies** . . . 95
Olga Pawelek and Eric F. Reichman

16 **Digital (Tactile) Orotracheal Intubation** 100
O. John Ma and Amanda Munk

17 **Lighted Stylet Intubation** 102
Philip Bossart and Michael Wallace

18 **Supraglottic Airway Devices** 106
Fred A. Severyn

19 **Laryngeal Mask Airways** 110
Katrin Takenaka and Theltonia Howard

20 **Double Lumen Airway Tube Intubation** 122
Joseph Weber

21 **Fiberoptic Endoscopic Intubation** 127
Erika D. Schroeder, M. Scott Linscott, and Joseph Bledsoe

22 **Nasotracheal Intubation** 134
Ned F. Nasr, Raed Rahman, and Isam F. Nasr

23 **Retrograde Guidewire Intubation** 139
Roland Petri

24 **Percutaneous Transtracheal Jet Ventilation** 143
Eric F. Reichman and Aaron Brown

25 **Cricothyroidotomy** 148
Eric F. Reichman

26 **Tracheostomy** 161
Teresa M. Romano and Christopher J. Haines

27 **Tracheostomy Care** 171
H. Gene Hern Jr.

28 **Transtracheal Aspiration** 177
Joseph A. Salomone III

SECTION 3 Cardiothoracic Procedures 181

29 **Cardiac Ultrasound** 181
Gregory M. Press and Amy Rasmussen

30 **Cardioversion and Defibrillation** 193
Payman Sattar

31 **Transcutaneous Cardiac Pacing** 197
Todd M. Larabee

32 **Transthoracic Cardiac Pacing** 202
Simon M. Pulfrey

33 **Transvenous Cardiac Pacing** 205
Eric F. Reichman, Myles C. McClelland, and Brian Euerle

34 **Pacemaker Assessment** 212
Nnaemeka G. Okafor

35 **Automatic Implantable Cardioverter-Defibrillator Assessment** 218
Carlos J. Roldan

36 **Pericardiocentesis** 225
Eric F. Reichman, Elisabeth Kang, and Jehangir Meer

37 **Intracardiac Injection** 236
Payman Sattar

38 Needle Thoracostomy . . . 238
Eric F. Reichman and Elizabeth Sowell

39 Tube Thoracostomy . . . 242
Kimberly T. Joseph

40 Thoracentesis . . . 250
Eric F. Reichman, Cristal R. Cristia, and Jehangir Meer

41 Open Chest Wound Management . . . 263
Eric F. Reichman

42 Emergency Department Thoracotomy . . . 267
Kenny Banh

43 Open Cardiac Massage . . . 271
Eric F. Reichman

44 Cardiac Wound Repair . . . 274
Eric F. Reichman

45 Hilum and Great Vessel Wound Management . . . 280
Eric F. Reichman

46 Thoracic Aortic Occlusion . . . 282
Eric F. Reichman

SECTION 4 Vascular Procedures . . . 287

47 General Principles of Intravenous Access . . . 287
Daniel Belmont

48 Venipuncture and Peripheral Intravenous Access . . . 296
Daniel Belmont

49 Central Venous Access . . . 308
Arun Nagdev and Craig Sisson

50 Ultrasound-Guided Vascular Access . . . 327
Srikar Adhikari

51 Troubleshooting Indwelling Central Venous Lines . . . 337
James J. McCarthy

52 Accessing Indwelling Central Venous Lines . . . 340
Lisa Freeman Grossheim

53 Pulmonary Artery (Swan-Ganz) Catheterization . . . 344
Pratik Doshi

54 Peripheral Venous Cutdown . . . 350
Flavia Nobay

55 Intraosseous Infusion . . . 361
Amanda Munk and O. John Ma

56 Umbilical Vessel Catheterization . . . 369
Eric F. Reichman, Amy Noland, and Antonio E. Muñiz

57 Arterial Puncture and Cannulation . . . 376
Zak Foy and Susan Stroud

SECTION 5 Gastrointestinal Procedures . . . 387

58 Nasogastric Intubation . . . 387
Lisa Freeman Grossheim

59 Activated Charcoal Administration . . . 391
Jenny J. Lu

60 Gastric Lavage . . . 393
Jenny J. Lu

61 Whole Bowel Irrigation . . . 398
Steven E. Aks and David D. Gummin

62 Esophageal Foreign Body Removal . . . 401
Bashar M. Attar

63 Balloon Tamponade of Gastrointestinal Bleeding . . . 407
Bashar M. Attar

64 Gastrostomy Tube Replacement . . . 414
Maggie Ferng and Ryan C. Headley

65 Paracentesis . . . 421
Susan B. Promes, Elizabeth M. Datner, and Sam Hsu

66 Diagnostic Peritoneal Lavage . . . 431
Sandeep Johar and Umashankar Lakshmanadoss

67 Anal Fissure Management . . . 439
Marilyn M. Hallock and Eric F. Reichman

68 External Hemorrhoid Management . . . 443
Charles Orsay and Eric F. Reichman

69 Prolapsed Rectum Reduction . . . 446
Jamil D. Bayram and Eric F. Reichman

70 Anoscopy . . . 449
Charles Orsay and Eric F. Reichman

71 Rigid Rectosigmoidoscopy . . . 453
Charles Orsay and Eric F. Reichman

72 Rectal Foreign Body Extraction . . . 458
Charles Orsay and Eric F. Reichman

SECTION 6 Orthopedic and Musculoskeletal Procedures . . . 465

73 Bursitis and Tendonitis Therapy . . . 465
Dedra Tolson

74 Compartment Pressure Measurement . . . 473
Matt Kleinmaier and Sanjeev Malik

75 Fasciotomy . . . 480
Justin Mazzillo, Sobia Ansari, and Eric F. Reichman

76 Extensor Tendon Repair . . . 490
Jaime Harper, Stanley Harper, and Ramasamy Kalimuthu

77 Arthrocentesis . . . 495
Eric F. Reichman, John Larkin, and Brian Euerle

78 Methylene Blue Joint Injection . . . 517
Joseph E. Tonna, Heather H. Bohn, and Matthew R. Lewin

79 Basic Principles of Fracture and Joint Reductions . . . 522
Scott C. Sherman

80 Sternoclavicular Joint Dislocation Reduction . . . 526
Eric F. Reichman

81 Shoulder Joint Dislocation Reduction . . . 531
Eric F. Reichman

82 Elbow Joint Dislocation Reduction . . . 549
Angelique S. Kelly Campen

83 Radial Head Subluxation ("Nursemaid's Elbow") Reduction . . . 553
Mark P. Kling and Eric F. Reichman

84 Metacarpophalangeal Joint Dislocation Reduction 557
Michael Bublewicz and Antonio E. Muñiz
85 Interphalangeal Joint Dislocation Reduction 561
Matt Kleinmaier and Sanjeev Malik
86 Hip Joint Dislocation Reduction 565
George Chiampas and Steve Zahn
87 Patellar Dislocation Reduction 571
Mark P. Kling
88 Knee Joint Dislocation Reduction 574
Sharad Pandit and Zach Kassutto
89 Ankle Joint Dislocation Reduction 577
Jim Comes
90 Common Fracture Reduction 582
Eric F. Reichman and Robert M. Zesut
91 Casts and Splints 592
Eric F. Reichman and Harold A. Sloas

SECTION 7 Skin and Soft Tissue Procedures 609

92 General Principles of Wound Management 609
Lisa Freeman Grossheim
93 Basic Wound Closure Techniques 623
Eric F. Reichman and Candace Powell
94 Tissue Adhesives for Wound Repair 647
Hagop M. Afarian
95 Advanced Wound Closure Techniques 650
Eric F. Reichman
96 Management of Specific Soft Tissue Injuries 659
Christopher J. Russo and Ajay Desai
97 Subcutaneous Foreign Body Identification and Removal 669
Samuel J. Gutman and Michael B. Secter
98 Ultrasound-Guided Foreign Body Identification and Removal 676
Daniel S. Morrison
99 Tick Removal 679
Zach Kassutto
100 Fishhook Removal 681
Eric F. Reichman and Renee C. Hamilton
101 Ring Removal 684
Steven H. Bowman
102 Subungual Hematoma Evacuation 690
Steven H. Bowman
103 Subungual Foreign Body Removal 694
Steven H. Bowman
104 Nail Bed Repair 697
Raemma Paredes Luck and Eric F. Reichman
105 Ganglion Cyst Aspiration and Injection 704
Thomas P. Graham
106 Subcutaneous Abscess Incision and Drainage 706
Samuel J. Gutman and Michael B. Secter
107 Paronychia or Eponychia Incision and Drainage 713
Lisa R. Palivos
108 Felon Incision and Drainage 716
Lisa R. Palivos
109 Pilonidal Abscess or Cyst Incision and Drainage 718
Lauren M. Smith
110 Perianal Abscess Incision and Drainage 722
Maggie Ferng and Ryan C. Headley
111 Sebaceous Cyst Incision and Drainage 728
Carlos J. Roldan
112 Hemorrhage Control 731
Christopher Freeman and Eric F. Reichman
113 Trigger Point Injections 738
Danielle Campagne
114 Escharotomy 741
Michael A. Schindlbeck

SECTION 8 Neurologic and Neurosurgical Procedures 747

115 Lumbar Puncture 747
Eric F. Reichman, Kevin Polglaze, and Brian Euerle
116 Burr Holes 761
Eric F. Reichman
117 Lateral Cervical Puncture 767
Eric F. Reichman
118 Ventriculostomy 770
Eric F. Reichman
119 Ventricular Shunt Evaluation and Aspiration 775
Eric F. Reichman
120 Subdural Hematoma Aspiration in the Infant 779
Eric F. Reichman
121 Skeletal Traction (Gardner-Wells Tongs) for Cervical Spine Dislocations and Fractures 783
Eric F. Reichman
122 Edrophonium (Tensilon) Testing 786
Eric F. Reichman

SECTION 9 Anesthesia and Analgesia 789

123 Local Anesthesia 789
Michael A. Schindlbeck
124 Topical Anesthesia 795
Erika D. Schroeder and Peter Taillac
125 Hematoma Blocks 799
Thomas P. Graham
126 Regional Nerve Blocks (Regional Anesthesia) 802
Eric F. Reichman, Jehangir Meer, and Nikesh Seth
127 Intravenous Regional Anesthesia 843
Christopher Freeman
128 Nitrous Oxide Anesthesia 849
Antonio E. Muñiz

129 Procedural Sedation and Analgesia (Conscious Sedation) . . . 854
Hagop M. Afarian

SECTION 10 Obstetrical and Gynecologic Procedures . . . 869

130 Ultrasound in Pregnancy . . . 869
Srikar Adhikari and Wes Zeger

131 Normal Spontaneous Vaginal Delivery . . . 883
Swati Singh and Susan B. Promes

132 Episiotomy . . . 896
Francisco Orejuela

133 Shoulder Dystocia Management . . . 904
Eric F. Reichman and Camaran E. Roberts

134 Breech Delivery . . . 910
Irene E. Aga

135 Postpartum Hemorrhage Management . . . 917
Leah W. Antoniewicz

136 Perimortem Cesarean Section . . . 922
Silvia Linares

137 Symphysiotomy . . . 928
Ikem Ajaelo

138 Bartholin Gland Abscess or Cyst Incision and Drainage . . . 930
Charlie C. Kilpatrick

139 Sexual Assault Examination . . . 935
Ann I. Schutt-Ainé and Audra E. Timmins

140 Culdocentesis . . . 945
David L. Levine

141 Prolapsed Uterus Reduction . . . 948
Eric R. Snoey

SECTION 11 Genitourinary Procedures . . . 953

142 Urethral Catheterization . . . 953
Richard Dean Robinson and Eric F. Reichman

143 Suprapubic Bladder Aspiration . . . 963
Richard Dean Robinson, Sam Hsu, and Eric F. Reichman

144 Suprapubic Bladder Catheterization (Percutaneous Cystostomy) . . . 968
Richard Dean Robinson, Sam Hsu, and Eric F. Reichman

145 Retrograde Urethrography and Cystography . . . 976
Richard Dean Robinson and Eric F. Reichman

146 Anesthesia of the Penis, Testicle, and Epididymis . . . 981
Eric F. Reichman

147 Priapism Management . . . 984
Steven Go

148 Paraphimosis Reduction . . . 989
Ann P. Nguyen

149 Phimosis Reduction . . . 995
Eric F. Reichman and Natana Peres

150 Dorsal Slit of the Foreskin . . . 998
Carlos J. Roldan

151 Manual Testicular Detorsion . . . 1001
Steven Go

152 Zipper Injury Management . . . 1004
Zach Kassutto

SECTION 12 Ophthalmologic Procedures . . . 1007

153 Eye Examination . . . 1007
Shari Schabowski

154 Contact Lens Removal . . . 1022
Dino P. Rumoro

155 Ocular Burn Management and Eye Irrigation . . . 1026
Steven J. Socransky

156 Intraocular Pressure Measurement (Tonometry) . . . 1032
Michelle M. Verplanck, Mark A. Rolain, and Aaron D. Cohn

157 Digital Globe Massage . . . 1038
Carlos J. Roldan and Eric F. Reichman

158 Anterior Chamber Paracentesis . . . 1041
Rene Pineda Carizey

159 Corneal Foreign Body Removal . . . 1043
Eric F. Reichman

160 Corneal Rust Ring Removal . . . 1047
Eric F. Reichman

161 Eye Patching and Eye Shields . . . 1050
Rebecca R. Roberts

162 Lateral Canthotomy and Cantholysis or Acute Orbital Compartment Syndrome Management . . . 1053
Jamil D. Bayram and Sami H. Uwaydat

163 Globe Luxation Reduction . . . 1056
Jeffrey S. Schlab

164 Hordeolum (Stye) Incision and Drainage . . . 1058
Sami H. Uwaydat and Jamil D. Bayram

SECTION 13 Otolaryngologic Procedures . . . 1063

165 External Auditory Canal Foreign Body Removal . . . 1063
Rebecca R. Roberts

166 Cerumen Impaction Removal . . . 1070
Rebecca R. Roberts

167 Tympanocentesis . . . 1075
Paul J. Jones

168 Auricular Hematoma Evacuation . . . 1078
Eric F. Reichman

169 Nasal Foreign Body Removal . . . 1084
Raemma Paredes Luck

170 Nasal Fracture Reduction 1092
Eric F. Reichman

171 Nasal Septal Hematoma Evacuation 1099
Michael Friedman, Meghan Wilson, and George Chiampas

172 Epistaxis Management 1103
Stephen M. Kelanic, David D. Caldarelli, and Eric F. Reichman

173 Laryngoscopy 1113
Steven Charous

174 Airway Foreign Body Removal 1120
David L. Walner

175 Peritonsillar Abscess Incision and Drainage 1125
Eric F. Reichman, Kellie D. Hughes, and Jehangir Meer

SECTION 14 Dental Procedures 1131

176 Dental Anesthesia and Analgesia 1131
Eric F. Reichman

177 Dental Abscess Incision and Drainage 1141
Daniel J. Ross

178 Post-Extraction Pain and Dry Socket (Alveolar Osteitis) Management 1146
Eric F. Reichman

179 Post-Extraction Bleeding Management 1148
Eric F. Reichman

180 Defective Dental Restoration Management 1150
Daniel J. Ross

181 Subluxed and Avulsed Tooth Management 1154
Daniel J. Ross

182 Fractured Tooth Management 1161
Daniel J. Ross

183 Temporomandibular Joint Dislocation Reduction 1165
Marilyn M. Hallock

SECTION 15 Podiatric Procedures 1169

184 Ingrown Toenail Management 1169
Jeff Schaider

185 Toe Fracture Management 1173
George Chiampas and Steve Zahn

186 Neuroma Management 1177
Eric R. Snoey and Stephen Miller

SECTION 16 Miscellaneous Procedures 1181

187 Relief of Choking and Acute Upper Airway Foreign Body Removal 1181
Tamara Espinoza, Shekhar Menon, and John Bailitz

188 Induction of Therapeutic Hypothermia 1185
Mark Hansen, Mike Nelson, and John Bailitz

189 Hypothermic Patient Management 1191
Gary An and Nabil Issa

190 Hyperthermic Patient Management 1201
Eileen F. Couture

191 Autotransfusion 1205
Carlos J. Roldan and Amit Mehta

192 Helmet Removal 1209
Eric F. Reichman

193 Hazmat Patient Management 1215
Atilla B. Üner

194 Physical Restraints 1218
Cheryl Person, Dean Sagun, and Mark Fanning

195 Chemical Restraint 1224
David K. Duong and Hemal Kanzaria

Houston, Texas

Preface

The scope of Emergency Medicine is extremely broad and covers the neonate through the geriatric, surgical, and medical, and encompasses all organ systems. Emergency Medicine is rapidly evolving to reflect our increasing experience, knowledge, and research. Procedural skills must supplement our cognitive skills. Achieving proficiency in procedural skills is essential for the daily practice of Emergency Medicine. We have produced a clear, complete, and easy-to-understand textbook of Emergency Medicine procedures. This text will provide all practitioners, from the medical student to the seasoned Emergentologist, with a single procedural reference on which to base clinical practices and technical skills.

The primary purpose of this text is to provide a detailed and step-by-step approach to procedures performed in the Emergency Department. It is expressly about procedures. While well referenced, it is not meant to be a comprehensive reference but an easy-to-use and clinically useful procedure book that should be in every Emergency Department. The contents and information are complete. It is organized and written for ease of access and usability. The detail is sufficient to allow the reader to gain a thorough understanding of each procedure. When available, alternative techniques or hints are presented. Each chapter provides the reader with clear and specific guidelines for performing the procedure. Although some may use this text as a library reference, its real place is in the Emergency Department where the procedures are performed. Despite its size, we hope that this book will find its way to the bedside to be used by medical students, residents, and practicing clinicians.

This book will satisfy the needs of physicians with a variety of backgrounds and training. While this text is primarily written for Emergentologists, many other practitioners will find this a valuable reference. This book is written for those who care for people with acute illness or injury. Medical students and residents will find this an authoritative work on procedural skills. Medical students, residents, nurse practitioners, physician's assistants, and practitioners with limited experiences will find all the information in each chapter to learn the complete procedure. Family Physicians, Internists, and Pediatricians will find this text useful to review procedures infrequently performed in the clinic, office, or urgent care center. Intensivists and Surgeons involved in the care of acutely ill patients will also find this book a wonderful resource. The experienced clinician can get a quick refresher on the procedure while enhancing their knowledge and skills. Physicians actively involved in the education of medical students and residents will find this text an easy-to-understand and well-illustrated source of didactic material.

The text has 16 sections containing 195 chapters. The contents are organized into sections, each representing an organ system, an area of the body, or a surgical specialty. Each chapter is devoted to a single procedure. This should allow quick access to complete information. The chapters have a similar format to allow information to be retrieved as quickly and as efficiently as possible. There are often several acceptable methods to perform a procedure. While alternative techniques are described in many chapters, we have not exhaustively included all alternative techniques. Key information, cautions, and important facts are highlighted throughout the text in bold type.

Each chapter, with a few exceptions, has a standard format. The relevant anatomy and pathophysiology are discussed followed by the indications and contraindications for the procedure. A list is provided of the necessary equipment. The patient preparation, including consent, anesthesia, and analgesia, is addressed. The procedure is then described in a step-by-step format. Cautions are placed where problems commonly occur. Alternative techniques and helpful hints for each procedure are presented. The aftercare and follow-up are discussed. Any potential complications are described, including the methods to reduce and care for the complications. Finally, a summary contains a review of any critical or important information.

This book covers a wide variety of procedures. We have made an effort to think of most procedures that may be performed in a rural or urban Emergency Department and have incorporated it into this text. This includes procedures performed routinely or rarely. It also includes procedures that are often performed in the acute care, clinic, and office setting. Some of the procedures in this book may be performed frequently in the daily practice of Emergency Medicine, such as laceration repair or endotracheal intubation. Other procedures, such as a cricothyroidotomy, are seldom to rarely performed but critical to the practice of Emergency Medicine. While many of the procedures are well known to the Emergentologist, some are uncommon and may not be known to the reader. This provides an opportunity to acquire new information that may be converted, with proper practice and training, into a useful skill. A few of the procedures are performed only by Surgeons. They are included to promote understanding by those who may later see the patients in the Emergency Department and have to provide emergent care for a complication. This edition has added chapters to cover additional procedures, especially the Respiratory section. A few chapters of seldom used procedures have been eliminated.

We have drawn on a wide variety of authors. The majority of authors are residency-trained, board-certified, and practicing Emergentologists. We have the honor of having many contributors from outside the field of Emergency Medicine, who are experts in their own specialty. The authors do have biases because of differences in education, experience, and training. We have tried to base all recommendations on sound clinical and scientific data. However, we have not excluded personal experience or preferences when appropriate. In these cases, the authors also present alternative techniques.

Hopefully, this book has grown and changed with this second edition. Suggestions from you, the reader, would be most appreciated. Let us know what additional procedures should be included or excluded in the future.

Eric F. Reichman, PhD, MD

Acknowledgments

This has been educational and time-consuming. I must thank my wife Kristi for all of her patience during this endeavor that took thousands of hours and four years. Joey, Phoebe, Jake, and Rocky always kept me entertained, day and night.

I would like to acknowledge the support of friends, colleagues, current residents, and former residents in the Departments of Emergency Medicine at The University of Texas at Houston Medical School and Cook County Hospital. They provided friendship and encouragement, and were always there when needed. A special thanks goes to Bob Simon and Jeff Schaider who got me started and set me on this academic path.

A special thanks goes to Brent King, MD, Patricia Butler, MD, and Nancy McNiel, PhD, for all their support and encouragement.

I would also like to acknowledge Marcy, Venettea, Shadi, Jim, Hoan, and especially Yolanda of the SCSC. Their daily support was invaluable.

I want to thank all the authors. Many of you are good friends that I cherish and whom gave of themselves and their time.

Susan Gilbert is a wonderful medical illustrator and friend. Her input and assistance only added to the illustrations of both editions of this book.

Thanks to all those at McGraw-Hill, especially Anne Sydor and Brian Kearns. You kept me on track, and provided assistance when needed and a kick in the butt when needed.

Eric F. Reichman, PhD, MD

SECTION 1

Introductory Chapters

1 Informed Consent for Procedures in the Emergency Department

Eric Isaacs

This chapter is designed as a practical reference for the Emergency Physician (EP). It focuses on the unique challenges of informed consent in the Emergency Department (ED). It presents a practical guide for the informed consent process, reviews the exceptions, and offers suggestions on difficult scenarios of informed consent in the ED.

INFORMED CONSENT

The right of a patient to make decisions about their body, including the refusal of recommended procedures and treatment, is an important concept in medical practice with foundations in law and medical ethics. **Informed consent is the process of communication that demonstrates a physician's respect for a patient's right to make autonomous decisions about their healthcare. Informed consent is both an ethical practice and a legal requirement for all procedures and treatments.**

UNIQUE CHALLENGES OF INFORMED CONSENT IN THE ED

Each practice environment presents its own challenges to the process of obtaining informed consent. Physicians frequently fail to fulfill all the requirements of obtaining informed consent.[1] The ED presents significant challenges, which, despite assumptions to the contrary, results in a greater need to spend time delivering information and engaging patients in their care decisions to the fullest extent possible (**Table 1-1**). Time pressure and acuity are the most critical factors that influence the care paradigm in the ED. Care provided in the ED spans the full continuum of care (nonacute care is increasingly sought in the ED) and addresses the full spectrum of society (patients from diverse health literacy, language origins, socioeconomic backgrounds, and other recognized vulnerable populations—elderly, children, prisoners). Emergency Physicians need to be prepared to address the broad clinical needs of diverse patients under pressure without the historical physician–patient relationship. Systemic constraints exacerbate this challenged professional context as patients have no choice in the treating physician or the treating facility, which is often dictated by EMS protocols. Tension may arise when a patient's wishes conflict with greater societal or institutional needs for efficiency and protocol compliance independent of the patient's preferences and needs. Examples include a trauma activation or a public health emergency. Increasing space constraints and crowding found in most EDs create a lack of privacy that can impede the free exchange of sensitive information. Procedural interventions in the ED are often concurrently diagnostic and therapeutic, further complicating informed decisions.

TABLE 1-1 Challenges for the Emergency Physician to Spend Time Engaged in Conversation with a Patient

Time pressure
Little privacy
Pace of care challenges lay person decisions
No prior relationship
Lack of facility choice
Public health- or system-imposed constraints

The torrent of complex medical information physicians provide patients is overwhelming in the most controlled settings, and is only made worse in the high emotion and high stress environment of the ED. Emergency Physicians often make rapid decisions with limited information on a daily basis. Many of our colleagues in other specialties may not share this skill, and our expectations of patients must be equally, if not more, tolerant. The absence of an ongoing physician–patient relationship offers no basis on which to build trust, elicit values, and draw preference knowledge. Lack of a prior relationship tests the EP's ability to establish an immediate rapport with the patient, and renders the patients' ability to express their values most important.

When there is uncertainty about a patient's preferences or a potential refusal, there may not be time to ponder the intricacies of medical ethics in the ED or to satisfy all the requirements of searching for the best surrogate decision maker. Many EPs will default to doing as much as possible in these difficult situations,[2] but there is often enough time to make a considered decision before acting in the most aggressive fashion. While some say that it is easier to withdraw care once the clinical picture becomes clearer, this aggressive course of action must be balanced with the knowledge that EPs may be performing a painful or unwanted procedure on a patient who has previously made their wishes clear. Traditionally, informed consent was often bypassed under the presumption that a patient would want aggressive treatment. The scope of ED care and societal norms have shifted in recent years. Informed consent for procedures in the ED needs to reflect the current standards of practice.

LEGAL FOUNDATION FOR INFORMED CONSENT

Consent originates in the legal doctrine of battery (touching of the body without permission). The notion of protecting a patient from the bodily trespass of a procedural invasion was framed by Justice Cardozo in 1914, "[e]very human being of adult years and sound mind has a right to determine what shall be done with his own body; and a surgeon who performs an operation without his patient's consent commits an assault, for which he is liable in damages…."[3] By 1957, the notion of consent shifted from mere permission to an authorization following "the full disclosure of facts necessary to an informed consent."[4] Emerging at the same time as the bioethics movement's shift away from paternalistic medicine toward a patient's rights focus in medicine was *Canterbury v Spence*.[5] This case resulted in **an appeals court establishing a physician's duty to disclose the risks and benefits of a procedure and its alternatives and introduced the reasonable patient standard. The reasonable patient standard is what a reasonable patient would**

need to know to make an informed choice shifting away from the professional standard, what most physicians deemed necessary. Today, the standard for disclosure varies by state.[6] As a result of the informed consent "duty," the legal and risk management function of informed consent (consent process that meets institutional and/or legal parameters for formal recognition referred to as **'effective consent'**) overshadows the ethically driven process of informed consent (consent as communication process that demonstrates respect for a patient's autonomy referred to as **'autonomous authorization'**). Often conflated under the "informed consent," these two aspects serve distinct functions. Both are necessary for valid informed consent and are addressed separately throughout this chapter.[7]

LEGAL FOUNDATION OF THE EMERGENCY EXCEPTION

The exception presuming permission to treat in an emergency has equally deep roots. Justice Cardozo's opinion continues, "[t]his is true except in cases of emergency where the patient is unconscious and where it is necessary to operate before consent can be obtained."[3] In *Canterbury v Spence*, "the emergency exception" is included as a privilege from the duty to disclose when "the patient is unconscious or otherwise incapable of consenting, and harm from a failure to treat is imminent and outweighs any harm threatened by the proposed treatments." It also states that a "physician should, as current law dictates, attempt to secure a relative's consent if possible." **In the emergency context one may presume permission: (1) to do what is necessary when (a) there is imminent harm from nontreatment and (b) harm from nontreatment outweighs the harm from the proposed intervention; (2) where the patient is unconscious or unable to participate in care decisions; and (3) the patient's preferences are not known and no surrogate is immediately available to provide authorization.**[8]

ETHICAL FOUNDATION FOR INFORMED CONSENT

In an era of patients' rights and shared decision making, robust informed consent reflects a process of communication that secures that a patient "gives an informed consent to an intervention if (and perhaps only if) one is competent to act, receives a thorough disclosure, comprehends the disclosure, acts voluntarily, and consents to the intervention."[9]

It is not uncommon to encounter the challenge of a patient refusing a recommended procedure or intervention in a healthcare environment where there is an expectation for more active patient participation in healthcare decisions. Central to a strong patient–physician relationship is the desire to promote patient well-being and simultaneously respect patient autonomy. Conflict between EPs and patients may arise when views of what is in a patient's best interest differ. Emergency Physicians with the greatest integrity come to work with the intention to act in the best interests of patients, and do so with a focus on the prevention and eradication of disease in order to preserve life and improve disability. After an EP has fully informed a capable patient about an intervention in an understandable way, the patient may consent or refuse the recommendation. An initial refusal of recommended treatment should begin a critical conversation that confirms all the elements of an informed refusal. Ultimately, this informed refusal process will respect patient autonomy by accepting a patient's view of well-being and may require honoring a refusal of the EP's recommendation.[10]

EMERGENCY PHYSICIAN'S ROLE AND GOALS IN INFORMED CONSENT PROCESS

The EP's role in the informed consent process is to provide patients the information needed to make their own decisions. It is important not to overwhelm a patient with too much information or complex clinical decisions. Including patients in appropriate care decisions, such as the informed consent process for a procedural intervention, is an ethically important goal.

TABLE 1-2 The Goals of Emergency Physicians in the Informed Consent Process

Support patients to make their own decision
Give information (more than we think we need to give)
Make information accessible
Offer guidance in weighing information
Allow autonomous authorization (patient may consent or refuse)

Emergency Physicians must pay particular attention to the informed consent process to accomplish the goal of respect for autonomy (**Table 1-2**). Foremost, EPs need to provide more information to the patient than they think is needed. Research indicates that patients need more information than physicians think they need in order to feel "informed" in the decision-making process.[11] The need for a procedure seems obvious to the EP and the balance of the considerations clearly tips in the favor of "do it." Emergency Physicians must slow down to fully explain the rationale for their recommendation with the patient and to offer the patient information that allows their meaningful consideration of the recommendation allowing them to reach their own decisions. A good guideline is to offer more time and information for procedures carrying greater risk.[12] **Emergency Physicians must make an effort to work against the features of the ED (Table 1-1 and presumption of consent) and allow patients who are capable of engaging in their care decisions to express autonomous authorization.** This is achieved by giving patients sufficient information, in an understandable way, and by honoring their decisions.

COMPONENTS OF THE INFORMED CONSENT AND INFORMED REFUSAL PROCESS

Informed consent is the communication process that both demonstrates and protects a patient's self-determination by providing a patient with decision-making capacity with sufficient, understandable information and allowing the patient to make a voluntary, knowledgeable decision. There are five requirements that must be satisfied.[13] These include the patient having decision-making capacity, the EP providing sufficient information, the patient understanding the information, the patient giving consent in a voluntary fashion without coercion, and the patient communicating their decision (**Table 1-3**).

DECISION-MAKING CAPACITY

While the terms "competence" and "decision-making capacity" are frequently used interchangeably, their strict meanings are different.

TABLE 1-3 Requirements of the Informed Consent Process[13]

1	Does the patient have the decision-making capacity to make this decision?
2	Has there been disclosure of relevant procedural information (including risks/benefits for intervention, alternatives, and nonintervention)?
3	Has the information been presented in a way that is understandable to the patient?
4	Has the information been presented in a way that allows the patient to make his or her own decision voluntarily while still being informed of the physician's recommendation?
5	Has the patient communicated a decision?
6	Does an exception apply?

Competence is a legal term with broader applications related to financial matters and the determination of personal choices. **Decision-making capacity is a clinical term that speaks to the specific capacity to make a particular clinical decision.** Many people who are legally "incompetent" retain healthcare decision-making capacity. If the patient does not have decision-making capacity, informed consent cannot be obtained and it must be obtained from a surrogate decision maker, or the patient may fall into an exception from informed consent.

DETERMINING DECISION-MAKING CAPACITY

The determination that a patient has decision-making capacity is at the core of informed consent. By default, EPs assume that a patient has capacity and confirm this through routine dialogue with the individual. There are six elements that should be confirmed when there is a question about a patient's capacity to make an informed decision about procedures or treatment.[14] The patient must be able to: understand and process the options, weigh the benefits and risks, apply a set of values and goals to the decision, arrive at a decision, communicate a choice, and demonstrate capacity to make the decision (**Table 1-4**).

Determination of capacity is a clinical decision based on the judgment of the EP regarding the patient's actual level of functioning and appreciation of the ramifications of the clinical situation. The degree of capacity needed to understand risks and benefits of suturing a finger laceration differs from a cardiac catheterization. As such, a patient may be able to understand one choice, but not another. An Alzheimer patient (who is pleasant, oriented to place and year) may be unable to appreciate the consequences of a decision. While this patient may have capacity for some tasks, they may lack the capacity to consent for a specific procedure such as a lumbar puncture.

The EP needs to assess the ability for the individual to weigh the risks in light of their own values. An example would be the ramifications of a fracture reduction on the dominant hand. A construction worker or musician may make a decision different than an individual whose livelihood does not depend on perfect hand function.

A recognized element of decision-making capacity is whether the patient's decision is consistent over time. This is not necessarily applicable specifically to the ED. A possible heuristic is whether the decision is consistent with the person's narrative and values as expressed consistently over time in life choices. The decision-specific nature of capacity acknowledges that the level of capacity needed depends on the complexity of the decision, with greater capacity needed for decisions with graver consequences. The degree of capacity needed to consent does not necessary equal the degree of capacity needed to refuse a recommended intervention.[10] Informed refusal will be discussed later in this chapter.

Decision-making capacity is a dynamic process and changes depending on the patient's evolving condition and task in question. The ED patient may be able to participate to a greater or lesser extent depending on fluctuations in their condition and alterations of their sensorium from the administration of medications. Efforts should be made whenever possible to enhance the patient's decision-making capacity (reduce pain medication temporarily or visit patients at optimal times) in order to engage them to the fullest extent possible in their care.

TABLE 1-4 Elements to Determine if a Patient has Decision-Making Capacity

1	The patient is able to understand and process the options presented
2	The patient is able to weigh the relative benefits, burdens, and risks of the options
3	The patient is able to apply a set of values and goals to the decision
4	The patient is able to arrive at a decision that is consistent over time
5	The patient is able to communicate a choice
6	The patient demonstrates capacity appropriate and sufficient to make this decision

Emancipated minor and adolescent laws vary from state to state.[9] It is important to note that emancipated minors are legally recognized as adults and responsible for their own finances and care. They are able to provide fully informed consent. It is important for EPs to know their local laws where minors who are not emancipated may give consent for sensitive conditions or procedures such as those of a reproductive nature or substance abuse.

Informed consent may not be possible with some populations, such as young children and elderly with dementia. It is still possible to inform these patients of the procedure and to engage their assent. Unlike consent, assent is not determinative. It does offer the possibility of the individual participating in their care.[15]

PATIENTS LACKING DECISION-MAKING CAPACITY

It is not possible to obtain informed consent when a patient lacks decision-making capacity. Necessary treatment may be provided to patients who lack decision-making capacity without obtaining the patient's informed consent. However, EPs should make every effort to learn the patient's previously stated preferences for treatment (e.g., written advance directive or communication with a primary care provider). Efforts should be made to obtain consent from a surrogate decision maker if prior preferences are not available. A surrogate decision maker is a person entrusted with making healthcare decisions because they know the patient best and can bring the patient's values and goals into the clinical decision process. This role can be challenging for even the most capable decision makers. It is not uncommon for surrogates to have a role conflict between applying their own values and/or wishes and those of the patient.

Emergency Physicians must pay attention to the language used when asking a surrogate decision maker for consent. Frame the discussion with phrases asking what the patient would want in the situation such as "How would your father view this situation?" or "What would your father's preference be based on his values?" Avoid general phrases such as "What should we do?", "What do you want us to do?", or "What do you think he would want?" If the decision seems to stem from a role conflict, an EP can ask the surrogate "Why do you think he would choose that?" No prior conversation covers every clinical scenario perfectly and the gravity of the decision can frequently be overwhelming for the surrogate.[10]

The choice of a surrogate decision maker may be quite obvious in some cases such as the parent or legal guardian of a child. The choice can be more complex in other cases. Who may serve as a surrogate and their scope of authority varies by state. What if the appropriate surrogate is in question and there is no statutory guidance? A useful guide is that the surrogate's authority arises from a close relationship to the patient that affords accurate and informed communication of the patient's values. Challenges in resolving conflict between potential surrogates (e.g., siblings with different opinions regarding parental care) should be referred to an ethics committee or other institutional mechanisms to offer guidance unless emergent conditions make that impractical.

INFORMATION TRANSMITTAL

The EP must relate sufficient information about the procedure to the patient. This raises the questions of what information to present and how much to present. **Relevant information includes the risks and benefits of the procedure, any alternatives to the proposed course of action, and the consequences of nonaction.** The question remains how much information needs to be disclosed to

patients, particularly in light of the potential that legal action may be taken if an EP does not obtain informed consent properly.[16]

There are two standards that are commonly used, and these standards vary by state. The traditional "professional standard" requires the EP to provide information based on what the profession's standard of practice would deem necessary to disclose for a patient to be informed. The more common "reasonable person standard" requires the EP to include all the information that a reasonable patient would want to know in order to make a knowledgeable decision. Information that should be communicated includes: the patient's current medical condition and how will it progress if no treatment is given, the treatment alternatives, the risks and benefits of each potential treatment and their probabilities, and the financial costs of each if those estimates exist. Finally, the EP should provide a personal recommendation as to the best alternative.[17]

UNDERSTANDABLE PRESENTATION OF INFORMATION

Information must be given in a way that is understandable. The patient must be able to adequately weigh the benefits, burdens, and risks of the treatment in the context of their own beliefs, life, values, and goals. The obvious differential in knowledge and understanding between patients and EPs may be exacerbated by language barriers, literacy, numeracy, and low educational levels.[18] Such barriers may be overcome by: speaking at a level easy for the patient to comprehend, being sensitive to patients who may be unable to read, and being sensitive of patients who may not be highly educated. Understanding is bidirectional and necessitates that EPs confirm that the patient understands what they are told.[19] Communicating numbers, such as risk and probabilities, is the most complex task asked of EPs.[20] Frame numbers in multiple ways and present outcomes in both positive and negative contexts to enhance informed consent.[20] For example, "3 out of 4 children have no side effect but one in four will have nightmares from this medication."

Language barriers are frequent in the ED and pose significant concern in obtaining and documenting informed consent.[21] Understanding languages is situational. Although some EPs may have additional language (non-English) proficiency, it is imperative to know when to call an interpreter. Limited language skills allow the EP to extract critical clinical information. Patients may need more information than the EP's skills allow. Calling an interpreter may be essential for meeting a minimum standard of care.[22]

VOLUNTARY NATURE OF THE DECISION

Forced treatment where any real choice is removed from the patient being involved in the decision-making process violates the doctrine of informed consent. Any form of coercion based on threats or intolerable consequences, such as the withholding of pain medication, would fall into this category. Emergency Physicians cannot manipulate patient decisions by withholding or distorting information that the EP believes may sway the patient toward a preferred course. Persuasion is permissible, and it is an obligation as trained professionals to synthesize the information and recommend a course of action. An appropriate recommendation includes laying out the risks, benefits, and reasoning behind one's recommendation as well as explaining the reasoning for not selecting an alternate approach. Emergency Physicians can also utilize the resources of the patient's family or significant others to provide arguments in favor of a particular course of treatment. The EP must be careful to avoid overwhelming the patient as the goal should be a shared solution by consensus and not forcing the patient to surrender to the wants of others.[23] Strategies to approach a patient's refusal are discussed in depth later in this chapter.

EFFECTIVE INFORMED CONSENT AND REFUSAL

There is a difference between the autonomous authorization informed consent (information and dialogue) and the effective informed consent (to meet legal and institutional requirements). **The EP should document the discussion of the benefits, burdens, risks, and alternatives addressed in the discussion with the patient in order for an autonomous authorization to be recognized as effective and, thus, the entire informed consent valid.** Local institutional policies should be referenced to confirm an effective informed consent or refusal.[7]

Some hospitals have patients sign "blanket" consent forms agreeing to all emergency tests and treatments on their registration in the ED. Such consent forms provide no information regarding specific individual procedures. These forms are not acceptable because they fail to respect patient autonomy. Blanket consent forms cannot substitute for the usual informed consent process for procedures in the ED, where a dialogue with the patient is required.[24]

EXCEPTIONS TO THE INFORMED CONSENT PROCESS

THE EMERGENCY EXCEPTION

Society's overriding assumption is that a person would want lifesaving treatment in an emergency situation. Consent to treatment is generally presumed under specific emergency circumstances where intervention is necessary to save life or limb, the harm of nontreatment is greater than the harm of the intervention, a patient is unable to participate in care decisions, and patient preferences are not known with no surrogate available. This emergency exception is not absolute. This is particularly true when there is clear evidence that the patient's wishes are contrary to the intervention being considered, such as a prehospital advance directive or wallet card stating no blood transfusions.

Some EPs believe that any patient in the ED qualifies for an emergency exception by virtue of the fact that they are in the ED. This is not true. Location by itself can be used neither to justify the emergency exception nor to infer an "implied consent" for broad ED care. Rather, the emergency exception may be invoked only when the patient will be harmed by the delay necessary to obtain informed consent.[25] EPs should ask themselves a few brief questions to determine if a patient meets the criteria for an emergency exception to informed consent (**Table 1-5**).

THERAPEUTIC PRIVILEGE

The therapeutic privilege is a disfavored concept but recognized exception. It excuses EPs from the duty to disclose in the limited circumstances where disclosure might create harm to the patient and interrupt the treatment process. This privilege is rarely invoked as it could almost negate the entire informed consent process.

TABLE 1-5 Questions to Justify an Emergency Exception

1	Will failure to treat quickly result in serious harm to the patient?
2	If their condition worsens, will the patient die or suffer serious harm before definitive care can be delivered?
3	Would most capable and reasonable people want treatment for this type of injury?
4	Is the patient unable to participate in care decisions?
5	Are the patient's preferences known or knowable in a timely way from a surrogate?
6	Is there any evidence that the patient would refuse this specific treatment?
7	Would failure to treat result in greater harm than the proposed intervention?

Therapeutic privilege may be applied when direct disclosure to a patient would create harm, generally recognized as occurring in some psychiatric conditions and for some cultural groups.[26]

WAIVER OF INFORMED CONSENT

While EPs have a duty to disclose information, patients may differ in how they approach their participation in care decisions. Some patients may prefer that another person, such as a close family member, receive healthcare information and make treatment decisions on their behalf (delegated autonomy). This may be due to personal preference or cultural variation. The delegation of the decision making must be confirmed with the patient and not assumed based on cultural norms. The delegation reflects a patient's right to waive informed consent. Their choice to delegate that right to another person demonstrates an autonomous choice that should be honored.[27]

Some patients may interrupt the informed consent process after only partial information is disclosed and elect to follow the EP's recommendation. If the EP confirms the patient's acceptance of the consequences of consent with only partial information, the EP may accept this as consent via waiver of the informed consent process.[25] The EP may accept a waiver of consent if, like other decisions, the patient has capacity, understands that they are giving up an important right, and has made the request voluntarily. Emergency Physicians who are uncomfortable with this responsibility may ask the patient to designate another person to assume this role.

IMPLIED CONSENT

Implied consent is also a disfavored concept. It may be considered to "apply" in the very limited circumstances when an EP is undertaking a clinical activity with a well-known risk/benefit profile.[28] The most favored implied consent example is when a patient extends his or her arm for a blood draw. The volitional act of extending the arm is deemed as implied consent to the blood draw and its risks (pain and possible bruising). The assumption of "implied consent" poses a dangerous trap for EPs, since what an EP considers routine and well-known risks may differ greatly from what the patient knows. This is particularly true in the ED where there is little trust and no knowledge of the patient's health literacy.

Emergency Medicine research shows at least 50% of patients wanted time spent on "detailed" information, including a review of the risks of only 1% chance of occurrence. For example, while lumbar punctures are clinically safe and pose little risk, patients perceive this as an invasive procedure that requires more information for informed consent.[11] It is important to note that implied consent is not sufficient when informed consent is required or possible.[10]

UNREPRESENTED PATIENTS/PATIENT ALONE

A patient who is unable to participate in care decisions and has no surrogate decision makers is known as the "unrepresented patient" or the "patient alone." These highly vulnerable patients have no social networks to assist the care team in navigating consent and care decisions, and attention to clinical decision making for this patient population is growing.[29] Statutory guidance on decision making for this patient population varies by region. Institutional policies should be reviewed to determine whether a policy exists for decision making for the "unrepresented patient." In the absence of such a policy, consultation with the ethics service is recommended and efforts should be made to develop a consistent and transparent approach to care decisions for this vulnerable population.[27]

INFORMED REFUSAL

Emergency Physicians often begin with the presumption that patients possess decision-making capacity to both consent and refuse procedures. It is notable that in practice, EPs may question a patient's capacity more readily when they disagree with recommendations.

UNDERSTAND THE REASONS FOR REFUSAL

A refusal for recommended intervention should be the beginning of an important conversation with the patient. On first encounter, a refusal of a recommendation may seem a rebuff or potential time challenge. Approach a refusal with openness and curiosity. Help the patient not feel cornered into following the recommendation while confirming their informed refusal. A refusal is an opportunity to learn how to practice persuasive reasoning. During the barrage of information disclosure, a patient might have misheard numbers or the proposed procedure may resemble a prior negative experience. Take time to listen to the patient's concerns and reasons for refusal. This can help navigate the informed refusal process.

CONFIRM THE ADEQUACY OF INFORMATION WITH AN EMPHASIS ON UNDERSTANDABILITY

With the patient's reasons for refusal in mind, EPs should reflect these reasons back to the patient so that they feel they have been heard. It is important for EPs to acknowledge the patient's perspective, even if they disagree with the reasons. This allows the patient to engage in listening as the EP provides additional information to support the recommendation. Normalizing an "irrational concern" allows the patient to feel "OK" and still follow the EP's recommendation. For example, "I can understand that your sister's complication from procedural sedation several years ago would give you some concerns about this recommendation. And I want to reassure you that today we take these additional steps…." Tailor the revised recommendation to address the concerns of the patient and focus on making sure that the information provided is simple, direct, and understandable.

ADDRESS BARRIERS TO UNDERSTANDING

Significant efforts should be undertaken to enhance the patient's ability to understand the information when a refusal occurs. **A professional interpreter must be utilized to compensate for any communication barriers to the patient's understanding in an informed refusal process.** The EP should revisit all the information from the initial discussion of information that occurred with an informal interpreter (e.g., family member or healthcare provider). Residual misinformation can prolong a patient's refusal. Starting from the beginning of the clinical communication, even if it takes more time, can often remedy the situation. Use language or pictures tailored to a patient's lower educational or functional level when necessary.[19] Anxiety and pain may contribute as a barrier to understanding and should be addressed as quickly as possible.

CONFIRM CAPACITY TO REFUSE RECOMMENDATIONS

Is decision-making capacity a potential issue? The EP must take steps to mitigate any factors leading to impaired decision making so that the patient may participate in their care to the fullest extent possible.

In the past, it was thought that patients with certain diagnoses by default lacked decision-making capacity. Many clinicians now recognize that patients with severe mental illness, early dementia,

TABLE 1-6 Red Flag Scenarios that Require Additional Assessments of the Patient's Decision-Making Capacity

Refusal of recommended treatment
Patients readily consenting to invasive or risky treatment
Abrupt change in mental status
Chronic psychiatric or neurologic conditions
Cultural and language barriers
Limited education
Anxiety or untreated pain
Extremes of age

TABLE 1-7 Mnemonic for Documentation of Decision-Making Capacity Assessments

"U *and* I GLAD"
U—understanding of the procedure/discussion
I—impairing conditions
G—goals and values
L—logic used to decide
A—actual functioning
D—danger or risks of decision

and some organic brain syndromes are at risk for impaired decision making but may possess decision-making capacity for selected procedures and treatments.[14] However, there are certain Red Flag scenarios when an EP should scrutinize a patient's decision-making capacity with greater depth (**Table 1-6**). Actions or decisions with greater consequences require a more intense evaluation of the patient's capacity. A more careful evaluation of capacity is indicated when the patient's choice seems unreasonable or if the patient is unwilling to discuss their thought process. Chronic psychiatric and neurologic conditions remain a risk for, but should not be equated with, impaired decision making. Cultural, educational, and language barriers certainly impact a patients' decision making. High levels of anxiety, whether from untreated pain or the inevitable stress of the ED, are known to impair decision making as well.[30]

Many providers outside the ED setting will utilize psychiatric consultations to assist with the evaluation of a patient's decision-making capacity. The utility of such a consultation in the ED is frequently limited by time and consultant availability. Consultations in the ED may prove useful when evaluating a thought or delusional disorder that may impede understanding.

EFFECTIVE AUTHORIZATION: DOCUMENTATION OF INFORMED REFUSAL

Honoring a refusal of emergency treatment that would be beneficial or may result in decompensation or death is never easy. Use of the standard hospital "Against Medical Advice" form can create an adversarial relationship that an EP may find damaging to future patient interactions and the subsequent treatment plan. However, anecdotal reports include cases where patients reconsidered their decision when presented with such a document. It is important to document refusal of care, not only for medicolegal protection but also to confirm that clear communication with the patient had occurred.

Documentation recommendations when a patient refuses treatment should include the following elements: the patient has refused the recommended procedure, test, or treatment; the patient's reasons for refusal; the consequences of the refusal were explained to the patient including the alternatives, if any, being offered or performed in lieu of the recommended procedure. Documentation should also include statements that show the patient understood and continued to refuse the specific procedure or treatment and has the capacity to do so. Document that the patient's wishes are being honored against medical advice. It would be preferable if the EP could have the patient read this documentation followed by the patient signing the medical record below this documentation in acknowledgment.

Additional documentation is required when an EP recognizes a "Red Flag" scenario for impaired decision making or has other reasons for concern (**Table 1-7**). These are essential items that must be documented in these cases. Document the patient's medical condition and the procedure or treatment that is suggested, including the urgency and necessity. Document the patient's current decision-making abilities with a description of the impediments to capacity and the actions taken by the provider to maximize capacity. Additional documentation should include the availability of family or other surrogate decision makers and any relevant discussions.

Documentation will vary by institution and local laws. Being familiar with the appropriate measures to make an informed consent or refusal is effective and is a critical part of the informed consent/refusal process in the ED.[31]

2 Aseptic Technique

John S. Rose

INTRODUCTION

The proper use and an understanding of aseptic technique are critical for the care of patients in the Emergency Department (ED). Aseptic technique dovetails with prescribed universal precautions and is central to our practice. Knowledge of proper aseptic technique ensures that procedures performed in the ED provide maximal protection for both the patient and the physician while keeping the risk of contamination as low as possible.[1–15]

Wound infection and sepsis are the two major complications resulting from poor and improper aseptic technique. Other complications that may contribute to the patient's morbidity and mortality include increased length and cost of hospital stay, patient discomfort, scarring, and even death. With this is mind, it is clear that aseptic technique is warranted except in the most dire circumstances.

Numerous terms are used to describe the establishment and maintenance of a "sterile" environment. These include aseptic, sterile technique, and disinfection, to name a few. Many people often, and incorrectly, interchange these terms. The proper definitions of the terms used to describe aseptic technique or associated with it can be found in **Table 2-1.**

ANATOMY AND PATHOPHYSIOLOGY

The skin and hair are colonized with various organisms. The stratum corneum layer of the epidermis is colonized with a polymicrobial flora. This includes *Staphylococcus aureus, Staphylococcus epidermidis,* various *Streptococcus* species, viruses, yeasts, and molds. Many of these organisms are nonpathogenic, even when placed in environments considered appropriate for infection. *S. aureus* is the most common cause of wound infections. It can result in an infection when introduced into deeper skin layers. Some species, such as *S. epidermidis,* are pathologic only when inoculated into deeper layers of the skin and soft tissue. For most infections, a significant

TABLE 2-1 Definitions of Terms Used to Describe Aseptic Technique or Associated Processes

Term	Definition
Aseptic	Freedom from infection. Prevention of contact with microorganisms. Involves the use of sterile technique and skin disinfection
Clean technique	The practice of using nonsterile equipment to perform procedures. This is considered as part of the universal body fluid precautions
Disinfection	The cleaning of an area to make it free of pathogenic organisms and microbes
Sterile field	The zone in which strict sterile technique is maintained. Generally consists of an area 3 to 10 times larger than the area of the primary procedure
Sterile technique	The practice of utilizing sterile equipment and procedures to maintain an aseptic environment
Super aseptic	Ultrahigh state of an aseptic environment. Usually, this is achievable only in the operating room

inoculation is required to create a critical level for microbial growth to occur. **Aseptic technique decreases bacterial exposure and reduces the level of potentially pathologic organisms.**

INDICATIONS

The role of aseptic technique in the ED is primarily for invasive procedures. Despite this, invasive procedures require varying degrees of aseptic technique. Placement of a small peripheral intravenous catheter may require no more than a brief wiping of the skin. In contrast, a diagnostic peritoneal lavage requires operating room–level disinfection and strict sterile technique.

Routine and adequate provider disinfection involves careful hand washing, the use of clean and disinfected personal diagnostic equipment (e.g., stethoscopes), and wearing appropriately cleaned coats and clothing. This is critical in preventing iatrogenic infections in the ED. Aseptic technique in the ED can be referred to as clinical aseptic technique, since it is virtually impossible to achieve an operating room level of asepsis. Clinical aseptic technique involves the combining of adequate disinfection with sterile techniques and protocols at the bedside.

CONTRAINDICATIONS

There are very few contraindications to the maintenance of adequate clinical aseptic technique. One exception would be that extreme clinical circumstance in which time simply does not allow proper aseptic technique, as in an emergent thoracotomy. Even in such situations, however, the physician can still use sterile gloves and a quick application of an aseptic solution.

Always inquire about allergies and sensitivities to latex and antiseptic solutions. This information will affect the equipment that is chosen to properly prepare the patient.[8] Most, if not all, hospitals have a latex-free cart that contains equipment for use with latex-allergic patients. Do not use povidone iodine solution in patients allergic to iodine. Alternative agents include chlorhexidine and hexachlorophene preparations.

EQUIPMENT

- Povidone iodine solution
- Chlorhexidine gluconate (chlorhexidine)– or hexachlorophene-based solutions
- Seventy percent isopropyl alcohol
- Sterile 4 × 4 gauze squares or applicator sticks
- Sterile gloves
- Face mask and eye protection
- Sterile drapes or towels
- Adequate lighting
- Sterile gowns
- Bedside procedure table

PATIENT PREPARATION

Inform the patient of what the procedure entails before performing any procedure in the ED. This should include an explanation of sterile technique and a request that the patient not touch the drapes or sterile equipment. Obtain any required informed consent (Chapter 1) before the patient is draped. The only exception to this is if an emergent and lifesaving procedure must be immediately performed.

Place the patient in the most comfortable position possible. Patient discomfort frequently results in movement and the potential loss of the sterile field. Utilize sedation and/or analgesia (Chapters 123-129) as necessary to facilitate proper patient positioning. The physician must also be comfortably positioned if possible and have adequate lighting.

TECHNIQUES

Aseptic technique can be divided into skin disinfection and sterile technique. Skin disinfection removes any microorganisms found on the skin and decreases potential contamination during the procedure. Sterile technique is performed for the same reason. There are different levels of aseptic technique, ranging from full aseptic technique (mask, gown, gloves, and drapes) to simple sterile gloves. The physician must use their judgment to determine which level is most appropriate to the task at hand.[8]

SKIN DISINFECTION

Disinfection involves the application and scrubbing of a disinfectant preparation onto the skin. Simple procedures, such as injections or venipunctures, may require little disinfection. Wipe the skin with gauze that has been impregnated with 70% isopropyl alcohol for simple procedures. The alcohol has an antibacterial effect. The mere force of wiping the skin reduces bacterial counts. No disinfection is used for simple venipunctures in some countries. More comprehensive skin preparation involves the use of a disinfectant agent such as povidone iodine or chlorhexidine solution.

Povidone iodine, 2% iodine tincture, and chlorhexidine are the most commonly used skin antiseptic solutions. Povidone iodine solution is highly germicidal for gram-positive and gram-negative bacteria, viruses, fungi, protozoa, and yeasts.[7] It rapidly reduces bacterial counts on the skin surface and these effects last up to 3 hours.[7,11] Allow the iodine solution to dry and then wipe it from the skin with 70% alcohol prior to beginning the procedure. The iodine solutions work by oxidation and cross-linking of sulfhydryl groups, killing bacteria as the solution dries. Isopropyl alcohol can be applied to the skin and scrubbed vigorously for 2 minutes to achieve disinfection, although this may cause skin irritation. Chlorhexidine or hexachlorophene preparations may be routinely used or as substitutes in iodine allergic or sensitive patients. These agents provide good bactericidal activity against gram-positive bacteria but somewhat less activity against gram-negative organisms.[8]

Chlorhexidine-based solutions are being used more commonly and are replacing the iodine-based solutions. Chlorhexidine

provides much longer antimicrobial activity (up to 48 hours) and is more gentle on the skin than iodine.[11–15] Chlorhexidine destroys cell membranes of gram-positive and gram-negative bacteria while precipitating the intracellular contents. Some preparations contain 70% isopropyl alcohol, further enhancing the antimicrobial activity.[12–14] The use of chlorhexidine solutions is proving to be superior to iodine solutions.[14,15]

Use a skin disinfectant for procedures other than simple venipuncture. Place the disinfectant solution onto either a sterile sponge or sterile gauze if it is not supplied inside a single-use applicator. Historically, the application of disinfectant to the skin is in a circular motion, beginning with the central area of the procedure and working out toward the periphery of the sterile field (**Figure 2-1**). There is no evidence to support this application method. It has been suggested that scrubbing in a back-and-forth motion creates friction to dislodge microbes and may be preferable to the traditional circular application.[9,10] The back-and-forth motion drives the disinfectant solution into skin crevices and deeper layers, thus killing more bacteria and hopefully preventing infections.

Regardless of the disinfectant solution used, repeat the application process three or four times using a new sponge, gauze square, or applicator each time.[8] This technique ensures that the central area where the procedure is to be performed is the most sterile area of the field. The area of disinfection must be much larger than the primary area of the procedure, as the number of organisms increases toward the periphery of the prepped area.

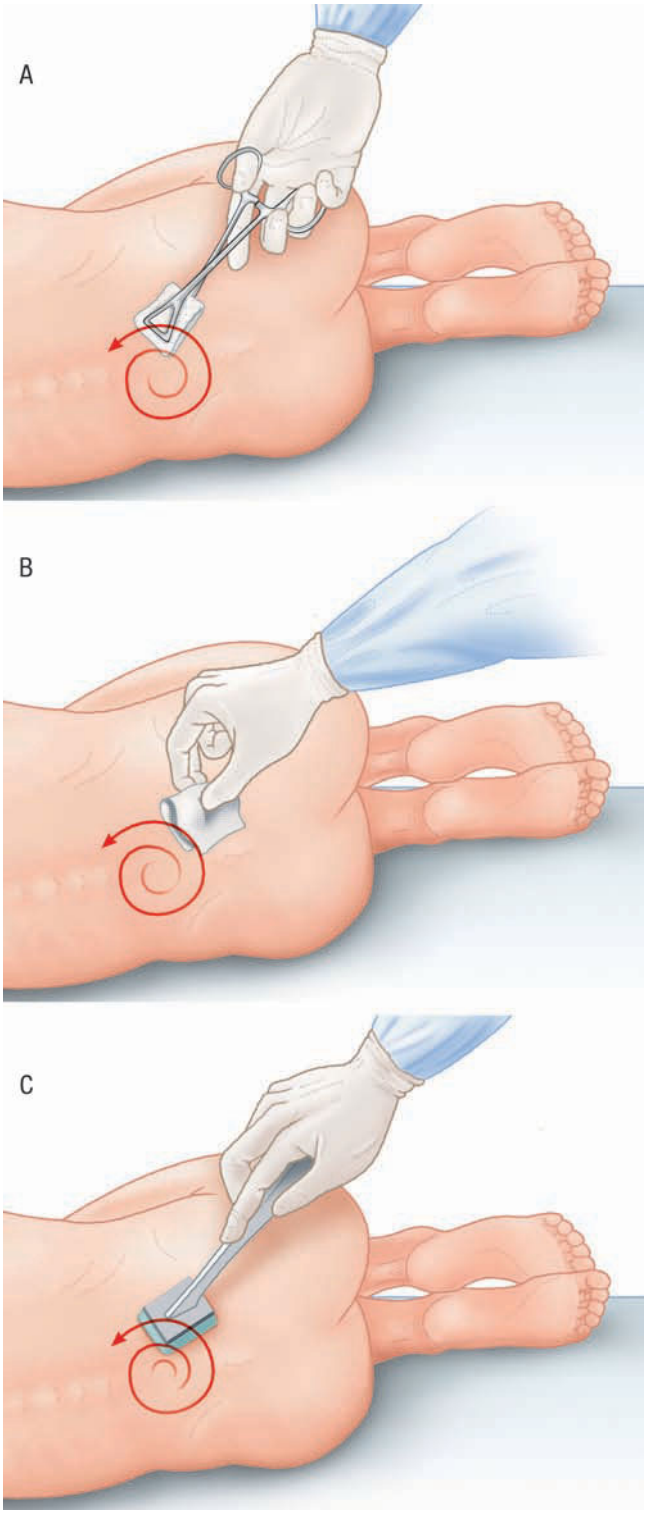

FIGURE 2-1. Preparation of the skin. Disinfectant solution is applied in a concentric circular pattern starting from the procedure site and working outward. Apply the disinfectant solution with sterile gauze held in a clamp (**A**), with sterile gauze held in a sterile gloved hand (**B**), or with a sponge on a stick (**C**).

STERILE TECHNIQUE

General sterile technique is described, followed by specific details for each step of the procedure. Strict sterile technique is virtually impossible in the ED. **However, make every effort to maintain a sterile field in order to minimize infection.** Assemble all equipment necessary and place it on a small procedure stand. **Do not use the patient or their bed to set up supplies or equipment.** Patient movement and their irregular body surfaces can result in items falling, breaking, becoming contaminated, or iatrogenic needle sticks. Avoid having different components scattered around the procedure area. Open all sterile items, using proper sterile protocol, so as to have them available once the physician has donned sterile gloves. Use anesthetic solution containers with removable caps. This allows the physician to draw up anesthetic without having an assistant and minimizes the risk of occupational needle exposure. Perform a thorough hand washing before the procedure.

Apply sterile gloves. Place sterile drapes or towels to form a field wide enough to allow for a comfortable work space. Drape the area near the patient closest to the bedside procedure table. This will minimize inadvertent contamination in moving from the table to the patient. Make a small flat sterile area near the procedure site to allow for placement of important items that must be immediately available. Open all caps, position stopcocks, and prepare all devices prior to starting the procedure. The likelihood of contamination increases if devices are not adequately prepared, thus requiring manipulation during the critical portion of a procedure. **Adhere to universal precautions guidelines.** Use eye and face protection during the procedure. This should be applied before donning gowns and gloves.

OPENING A STERILE PACK

Always make sure that the outer wrapping is intact, the sterility expiration date has not passed, and the sterility indicator tape is the appropriate color before opening a sterile pack.[2] Wash your hands and then remove the outer wrap if applicable. Remove the sterility indicator tape (**Figure 2-2A**). Place the sterile pack on a dry and level surface with the outermost flap facing away from you (**Figure 2-2B**). Grasp the corners of the outermost flap (**Figure 2-2B**). Hold your arms to the sides of the pack to avoid reaching over the sterile area. Lift the flap up and away from you (**Figure 2-2B**). Open the side flaps by grasping the folded corner with a thumb and index finger

FIGURE 2-2. Opening a sterile pack. **A.** Remove the sterility indicator tape. **B.** Grasp the edges of the outermost flap and open it away from you. **C.** Open the side flaps. **D.** Open the remaining flap toward you. **E.** The open pack.

and pulling the flap to the side (**Figure 2-2C**). Open the bottom flap (**Figure 2-2D**). Grasp and open the bottom flap while stepping back to prevent contaminating the wrap on your clothing (**Figure 2-2E**). **Make sure that your arms and clothes do not contaminate the contents of the pack when opening the flaps.** Repeat the procedure if the pack has an inner wrap.

PLACING STERILE SUPPLIES ON A STERILE FIELD

Sterile supplies are generally packaged in either a hard (hard pack) or a soft peel-back (soft pack) container. The general principle of opening these is the same, although there are subtle differences. Hold the hard peel-back container in the nondominant hand with

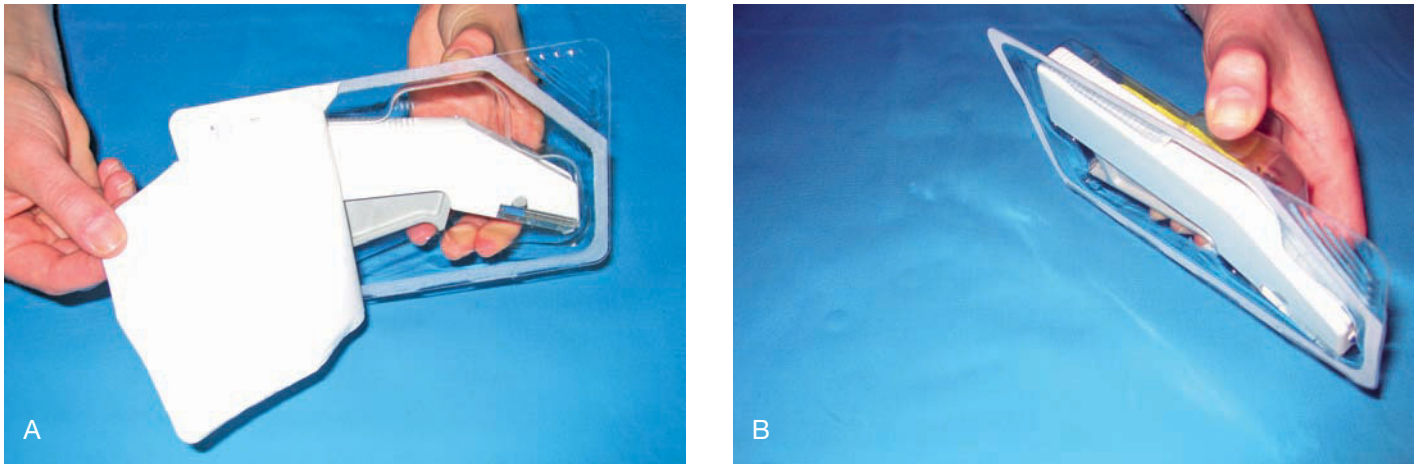

FIGURE 2-3. Opening a hard peel-back container. **A.** Grasp the container with the flap facing the sterile field. Remove the flap. **B.** Drop the contents of the hard container onto the sterile field.

the flap facing the sterile field (**Figure 2-3A**). Pull the flap toward you with the dominant hand so that the open end of the pack will be facing the field (**Figure 2-3A**). Hold the container 15 to 20 cm above the sterile field. This ensures that if the contents fall, it will be onto the sterile field where they are wanted. Drop the contents of the sterile pack onto the sterile field, taking care not to contaminate the field with the container itself (**Figure 2-3B**).

Gloves and syringes are wrapped in soft packs. Grasp both sides of the unsealed edge of the soft pack and pull them apart slightly (**Figure 2-4A**). Hold the open end facing the sterile field (away from you). Continue to open the soft pack. Fold the sides of the sterile packing back and over your hands to keep the contents sterile (**Figure 2-4B**). Gently drop the contents of the soft pack onto the sterile field.

APPLICATION OF A MASK

Surgical masks serve a dual role in the performance of aseptic technique. Masks have been shown to decrease contamination of the sterile field that may result from aerosolized droplets from the mouth and nose. Masks protect the caregiver's mucous membranes from exposure and possible splashing during the procedure. Wear a mask with an eye shield during high-risk procedures.

Apply the mask before donning gloves and other sterile equipment. Depending on the type and style of the mask, secure it by placing the elastic straps around the ears, placing the elastic straps around the head, or tying the mask securely to the face with ties around the head and neck. Pinch the metal nose clip securely to the bridge of the nose for a tighter fit and to minimize the gap between the mask and the nose.

HAND WASHING

A physician must thoroughly wash their hands despite the fact that sterile gloves are worn for all sterile procedures. Good hand washing technique should not be overlooked. A full surgical scrub is neither necessary nor feasible in the ED.

Rinse your hands in warm water prior to applying antiseptic soap. Apply soap, lather your hands, and rub them together vigorously for approximately 10 seconds. Wash each wrist with the opposite hand. Interlace the fingers of both hands and slide them back and forth to clean the web spaces. Clean around the nails with the fingertips and nails of the opposite hand. Completely rinse each hand from the fingers downward. Repeat the procedure a second time if your hands were grossly contaminated. Dry your hands with a disposable towel. Turn off the faucet, using the towel with which you dried your

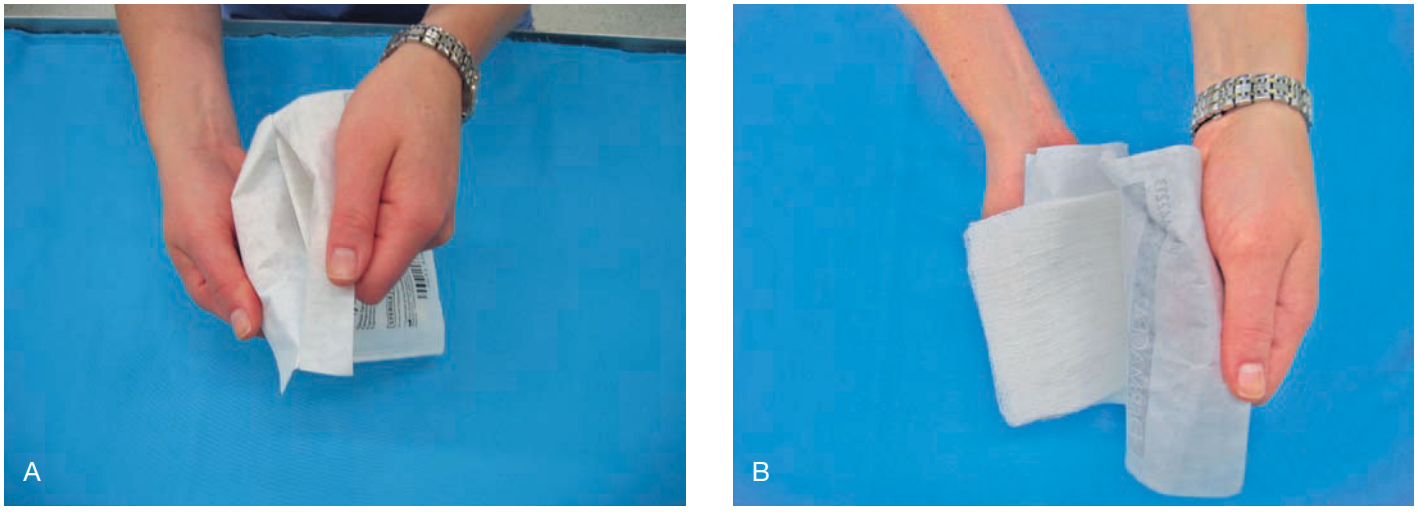

FIGURE 2-4. Opening a soft peel-back container. **A.** Grasp both sides of the unsealed edge and pull them apart. **B.** Face the pack toward the sterile field. Continue to open the edges until the contents fall onto the sterile field.

hands. Do not touch the faucet with clean hands. Otherwise they will become contaminated again.

APPLICATION OF A CLEAN GOWN

A clean (nonsterile) gown is often used as an additional barrier to contamination of both the field and the provider's clothing. Simply place your arms into the sleeves and pull on the gown with the opening toward the back. Secure the gown at the back of the neck and the lower back by tying the strings.

APPLICATION OF A STERILE GOWN

A sterile gown is worn for procedures requiring a stricter sterile technique (i.e., central venous access, diagnostic peritoneal lavage). To open a sterile gown, use the procedure previously described to open a sterile soft pack. Grasp and pick up the gown just below the neckline, touching only the inner surface of the gown. Hold the gown up and let it unfold with the inside facing you. Do not allow the gown to touch any nonsterile surfaces. Insert your arms into the sleeves until the gown is in place. Have an assistant grasp the back of the gown, pull it completely on, and tie the strings securely.

APPLICATION OF STERILE GLOVES

Wash your hands thoroughly before putting on sterile gloves. Apply a clean gown at this point if it will be worn during the procedure. Open the outer wrap of the sterile gloves and remove the inner wrap (**Figure 2-5A**). Place the inner wrap on a clean surface with the gloves' wrists facing toward you. Unfold the inner wrap, touching only the outside edges (**Figure 2-5B**). Open the inner wrap according to the procedure for opening a sterile pack (**Figure 2-5C**). Apply a sterile gown at this point if it will be worn during the procedure. Use the dominant hand to grab the opposite glove at the inner edge of its folded cuff (**Figure 2-5D**). Slip the nondominant hand into the glove, being careful not to touch the outer surface of the glove (**Figure 2-5E**). Pull the glove further onto the nondominant hand using the inner edge of the cuff (**Figure 2-5F**). Place the fingers of the gloved nondominant hand into the folded cuff of the other glove (**Figure 2-5G**). Slip the dominant hand into the glove (**Figure 2-5H**). Pull this glove over the dominant hand using the cuff (**Figure 2-5I**). Carefully unfold the cuff of each glove, taking care not to touch the fingers and palms of the gloves to nonsterile skin. Adjust each glove to ensure a snug fit over the fingers and hand.

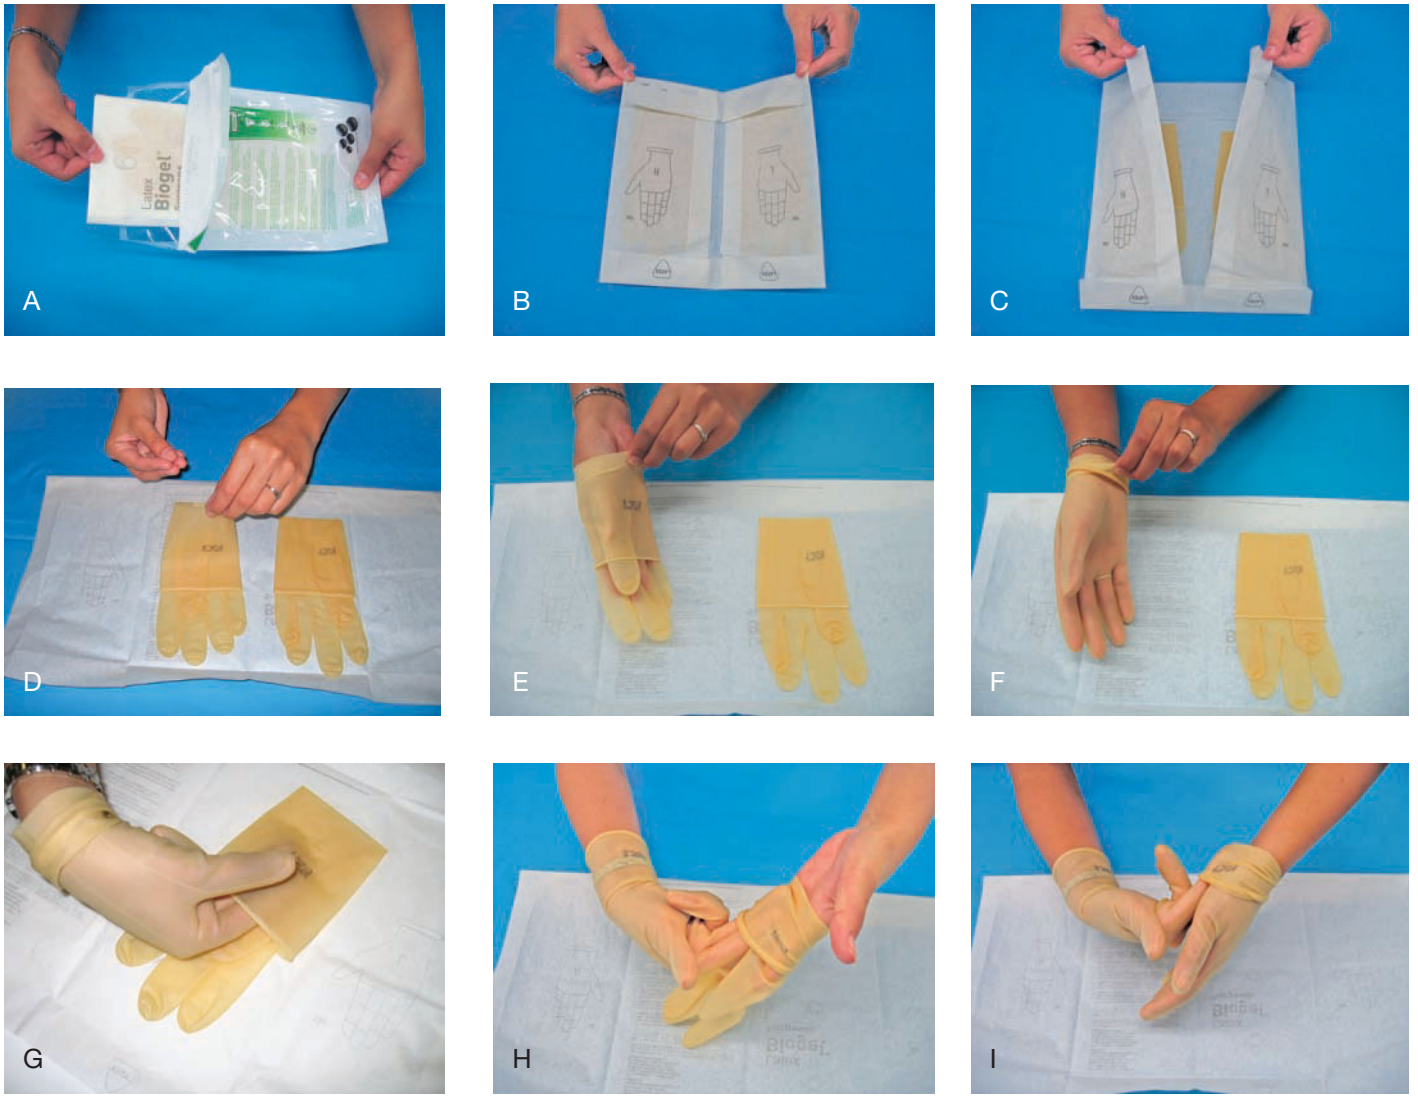

FIGURE 2-5. Application of sterile gloves. **A.** Open the outer wrap and remove the inner wrap. **B.** Unfold the inner wrap. **C.** Completely open the inner wrap. **D.** Grasp the cuff of a glove. **E.** Slip the glove onto the hand. **F.** Pull the glove onto the hand. **G.** Slip the gloved hand into the folded cuff of the second glove. **H.** Slip the glove onto the hand. **I.** Pull the glove onto the hand.

FIGURE 2-6. Removal of protective clothing. **A.** Untie the gown. **B.** Remove the gown by turning it inside out. **C.** Roll up the gown with the contaminated side facing inward. **D.** Remove the glove from the nondominant hand. **E.** Remove the glove from the dominant hand. Remove the face mask and wash your hands.

REMOVAL OF PROTECTIVE CLOTHING

Remove protective clothing in a systematic manner in order to protect yourself and others from the contaminants on your gown and gloves (**Figure 2-6**). Place all removed garments into appropriate waste containers. The first step is to untie the gown (**Figure 2-6A**). Have an assistant untie the neck strings of the gown or pull on both shoulders of the gown to break the neck strings. Untie the waist strings. Take off the gown by turning it inside out as it is removed (**Figure 2-6B**). Roll up the gown with the contaminated surface facing inward and away from you (**Figure 2-6C**). Dispose of the gown. Remove the gloves by turning them inside out, making sure that you do not touch the outside (contaminated) surface with your ungloved hands. Use the dominant hand to grasp the cuff of the glove on the nondominant hand (**Figure 2-6D**). Pull the glove inside out as you remove it and throw it away. Place the ungloved fingers of the nondominant hand into the inside edge of the gloved dominant hand and remove it by pulling the glove inside out (**Figure 2-6E**). Dispose of the glove. Remove the mask by untying its ties or removing the elastic straps from behind your ears. Dispose of the mask. Finally, wash your hands.

COMPLICATIONS

Properly performed aseptic technique has very few complications. The primary risk is in patients with sensitivities or allergies to latex or the disinfectant preparations. Although povidone iodine preparations are much less irritating than tincture of iodine, it is a good policy to clean all disinfectant off the patient at the end of the procedure so as to minimize any skin irritation. This is especially true of small children. Use alternate products for those patients with histories of allergies. **The main complication of improper aseptic technique is infection at the site of the procedure.[8] This only serves to underscore the need to perform aseptic technique properly.**

SUMMARY

Aseptic technique is an important component of all invasive procedures performed in the ED. Adequate skin disinfection and the proper use of sterile technique will greatly decrease the risk of iatrogenic infections. Aseptic technique allows a degree of protection for the caregiver as well as the patient.

3 Basic Principles of Ultrasonography

Gregory M. Press

INTRODUCTION

Emergency Physicians (EPs) have performed bedside ultrasound (US) for more than three decades. Today, US is ubiquitous in our specialty. Each year new physicians learn the skill, fresh evidence is brought to light supporting the practice, and novel indications are explored. Technological advances have delivered smaller machines with improved image quality that are less expensive than ever before. Several US manufacturers have developed machines targeted to Emergency Medicine (EM), taking into consideration our specific indications and less-than-forgiving work environment. US training is an important component of Emergency Medicine residency programs and a required core competency procedure of the Accreditation Council for Graduate Medical Education Residency Review Committee.[1] There are numerous opportunities for supplementary training in emergency US, ranging from local courses to established fellowship training programs.

Safety considerations have also contributed to the acceptance of bedside US. Sonography is noninvasive, safe in pregnancy, and does not require contrast agents that risk kidney failure, subcutaneous extravasation, and allergic reactions.[2] With increasing concern in the medical community over the long-term effects of ionizing radiation, US is recognized as an attractive alternative.[3] Additionally, the U.S. Department of Health and Human Services' Agency for Healthcare Research and Quality has highlighted US guidance for central line insertion as 1 of their top 10 recommended practices.[4]

The intent of this chapter is to provide an introduction to bedside US for the EP. The physician-sonographer should have a general understanding of the physics underlying the properties of an US wave. "Knobology" is a colloquial term used to describe the study of the buttons, dials, switches, and, of course, knobs, on the console of an US machine. It is important that all users have a good sense of their machine's operational functions. Typical machines and transducers used in the ED will be described.

THE PARADIGM OF BEDSIDE US

Bedside US is a relatively new paradigm in clinical medicine. Traditional radiology US involves a break in the patient–physician encounter. The multistep process involves the EP evaluating the patient and determining that an US is warranted, the radiologic technologist performing the study in an US suite, the radiologist reviewing the images and generating a report, and the EP ultimately correlating that information back to the patient (**Figure 3-1**).

Bedside US crafts a direct and immediate relationship between patient and EP (**Figure 3-1**). The technology is placed in the EP's hand for both image acquisition and interpretation. The EP can immediately synthesize US findings with clinical and laboratory data to paint a more complete diagnostic picture. A patient's condition can change on a moment's notice in the ED, and, fittingly, US is a dynamic tool that can be used swiftly and serially throughout a patient's course.

In the early years of emergency US, EPs often used large tank-like machines that were not conducive to a fast-paced work environment. The evolution of US has delivered small portable machines that produce high-quality images. Many US devices are the size of laptop computers that fit on maneuverable carts. "Pocket-sized" machines, not much larger than mobile phones, are being introduced and offer even greater portability (Signostics, Palo Alto, CA; GE Corporation, Fairfield, CT). The notion of the "sono-stethoscope" promises devices as small, easy to use, and available as the stethoscope, but with the superior insight of sonography. This device speaks to a true paradigm shift in clinical medicine.

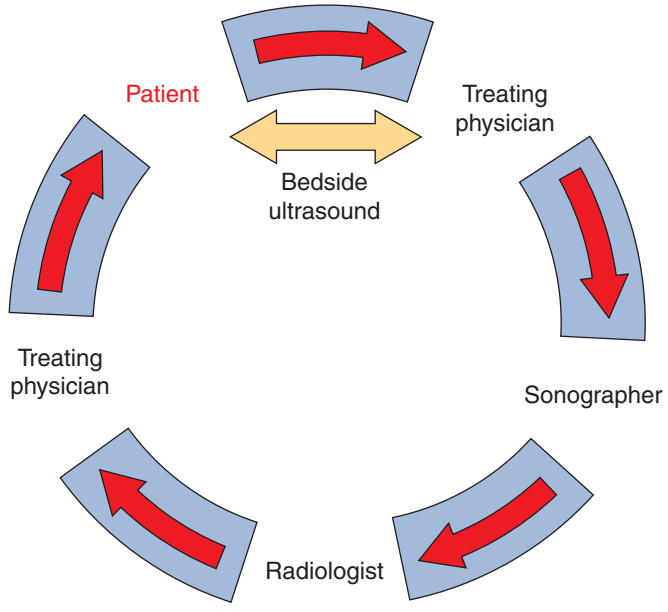

FIGURE 3-1. The paradigm of bedside US. The workflow of traditional US utilizing the radiology department (blue circle with red arrows) is a multistep process that may take hours to days to complete. Bedside US (double yellow arrow) establishes an immediate and direct interaction between patient and physician. (Courtesy of Christopher Moore, MD, RDMS, RDCS.)

INDICATIONS

The primary indications of emergency US have traditionally included: cardiac US for the presence of pericardial fluid and for cardiac activity; abdominal US for the identification of free peritoneal fluid; aortic US for abdominal aneurysms; biliary US for the detection of gallstones and cholecystitis; renal US for hydronephrosis and nephrolithiasis; and pelvic US for the identification of an intrauterine pregnancy and the exclusion of an ectopic pregnancy (**Table 3-1**). Basic emergency US has operated on the binary premise that emergencies are to be included or excluded by this diagnostic tool. As the field has developed, the boundaries between primary and secondary indications have blurred, and the yes/no equation for the evaluation of emergencies has matured.

TABLE 3-1 The Indications for Emergency Ultrasonography

Primary indications	Secondary indications	Procedural indications
Abdominal	Abscess	Arthrocentesis
Aorta	Deep vein thrombosis	Foreign body localization
Biliary	Gastrointestinal	Lumbar puncture
Cardiac	Genital	Nerve blocks
First trimester pregnancy	Lung	Paracentesis
Renal	Musculoskeletal	Pericardiocentesis
	Ocular	Thoracentesis
	Shock	Transvenous pacer placement
	Other	Vascular access
		Other

The list of indications for present-day emergency US is long and continually expanding (**Table 3-1**). Other common indications include the evaluation for deep vein thrombosis. Lung US can be used to diagnose pneumothorax, pleural fluid, and interstitial lung diseases. US evaluation for abscesses, primarily subcutaneous but also peritonsillar, deep-space, and abdominal is common. Ocular US can be used to identify a retinal detachment, lens dislocation, vitreous hemorrhage, foreign bodies, and optic nerve sheath assessment for increased intracranial pressure. Patients in shock or hypotensive may be evaluated by US of the inferior vena cava and internal jugular veins to estimate central venous pressure. Gastrointestinal US is used for the identification of appendicitis, pyloric stenosis, and other conditions. Male and female genitourinary US is used to assess for testicular and ovarian torsion, intrauterine pregnancy, and ectopic pregnancy. Musculoskeletal US is used to diagnose joint effusions, tendinopathy, and fractures. Procedural US is used for guided assistance of vascular access, paracentesis, thoracentesis, pericardiocentesis, arthrocentesis, lumbar puncture, foreign body removal, nerve blocks, and other procedures.

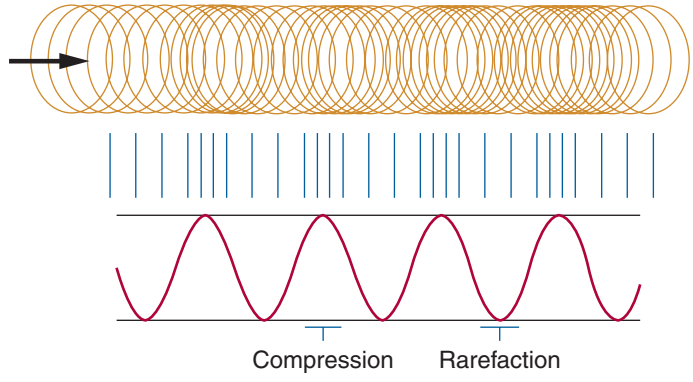

FIGURE 3-2. The longitudinal US wave. A force exerted in a parallel fashion along a coil will produce regions of compression and rarefaction. The particles of a sound wave vibrate in the direction the wave travels to create areas of high and low density and pressure. A sound wave is depicted as a classic waveform with peaks representing compression and valleys representing rarefaction.

US PHYSICS

HISTORY

Bats and toothed whales have used sound for echolocation for millions of years. Dolphins produce a series of clicks that pass through the lipid-rich melon on their heads, an acoustical lens of sorts that focuses the sound waves into a beam. Returning echoes are processed to determine the location of objects for navigational and hunting purposes.[5] Sonar (acronym for *so*und *na*vigation and *r*anging) is a maritime technique that uses sound waves for identifying oceanic objects. It was initially introduced in response to the sinking of the Titanic in 1912.[6] It was further developed and employed in World War I for submarine detection.[6] In the early 1950s, a radiologist named Douglas Howry and a team of other physicians introduced the first diagnostic US machine using a water-bath immersion tank. In the 1960s, direct contact (probe to patient) scanners were developed, and the contemporary saga of US as a viable diagnostic modality commenced.[7]

SOUND

Sound is a variation in pressure traveling through a medium and it is described as a wave. We commonly understand the sound of our vocal communication to travel through air, but sound may also travel through fluid and solid structures. Pressure variations produced by sound waves mechanically displace or oscillate the particles of the medium. This oscillation produces cycles of higher and lower densities, or compression and rarefaction, respectively. Sound waves differ from water waves in that they are longitudinal, meaning the cycles of compression and rarefaction travel in the same direction as the wave. Imagine an analogous spring coil with a force exerted into its length. A wave, or region of compression, will pass down through the coil in a longitudinal or parallel fashion (**Figure 3-2**). It is important to have an understanding of the terms that describe sound waves as described in the following sections.

FREQUENCY AND PERIOD

Frequency is the number of cycles of pressure variation per 1 second. A single cycle begins at a baseline of absent sound, increases to a maximum value (compression), decreases to a minimum value (rarefaction), and returns to baseline (**Figure 3-2**). Frequency is measured in hertz with a unit of cycles per second and corresponds to the pitch or tone of a sound. The upper acoustical frequency of human hearing is approximately 20,000 Hertz (Hz), beyond which is considered "US." Diagnostic US frequencies are generally in the range of 1 to 10 million Hz or MHz. US transducers operate on either the "low" or "high" end of this frequency spectrum, although for each transducer frequency can be adjusted within a limited range. Frequency is a principal determinant of the resolution and penetration of an image.

Period is the time required for one cycle to occur. Thus, it is the inverse of frequency (**Figure 3-3**). In ultrasonography, period is typically measured in microseconds (μs).

WAVELENGTH AND PROPAGATION SPEED

While period measures the duration in time of a single cycle, wavelength measures the distance in space of a single cycle (**Figure 3-3**). Wavelength is related to the propagation speed and the frequency of a wave. It is represented by the following equation: wavelength = propagation speed/frequency.

Propagation speed is the velocity at which sound travels through tissue. An average speed through soft tissues of 1540 m/s is generally assumed in basic US. Newer US machines incorporate the propagation speeds of different tissues to provide enhanced imaging.

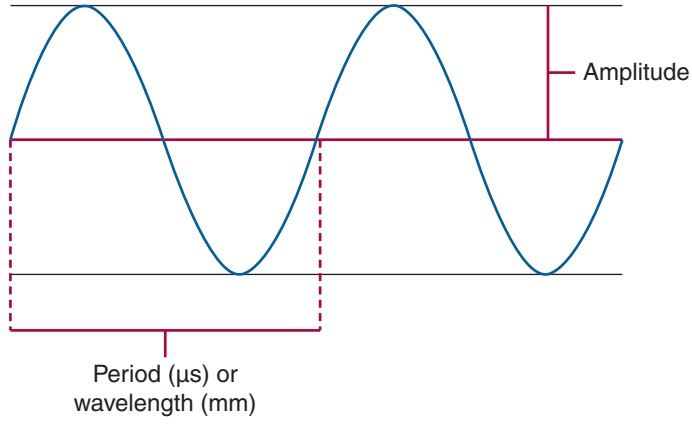

FIGURE 3-3. The characteristics of an US wave. Period is the duration in time of a single cycle of a wave, while wavelength is the distance in space. Amplitude measures the wave's variation (height) from baseline.

AMPLITUDE, OUTPUT, AND BIOEFFECTS

Amplitude is a measure of the height or maximum variation of a wave from baseline (**Figure 3-3**). While frequency corresponds to the pitch or tone of a sound, amplitude is the "loudness" or volume of a sound. In US, this correlates to the brightness of the image. Adjustments of the machine's output affect the amplitude, but changing the gain produces a similar effect on received echoes. It is preferable to alter brightness on the back end with gain, rather than subject the patient to increased output. While diagnostic US has proven to be exceedingly safe, concerns do exist over possible thermal and mechanical adverse bioeffects.[8] EPs should strive to perform studies in the shortest time frame and at the lowest output possible, in line with the safety acronym ALARA (*a*s *l*ow *a*s *r*easonably *a*chievable).

PULSED US

The earliest US machines produced a continuous stream of US waves. Today's machines release pulses or packets of waves, that is, a few cycles of US at a time. The repetitive pulses are separated by gaps of no sound. Machines can generate pulses of varying duration, frequency, and fraction of time with respect to the soundless gaps. Pulsed US has been essential in the development of advanced imaging.

AXIAL RESOLUTION

Axial resolution refers to the ability of the US machine to distinguish two separate structures that lie on top of one another and in a parallel plane to the US beam (**Figure 3-4**). As viewed on the screen, this is one structure on top of another. The structures must produce two separate echoes for each to be recognized as distinct. The smaller the wavelength of the transmitted US beam, the closer in position can be the two tiny distinguishable structures. The size of the wavelength can be decreased by increasing the frequency of the US beam. Increasing the frequency delivers greater axial resolution. But a sacrifice is seen in penetration because of increased attenuation at higher frequencies.

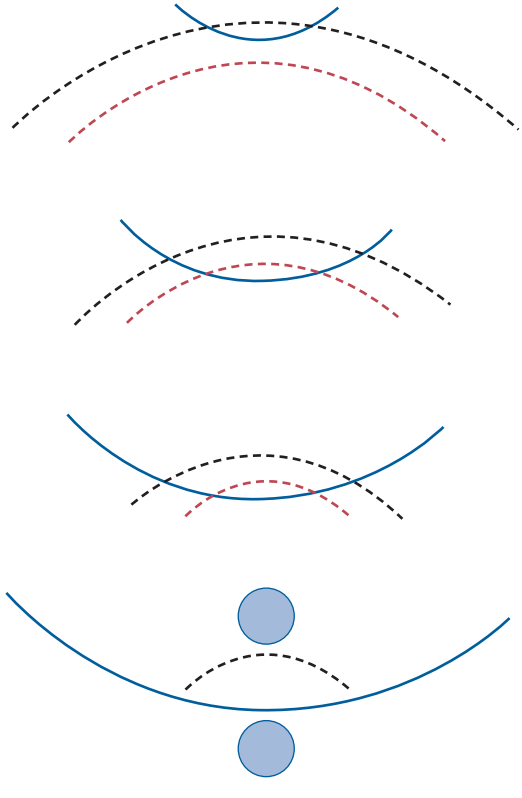

FIGURE 3-4. The axial resolution of structures. Blue curves represent the transmitted US beam. Red and black curves represent the returning echoes of the superficial and deep structures, respectively. Increasing the frequency, which shortens the wavelength, improves axial resolution.

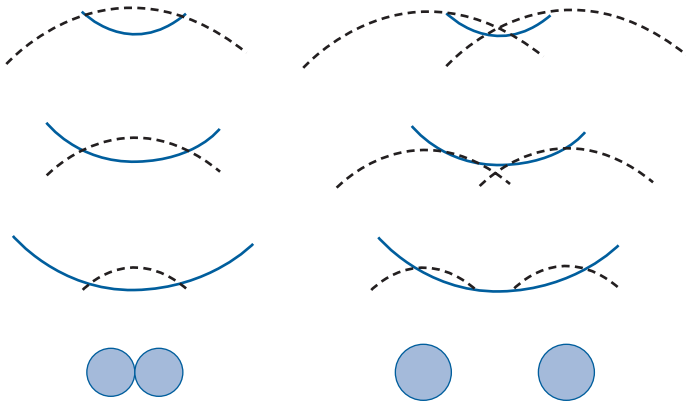

FIGURE 3-5. The lateral resolution of structures. Blue curves represent the transmitted US beam. Black curves represent the returning echoes. The structures must be able to produce separate echoes for the US machine to distinguish them. Focusing of the beam width improves lateral resolution.

LATERAL RESOLUTION AND FOCUS

Lateral resolution refers to the machine's ability to distinguish two separate structures that lie side-by-side in a plane perpendicular to the US beam (**Figure 3-5**). As seen on the screen, this is one structure to the side of another. Lateral resolution is a function of the beam width. The narrower the beam, the greater is the ability to produce separate echoes for two adjacent objects. Focusing narrows an US beam at specific depths. The focal zone is the narrowest part of the hourglass-shaped US beam. Focusing can be achieved automatically by the machine or manually by the operator. One or multiple focal zones can be set at specific depths to narrow the beam for optimal lateral resolution.

TEMPORAL RESOLUTION

Continuous US scanning is actually a collection of still frames displayed rapidly over time. US machines produce numerous frames per second as the scan beam is transmitted over and over again through the tissue. The number of frames per second is known as the frame rate. The greater the frame rate, the better the temporal resolution, and the smoother the moving image appears. High frame rates are particularly important for scanning moving structures such as the heart. Employing additional functions such as Doppler scanning may limit the machine's ability to produce high frame rates.

ECHOES

Diagnostic US is predicated on sound waves not only transmitting through tissues but also reflecting back to the transducer (**Figure 3-6**). At an interface of two different tissues, the proportion of transmission and reflection is determined by the acoustic impedance of the tissues. Acoustic impedance is a measure of a tissue's resistance to sound penetration (density × propagation speed). Acoustic impedance is high in "hard" tissues such as bone, lower in visceral organs, and negligible in fluid. Reflection of an echo is a function of the difference between the acoustic impedance of two

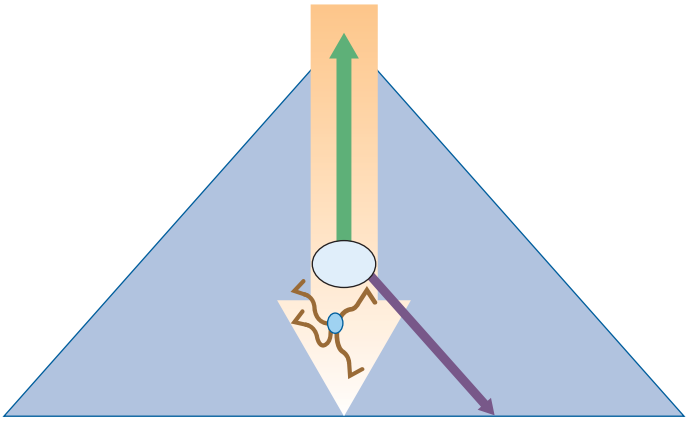

FIGURE 3-6. The echoes produced as the US beam penetrates tissue. The transmitted beam (orange) attenuates as it penetrates. A reflected echo (green) is produced at an interface. Refraction (purple) and scatter (brown) contribute to attenuation. Scatter produces the imaging within homogenous tissue.

adjacent tissues. For instance, when a sound wave travels from soft tissue to bone, a significant proportion of the wave will reflect back to the probe, and a minimal amount will transmit through for imaging of deeper structures.

When an US beam travels through parenchymal tissue without interfaces (of homogenous acoustic impedance), such as the liver, imaging is generated not by reflection but rather by scatter. Scattering occurs when a sound wave encounters particles smaller than its wavelength or objects with rough and irregular surfaces. An analogous effect is seen when light is shone through fog. There is some transmission and reflection of the light, but it is the scattering of light that reveals the mass of fog.

In order for an US machine to generate an image, it must determine not only the intensity of the returning echo but also the location of the reflecting structure (aka reflector). With a given propagation speed (velocity of sound through tissue), the machine uses the travel time of the sound wave to calculate the distance the reflector sits from the transducer. The longer the travel time, the deeper is the reflector or structure.

ATTENUATION

Sound weakens or attenuates as it propagates through a medium (**Figure 3-6**). Attenuation is a result of absorption, reflection, refraction, and scattering of the US wave. Absorption is the conversion of sound to heat as the wave passes through tissue and accounts for the vast majority of attenuation. Absorption has very limited clinical effect for diagnostic US but is the basis of therapeutic US. Reflection is the "echoing" of the wave back to the transducer. Refraction and scattering are the redirection of waves on encountering certain interfaces.

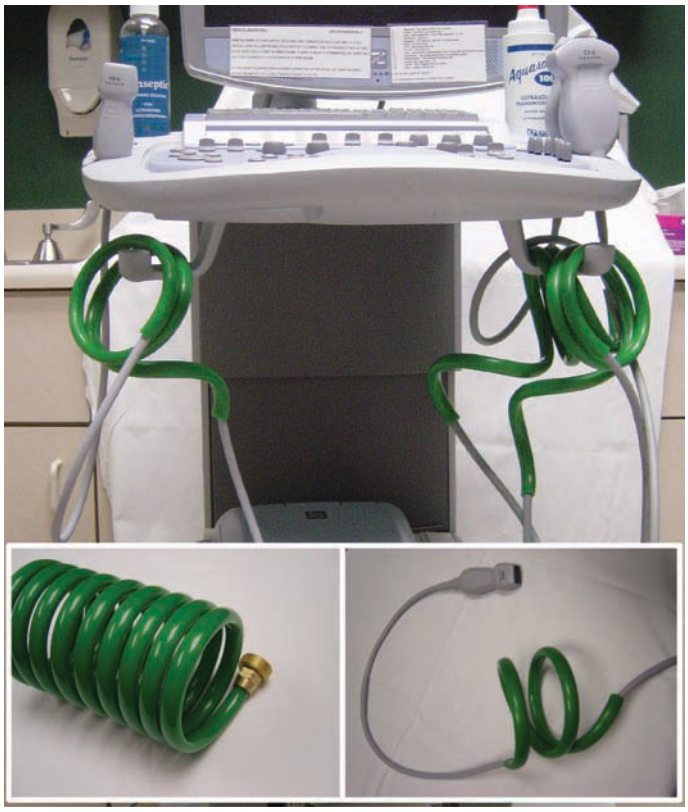

FIGURE 3-7. The Press-ervation technique for transducer cords. Segments of a coiled garden hose are sliced along their length and placed around the middle portion of a transducer cord. This prevents damage from wheels running over dangling cords.

US TRANSDUCERS (PROBES)

There are many types of transducers (also called probes) that vary in size, shape, construction, transmitted frequency, and function (**Table 3-2**). Transducers can be expensive and are at risk for damage in a busy ED. Probes are often dropped and cords frequently run over by the wheels of the US machine. Creative solutions to prevent damage to dangling cords have been developed (**Figure 3-7**), but the expense of replacing transducers should be factored into

TABLE 3-2 Common Types of US Probes Used in the ED

Transducer type	Vascular	Abdominal	Endovaginal	Cardiac
Transducer shape				
Type of scanning	Linear sequenced	Curved sequenced	Microcurved sequenced	Phased array
Transducer frequency Megahertz	High 7–10	Low 2–5	High 7–100	Low 2–5

Photographs courtesy of Zonare Medical Systems.

any warranty and maintenance considerations. Many US manufacturers offer multiport transducer connections that allow a number of probes to be connected at once, each activated by the push of a button. Limiting the connecting and disconnecting of transducers decreases the chance of damaging fragile connector pins.

Transducers are the link between the US machine and the patient. The essential component of the transducer for generating an image is the piezoelectric element. The piezoelectric principle states that when an electrical voltage is exerted on certain materials, a mechanical pressure or vibration will be produced. A transducer's piezoelectric elements, or crystals, when vibrated by an electrical voltage will generate a mechanical sound wave. The returning sound wave in turn vibrates the elements creating an electrical voltage that carries image data back to the US machine.

AUTOMATIC SCANNING

Transducers are constructed of numerous elements arranged along the width of the probe. Unlike a flashlight that emits a single continuous beam of light, the US beam is a composite of pulsed firings of the elements. Automatic scanning is the electronic activation of the elements or arrays of crystals to generate a beam for a cross-sectional image. Two types of automatic scanning currently employed by transducers are sequenced array and phased array scanning.

SEQUENCED ARRAY

Sequenced array scanning involves the sequential firing of groups of elements across the transducer assembly (**Figure 3-8**). One scan line after another is generated along the width of the probe. Linear transducers are flat-topped and produce a rectangular beam made up of parallel scan lines. Curved transducers transmit scan lines similarly, but following the curve of the probe and create a sector or pie-shaped image. The elements are fired rapidly and multiple frames of cross-sectional images are produced per second.

PHASED ARRAY

Phased array transducers generally have a narrow flat-topped footprint. The tightly packed elements are electrically activated as a single unit, but with a slight time lag between each element resulting in an angling of the pulse direction. The electronic activation and angling of each subsequent pulse is slightly changed, and the resultant composite beam is a sector or pie-shaped (**Figure 3-8**).

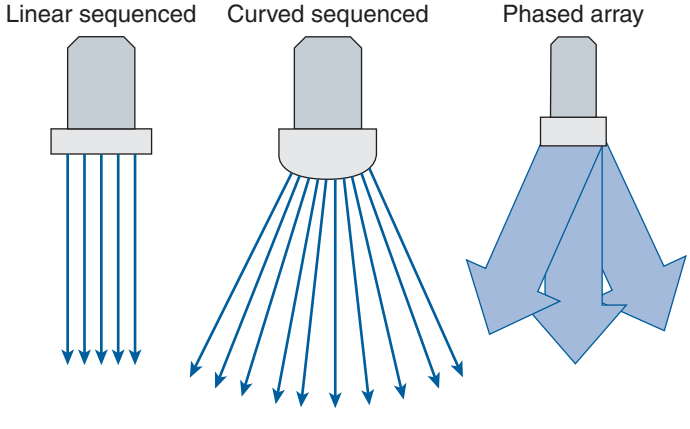

FIGURE 3-8. The basic types of transducers. Linear sequenced and curved sequenced array probes transmit beams in a sequential fashion following the shape of the transducer head to produce rectangular and pie-shaped images, respectively. The beams of phased array probes are steered by slight delays in the firing of the elements to produce a pie-shaped image.

TRANSDUCER TYPES

The typical arsenal of transducers for emergency US includes a low-frequency curvilinear or phased array probe, a high-frequency linear probe, and an endocavitary probe (**Table 3-2**). Numerous other types of transducers are manufactured. It is worthwhile evaluating the options available before purchasing a transducer.

CONVEX TRANSDUCERS

Convex or curved transducers are low-frequency probes that produce a sector-shaped image by sequenced array scanning. These are commonly used in EM, as they are useful for most US examinations of the torso. The resolution of these probes is inferior to that of linear transducers, but the greater penetration allows for imaging of relatively deep structures such as the aorta, gallbladder, liver, kidneys, and heart. Microconvex probes have a similar but smaller footprint with a tight curvature that allows for easier use between adjacent ribs.

PHASED ARRAY TRANSDUCERS

Phased array transducers are low-frequency probes made for echocardiography and general imaging of the torso. These probes have a small flat footprint ideal for maneuvering between ribs and imaging the heart.

LINEAR TRANSDUCERS

Linear transducers are high-frequency probes that are ideal for imaging superficial structures. They are generally wide and flat-topped, and produce a rectangular image by sequenced array scanning. These transducers are useful in the ED for imaging of blood vessels and guided line placement, skin abscesses, musculoskeletal pathology, pneumothoraces, ocular and testicular pathology, and a host of other superficial parts.

ENDOCAVITARY TRANSDUCERS

Endocavitary transducers are high-frequency probes that have elements arranged in a tight curve at the end of a long handle. They are designed primarily for vaginal insertion and high-resolution imaging of the female reproductive organs. These probes can be used for US-guided vascular access if no other high-frequency probe is available. The small footprint and room afforded by the handle may even prove superior to a linear probe in some instances. The probe can be used in a patient's mouth for the evaluation of oral and pharyngeal pathology, such as a peritonsillar abscess.

FREQUENCY AND TISSUE HARMONIC IMAGING

Transducers may differ in inherent frequency. The frequency of each probe can be adjusted within a narrow range of generally a few megahertz. If greater depth is required to view pertinent structures, lowering the frequency may be beneficial. Conversely, if finer resolution is desired more than deep penetration, increasing the frequency may improve visualization.

Tissue harmonic imaging is another means of enhancing US scanning. US echoes return from tissues in multiples of the transmitted frequency. The machine can filter out the transmitted frequency and focus on receiving the second harmonic frequency (twice the transmitted frequency). The returning harmonic beam is narrower than the beam of the fundamental frequency, and, hence, lateral resolution is improved. Artifacts and distortions are also reduced with harmonic imaging.

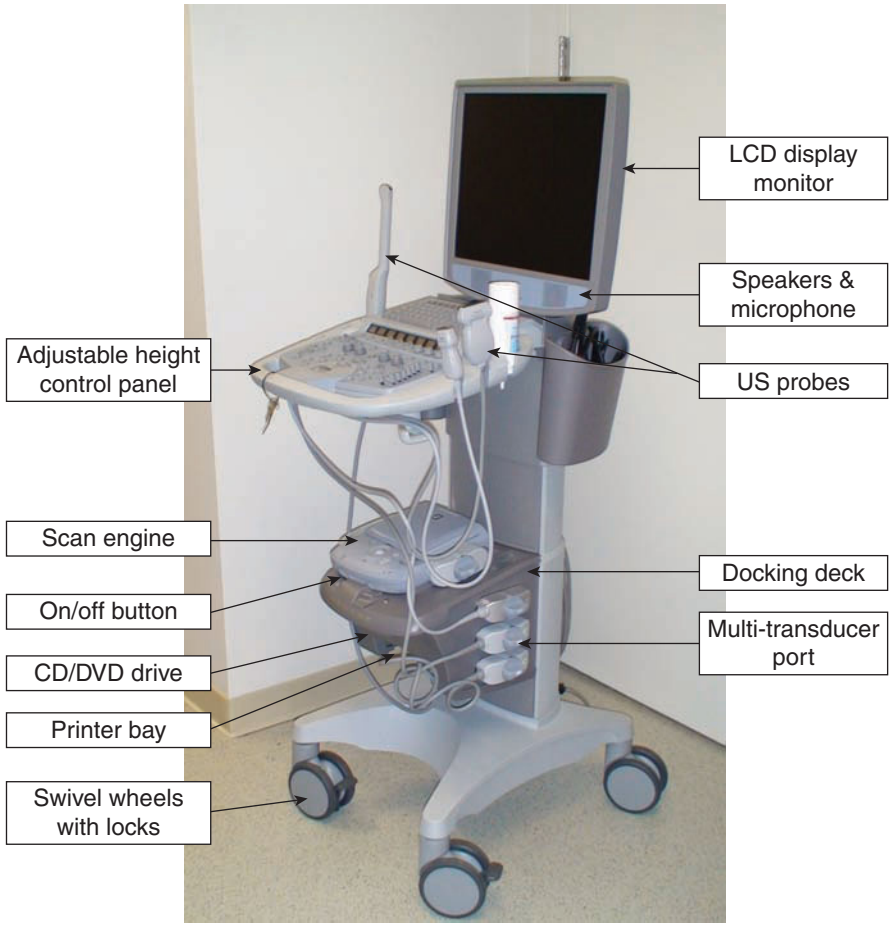

FIGURE 3-9. Components of a typical US machine.

COUPLING MEDIUM

Acoustic gel is the coupling medium used in diagnostic US. The gel obviates any air between the probe and the patient to improve US beam transmission. Apply the gel across the footprint of the probe or onto the patient's skin. A good rule of thumb is that too much gel is preferable to too little.

ULTRASOUND MACHINE INSTRUMENTATION

An US machine is made up of numerous components (**Figure 3-9**). The imaging system hardware consists of a beam former, signal processor, and image processor. The console allows the user to interface with and manage the imaging. The monitor screen provides for black and white as well as color viewing of the imaging. Transducers, single or multiple, have connecting ports onto the machine. Archiving tools, such as a printer or digital storage media, are available standard or as options. The following sections review the key functions that an EP should know when performing US examinations.

THE CONSOLE

The US console generally consists of a keyboard for data entry and numerous knobs, buttons, dials, and toggle switches for manipulating the images. Carefully read the user's manual or undergo a detailed operations briefing by the manufacturer's application specialist after purchasing a new machine. While there are many functions that are universal to US machines, each machine has its proprietary functions.

GAIN

Gain is the US analog to the volume control on a radio. It alters not the transmitted beam, but the returning echo to amplify intensity. Gain is measured in decibels and relates to the brightness of the image. Machines generally have a knob that can be dialed to adjust the gain, increasing or decreasing the overall brightness of the image (**Figure 3-10**).

Time gain compensation (TGC) allows for adjustments of gain at specific depths. Most TGC controls consist of a collection of sliding knobs arranged in a column (**Figure 3-11**). The knobs at the top of the column correspond to the near field and those at the bottom correspond to the far field. As an US beam penetrates to greater depths, the intensity of the beam is attenuated or dampened. TGC allows compensation for attenuation. For general abdominal imaging, arrange the sliding TGC knobs with a slope of increasing gain at greater depths. Use TGC to increase or decrease brightness at discreet depths of the image. To compensate for the artifactual brightness seen deep to a fluid-filled structure, decreasing the gain at that depth can improve visualization.

DEPTH

The depth of the field of view can be adjusted by the turn of a dial or toggle of a switch. Depth is conventionally measured in centimeters. Hash marks along the side of the image denote units of distance. Depth adjustments alter the penetration of the imaging beam and allow the user to appropriately "magnify" the organ or region of interest (**Figure 3-12**). If the depth is set too shallow

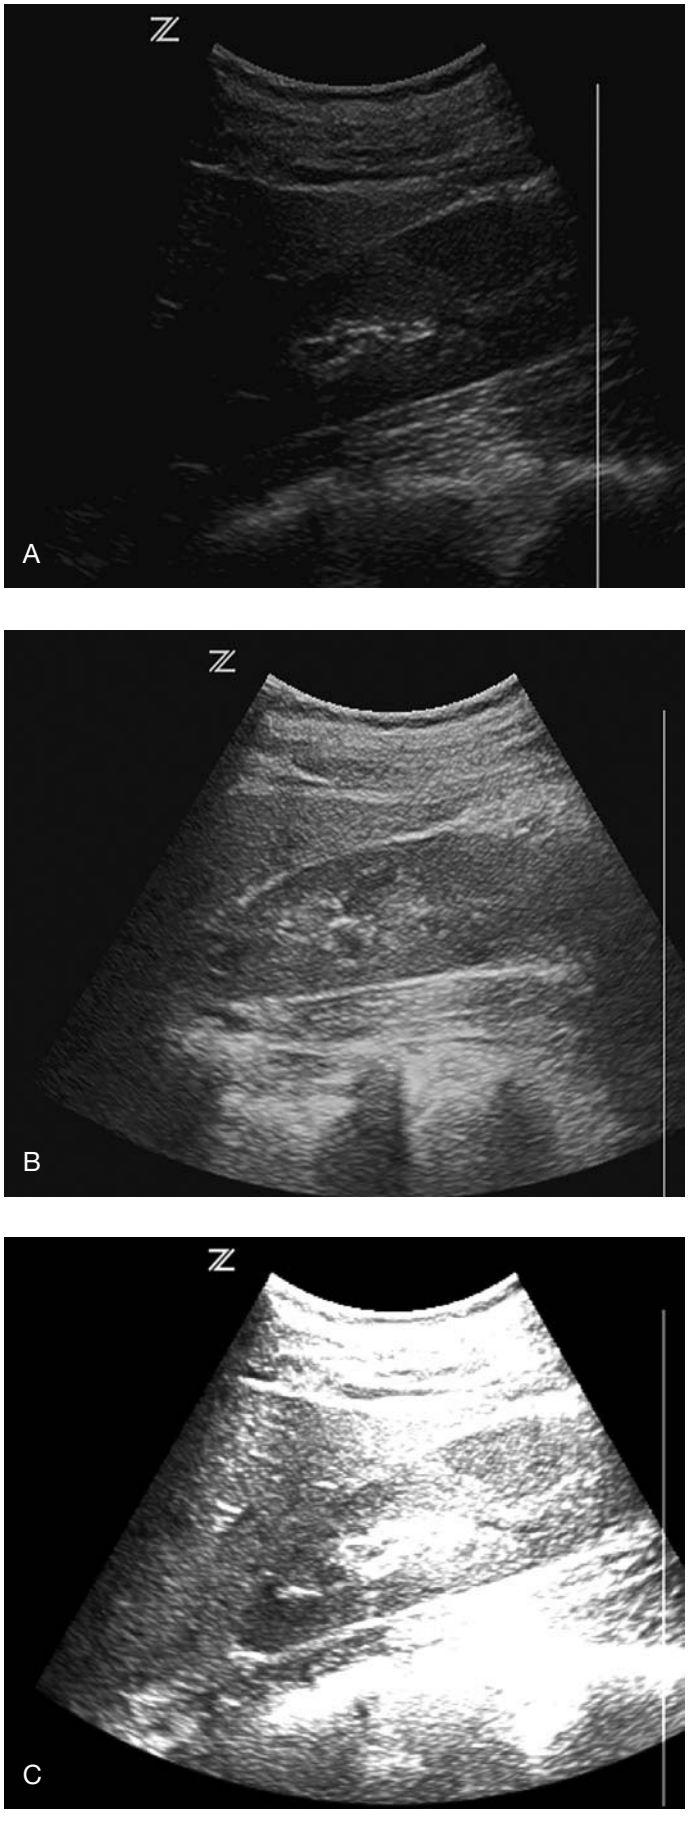

FIGURE 3-10. Gain adjustments brighten and darken the US image. These images of a kidney display a gain setting (**A**) too low, (**B**) appropriate, and (**C**) too high.

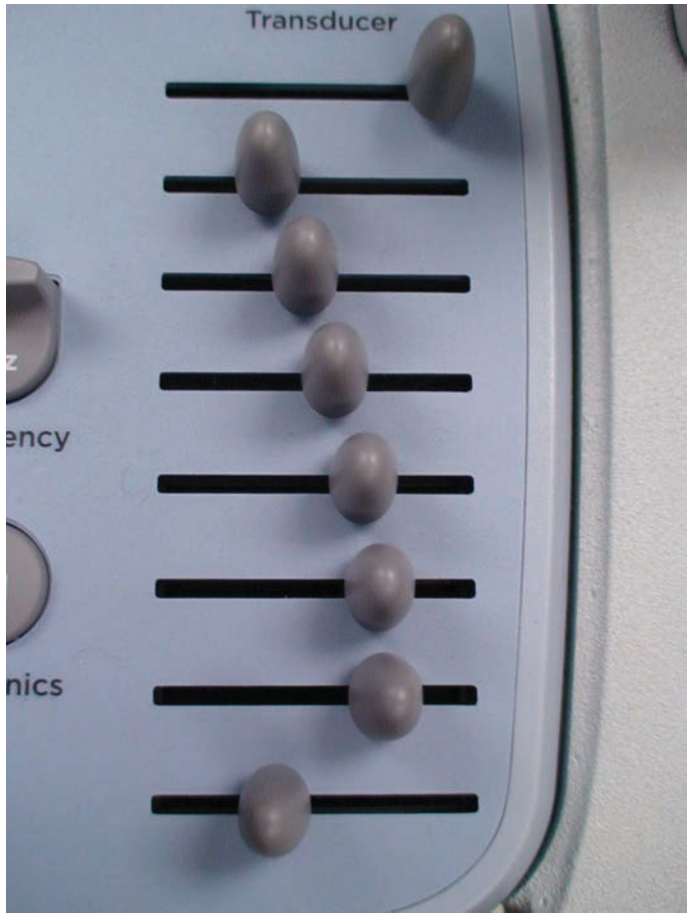

FIGURE 3-11. Time gain compensation (TGC) controls on an US machine consist of a column of knobs that slide back and forth to adjust the gain at specific depths.

("overmagnification"), the organ of interest will appear too large and its deepest portion may be cut off the screen. If the depth is set too deep ("undermagnification"), the organ of interest will appear too small in the near field with wasted space in the deeper regions.

PATIENT DATA ENTRY

All machines allow the entry of demographic information about the patient and the US examination. The patient data entry screen presents numerous fields that can be filled by typing on the keyboard. These fields commonly include patient name, medical record number, date of birth, and a comments section to name a few. Functions also often available on this screen are exam and transducer selection.

FREEZE AND CINE

Most machines allow both still images and video loops to be saved. Hitting the "freeze" button stops real-time continuous scanning. The most recent image is displayed on the screen with a few seconds worth of images (known as cine) available for review. Use the rollerball or trackpad to rewind through the cine memory of frames. This allows the viewing and subsequent saving of the most desired still image. A number of machines can allow the viewing of a loop of images as a video.

MISCELLANEOUS FUNCTIONS

There are numerous additional functions on the console. Magnify images with the "zoom" function. The "measure" button activates

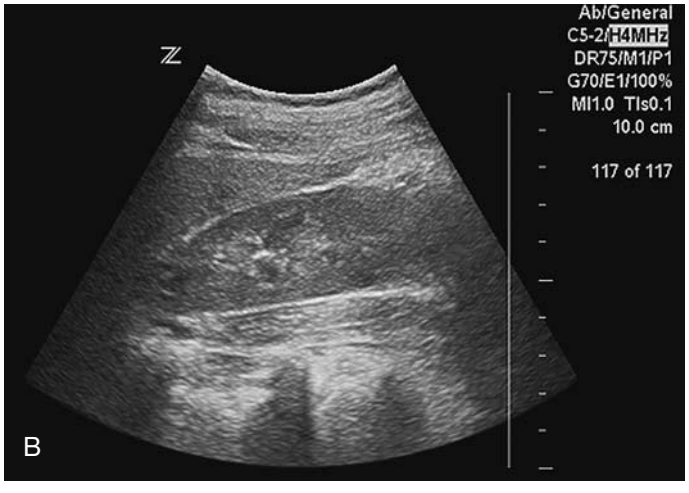

FIGURE 3-12. Depth adjustments increase and decrease the penetration of the US beam. These images of a kidney display a depth setting: (**A**) too deep at 22 cm, (**B**) appropriate at 10 cm, and (**C**) too shallow at 6 cm.

calipers that are moved with the trackpad or rollerball. This allows for precise measurements to the millimeter. Adjust the dynamic range to produce effects similar to modifying the contrast of a photograph. Other functions include gray-scale mapping, edge, and persistence for image alteration. A dual screen function displays two side-by-side imaging fields. Function keys can be set for easy access to commonly performed tasks.

PRINCIPLES OF GENERAL US IMAGING

DIMENSIONALITY

Imaging with US is akin to shining a flashlight in the dark. While a flashlight's beam is conical, the US beam is flat, and, hence, the image displayed on the screen is a two-dimensional slice. Sound transmits through most tissues to allow for visualization of deep structures in the cross-sectional slice. Scanning the beam back and forth stacks multiple two-dimensional slices in a movie format and provides a sense of spatial orientation. Rotating the probe 90° and scanning through the perpendicular plane helps to gain a three-dimensional comprehension of structures.

ORIENTATION

Orientation is entirely dependent on how the transducer is placed on the patient. Each transducer has a marker (usually a bump, ridge, or indentation) that correlates with an indicator on the screen to establish orientation. If the transducer is held with the marker aimed cephalad, the screen indicator is located on the left side of the screen (**Figure 3-13**). This results in the left side of

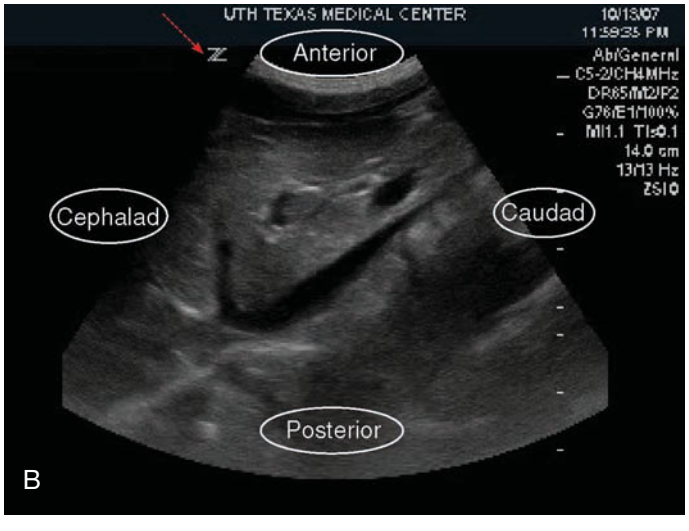

FIGURE 3-13. The orientation marker (white arrow) on the transducer corresponds with the indicator on the screen (red arrow).

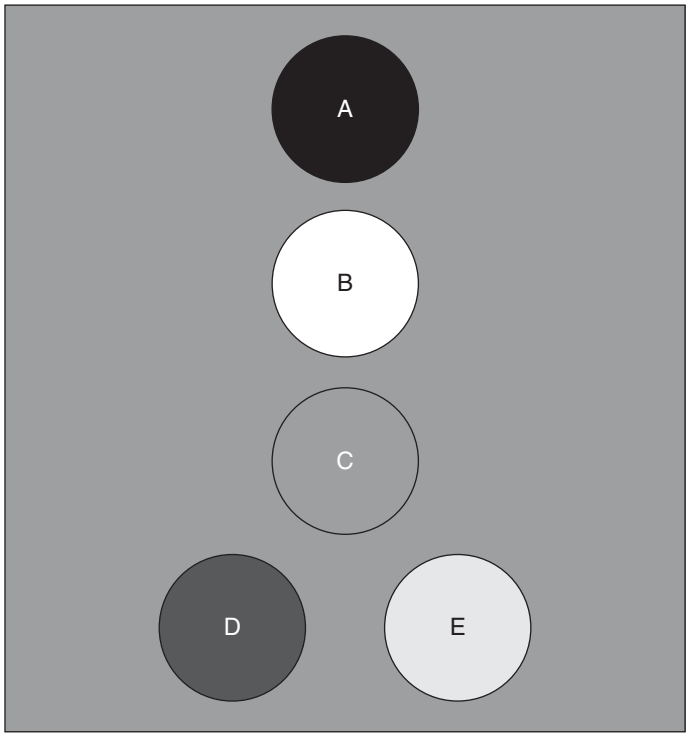

FIGURE 3-14. Echogenicity of structures is represented by their brightness on the screen. **A.** Anechoic fluid is black. **B.** Echogenic, or highly reflective, than adjacent tissues. **C.** Isoechoic, or same echo-texture, as adjacent tissue. **D.** Hypoechoic, or less echoic (darker), than adjacent tissues. **E.** Hyperechoic, or more echoic, than adjacent tissues.

the image representing the cephalad aspect and the right side the caudal aspect (**Figure 3-13**). For conventional radiology imaging, the screen indicator is located on the left side. Most emergency US examinations require views with the transducer marker aimed to the patient's head and the patient's right. The image is displayed with the near field (closest to the probe) at the top of the screen and the far field (farthest from the probe) at the bottom of the screen.

ECHOGENICITY

Fluid is anechoic, meaning US transmits through fluid without any reflected echoes. The echogenic silence is processed to generate black pixels on the screen. Highly reflective structures, such as the diaphragm and pericardium, are termed echogenic or hyperechoic. These structures will produce white imaging. Two structures of the same echo-texture are isoechoic. Less reflective tissue is hypoechoic and appears darker on the screen when comparing two tissues (**Figure 3-14**).

ARTIFACTS

Imaging artifacts are frequently encountered in ultrasonography. They are erroneous representations of the anatomy in the reflected echo. It is important to understand and expect certain artifacts to prevent misinterpretation of the images. Artifacts may also help to appreciate certain structures that would otherwise be less obvious.

SHADOWING

A highly reflective object allows very little of an US beam to transmit through it. Most of the beam is reflected back to the transducer and the structure is represented as hyperechoic or white on the screen. The US machine interprets the lack of returning

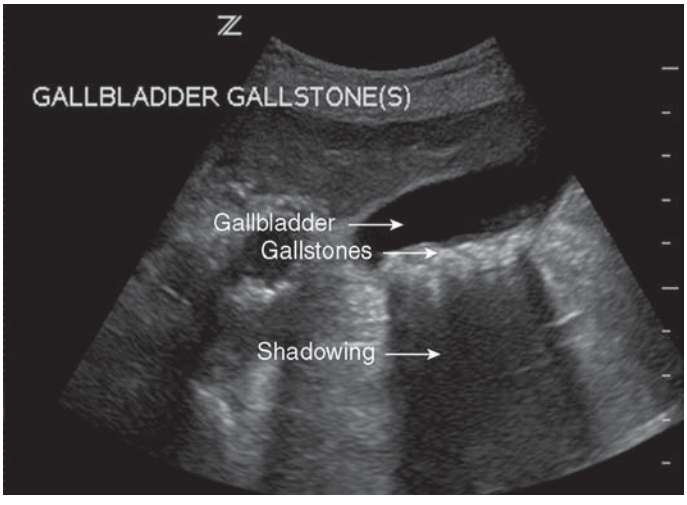

FIGURE 3-15. Echogenic gallstones are present in the gallbladder. Shadowing is seen deep to the gallstones.

echoes deep to a structure that is hyperechoic as the lack of reflection, similar to that seen with fluid. This is seen as a black shadow on the screen (**Figure 3-15**). While shadowing from ribs may obscure deep anatomy, the shadows of gallstones aid in their identification.

REVERBERATION

Highly reflective interfaces may result in multiple reflections. Bouncing of the sound beam between the reflector and the transducer can create false echoes known as reverberation (**Figure 3-16**). It can be seen when the sound beam encounters two closely spaced interfaces, such as the two walls of a needle or the visceral and parietal pleura. The echo reflects back and forth between the interfaces, but with some transmission of the beam back to the probe each time. These returning echoes generate artifactual reflections on the screen termed reverberation or comet tails (**Figure 3-17**).

FIGURE 3-16. The two walls (white arrows) of a cylindrical bullet are seen superficially. Reverberation artifact produces an additional false echo (red arrow). Shadowing is seen deep to the bullet.

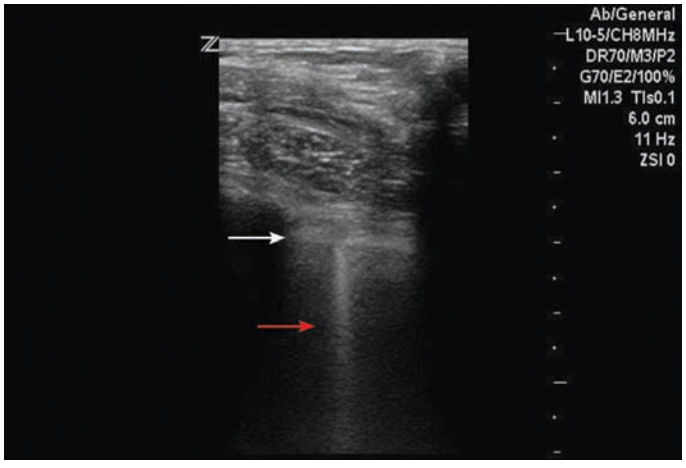

FIGURE 3-17. Each back and forth reflection between the visceral and parietal pleura (white arrow) results in an echo transmitted back to the probe. Multiple echoes returning one after another produce echogenic artifacts, each deeper than the next. The artifact resembles a comet tail (red arrow).

MIRROR IMAGE

Highly reflective tissues can cause mirror-image artifacts. Structures seen on the near side of a bright reflector are displayed on the other side of the reflector as well. This is common with the diaphragm. Triangulation of the beam path delays the return time of the echo to mirror a second reflector (**Figure 3-18**). Mirror-image artifact can help to exclude a hemothorax by visualizing the liver or spleen cephalad to the diaphragm (**Figure 3-19**).

ENHANCEMENT

Attenuation does not occur when a sound beam passes through a fluid-filled structure. The beam's high intensity is maintained through the fluid. A strong echo is generated off the posterior wall of the fluid-filled structure. The artifact seen on the screen is a very hyperechoic region deep to the fluid-filled structure that may obscure the actual anatomy (**Figure 3-20**).

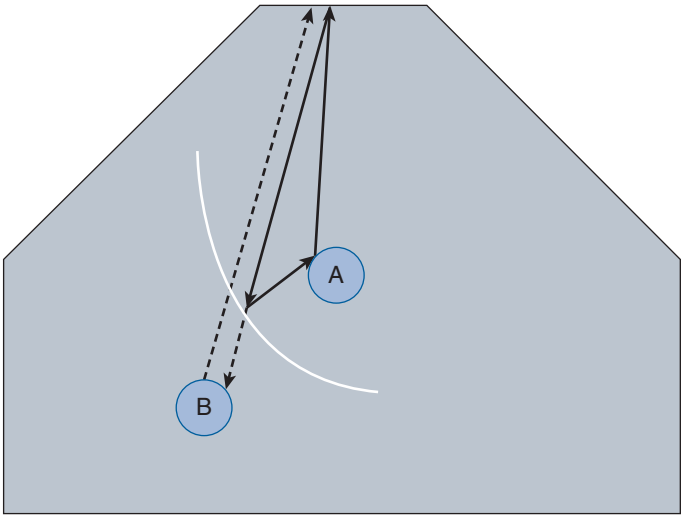

FIGURE 3-18. Bright reflectors like the diaphragm (white) can generate mirror-image artifacts. The initial beam (solid arrow) reflects off the diaphragm and then an anatomical structure (**A**) before returning to the transducer. The machine processes the delay as a signal from a deeper structure along the initial scan line (dashed arrow) and generates an artifact (**B**) on the screen.

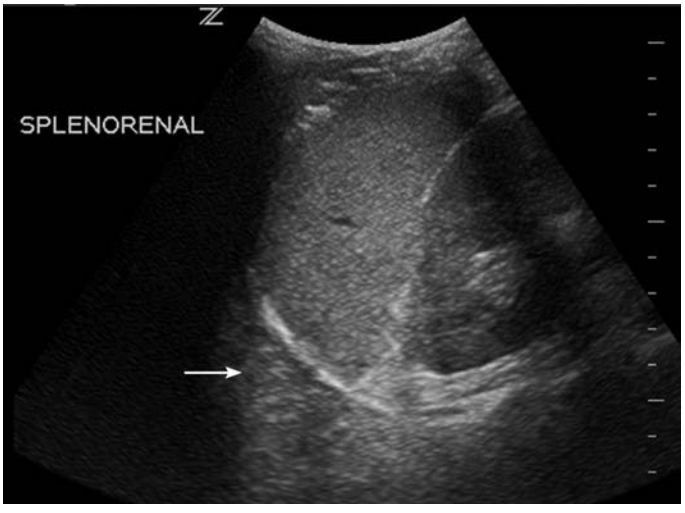

FIGURE 3-19. A mirror-image artifact (white arrow) of the spleen is seen cephalad to the diaphragm. This is distinct from fluid that appears black.

MISCELLANEOUS ARTIFACTS

A number of additional artifacts can interfere with imaging. Side lobes are weak beams emitted lateral to the central axis of the scanning beam that may produce false echoes. Section thickness artifact is a result of interfering information from the outside of the flat slice of the scanning beam. Refraction of the beam tangentially off an interface may produce a double image of a structure lateral to the original. Shadowing in the narrow angle of refraction may be seen deep to the interface.

US MODES

BRIGHTNESS MODE

Brightness mode is commonly referred to as B-Mode. This is the basic scanning mode for US. It displays the standard two-dimensional gray-scale image.

FIGURE 3-20. High-intensity echo returns from the posterior wall of the bladder result in a hyperechoic region of enhancement artifact (white arrow).

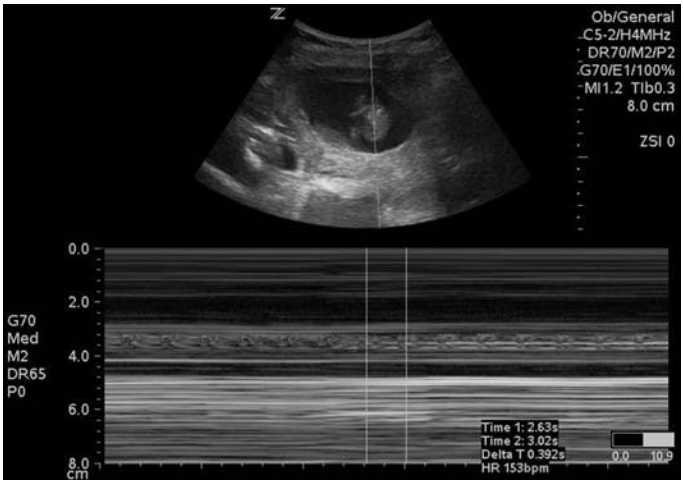

FIGURE 3-21. The M-Mode. The B-Mode image is displayed at the top of the screen. A green vertical line is seen over the B-Mode image. The area under the green line is displayed over time at the bottom of the screen. The fetal heartbeat is seen at a depth of 3.6 cm and measured at 153 beats/min.

MOTION MODE

Motion mode or M-Mode is used to assess moving structures. Activating M-Mode produces a vertical line on the image (**Figure 3-21**). The line can be moved left or right with the rollerball or trackpad. The US beam penetrating the tissue along that single line is displayed in a continuous graphical manner on the bottom of the screen (**Figure 3-21**). The *x*-axis of the display is depth and the *y*-axis is time. If the line is set on immobile tissue, there will be no variation in the M-Mode display. Movement along the line, such as a beating heart, allows measurements and rate determinations (**Figure 3-21**).

DOPPLER MODE

Doppler scanning allows the assessment of the presence, direction, speed, and character of blood flow and tissue movement. Doppler takes full advantage of the real-time dynamic nature of US. If an object is moving toward or away from the transducer, the frequency of the reflecting echo will be higher or lower, respectively, than the transmitted frequency. The Doppler shift is the difference between the transmitted and reflected frequencies. The US machine can calculate velocity using the Doppler shift. Turbulence, or the variance in velocity of multiple objects in flow, can be assessed. The complexities of Doppler physics and operations are beyond the scope of this chapter.

Emergency Physicians can utilize Doppler in the assessment of deep venous thromboses, testicular or ovarian torsion, compromised vascular flow in the extremities, inflamed or hypervascular tissues, to differentiate vessels from nonvascular structures for diagnostic and procedural purposes, and for advanced echocardiography.

COLOR DOPPLER MODE

A "C" button on the machine's console usually signifies color Doppler mode. Activating color Doppler produces a box, or region of interest (ROI), overlying the image. The ROI can be maneuvered over the desired area. The size of the box can be manipulated to be larger or smaller depending on the study being performed. Within the ROI, flow will be displayed in a color schematic (**Figure 3-22**). Flow toward the probe is typically red. Flow directed away from the probe is typically blue. Gradients of red and blue signify the speed of the flow.

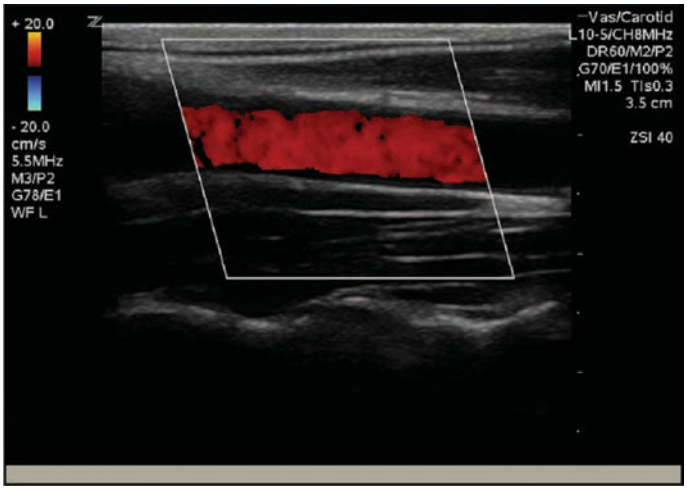

FIGURE 3-22. The color Doppler box, or region of interest (ROI), placed over the carotid artery reveals flow in the direction of the probe (red).

PULSED WAVE DOPPLER MODE

Pulsed wave Doppler provides a quantitative assessment of flow velocities. Activating pulsed wave Doppler splits the screen, typically placing the image at the top of the screen and a dynamic graph of flow velocities at the bottom (**Figure 3-23**). A small "gate" can be positioned over a specific vascular area to measure flow. The size of the gate can be adjusted, allowing very narrow regions to be accurately assessed. The dynamic Doppler graph displays time on the *x*-axis and velocity on the *y*-axis. Movement toward the probe is depicted as a positive velocity deflection. Movement away from the probe is depicted as a negative deflection.

POWER DOPPLER MODE

Power Doppler is another method of displaying blood flow or tissue motion (**Figure 3-24**). It utilizes the same ROI box as color Doppler, but with only one shade of color. Power Doppler is very sensitive in identifying the presence of flow but does not reveal direction. It is advantageous in identifying low flow states, subtle tissue motion, and imaging small or deep vessels.

FIGURE 3-23. The pulsed wave Doppler mode. A Doppler gate is placed over the center of the carotid artery. Flow is displayed in active graphical format at the bottom of the screen. Positive deflections indicate systolic flow in the direction of the probe.

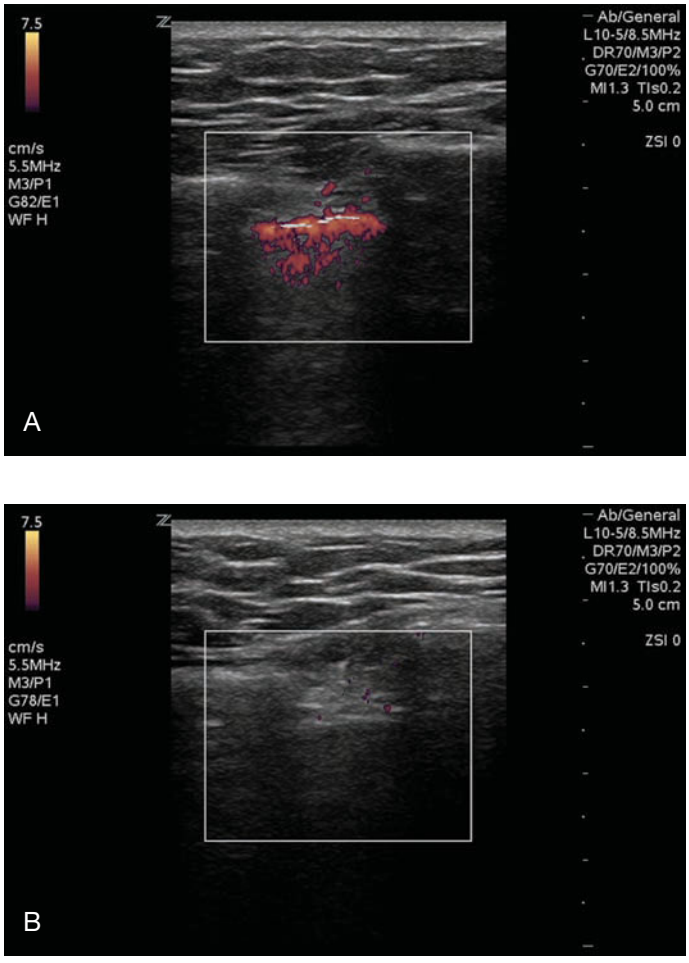

FIGURE 3-24. The power Doppler mode. **A.** Normal lung slide at the pleural line. The tissue movement generates a power Doppler signal. **B.** No lung slide or tissue motion is seen in the setting of pneumothorax.

US IMAGE ARCHIVING

There are numerous ways to archive US images. Still images can be sent to printers for hard copy archiving. Thermal printers are relatively small and can be attached to the US cart. The gray-scale printouts are fine reproductions of the image, but are at risk for degradation over time.

Digital archiving allows users to save both still images and videos with a far reduced need for physical storage space. Examinations can be saved to hard drives built into the US machine or to peripheral devices. Machines today offer many options for peripheral storage including compact discs, digital video discs, external drives with universal serial bus connections, and magneto-optical disks.

Specific formats for digital archiving of medical imaging have been developed, in particular the digital information and communication in medicine (DICOM) format. Most US machines today have the ability to save images in the DICOM file format. Picture archiving and communication system (PACS) has been developed for viewing medical imaging in DICOM and other formats. These systems are employed by radiology departments for viewing US images, as well as computed tomography, magnetic resonance imaging, plain radiographs, and other imaging modalities. Advantages to saving DICOM images on PACS include improved organization, reliability, and the ability to transmit remotely.

SUMMARY

Ultrasound is fast becoming a commonly used modality in EDs. All EPs should become familiar with US as it will soon become the standard of care for patient evaluation, patient management, and procedural guidance. Take the time to investigate the various options available for machines, probes, and accessories. A thorough understanding of the functioning and features of an US machine is essential before making clinical decisions. Training is readily available through US fellowships, CME courses, and ultrasound manufacturers.

4 Ultrasound-Assisted Procedures

Jehangir Meer, Sam Hsu, and Brian Euerle

INTRODUCTION

Emergency Physicians commonly perform invasive procedures. These procedures have traditionally been taught using surface landmarks, with the assumption that anatomy is reliably similar from patient to patient. The increasing use of ultrasound (US) to assist in procedural guidance has demonstrated that this is not the case. **Utilizing US to assist with procedures has numerous benefits.[1–9] It is safer for patients as it has been shown to reduce complications. US improves patient comfort and satisfaction. This is due primarily to decreased attempts at the procedure. The use of US usually decreases the duration of the procedure.**

This chapter reviews the basic information regarding the use of US to assist or guide procedures in the Emergency Department (ED). US can assist in many commonly performed ED procedures (**Table 4-1**). The specific US technique for a procedure is described in the chapter for the particular procedure.

The sonographer must make several decisions prior to beginning a procedure using US. Will the procedure be performed under real-time US guidance or will US only be used to map the anatomy? Will one person (the sonographer) or two people (the

TABLE 4-1 Common ED Procedures that Use US Assistance or Guidance

Body region	Procedures
Abdomen and pelvis	Paracentesis
	Suprapubic bladder aspiration
	Suprapubic bladder catheterization
Airway	Endotracheal intubation
Bones and joints	Arthrocentesis
	Closed fracture reduction
	Fracture identification

	Lumbar puncture
Soft tissue and musculoskeletal	Abscess identification
	Abscess incision and drainage
	Foreign body identification and removal
Vascular	Arterial line placement
	Central venous access
	Peripheral venous access

sonographer and an assistant) be necessary? Which US probe is the most appropriate for the procedure? Should the instrument or needle be imaged in the long-axis view or the short-axis view? Are needle guides necessary? What is the ideal location of the US machine in relation to the sonographer and patient? These general questions must be kept in mind when using US for invasive procedures and are discussed below.

US GUIDANCE VERSUS MAPPING

US can be used in one of the two ways for procedural assistance: the dynamic technique or the static technique. The dynamic technique is also known as US guidance. The sonographer uses US guidance in real time during the procedure to survey the anatomy, to confirm a diagnosis, and to visualize the needle or instrument as it enters tissue and reaches the target. The static technique is also known as US mapping. The sonographer uses US mapping prior to starting the procedure to map the local anatomy, to confirm a diagnosis, and to mark the site of needle entry. The US probe is then put away and the procedure performed in the traditional fashion without real-time US.

The decision between US guidance versus US mapping is influenced primarily by the degree of inherent danger of the procedure. Perform procedures that carry a higher risk or have greater technical difficulty (e.g., central venous access, pericardiocentesis, or foreign body removal) under US guidance. Perform lower risk procedures (e.g., thoracentesis, paracentesis, or abscess I&D) with US mapping. Another factor is sonographer experience. The experienced sonographer is more technically adept and comfortable doing procedures under real-time US guidance. Novice sonographers who do not have as much psychomotor training and experience may find it easier to use US mapping.

ONE-PERSON VERSUS TWO-PERSON TECHNIQUE

The decision to perform a procedure with one or two people is based on the sonographers experience and the availability of an assistant. Sonographers with more experience often prefer to guide the US probe and manipulate the instrument themselves. Their experience and expertise allows them to work with a higher efficiency without an assistant. Assistance during the procedure may not be an option during a busy ED shift, in an ED with single physician coverage or in an ED with limited personnel. For one-person US guidance, the sonographer holds the US probe with the nondominant hand and guides the needle or instrument with the dominant hand. This requires a degree of hand-and-eye coordination to maintain continuous alignment of the needle with the US probe.

Novice sonographers may find it less daunting to use the two-person technique and work with an assistant. The assistant holds the US probe while the sonographer guides the needle or instrument. The assistant's responsibility is to maintain alignment of the US probe with the needle during the procedure. The sonographer must maintain good communication with the assistant throughout the procedure in order to maintain sight of both the needle tip and the target organ on the US screen.

TYPES OF US PROBES

The following general principle will be helpful in determining which US probe is the most appropriate for a given procedure. **The higher the frequency of the US probe, the better the resolution of the structures visualized, but the shallower the maximum depth of view.** In other words, use a high-frequency US probe for superficial structures and a low-frequency US probe for deep structures. Low-frequency US probes include the curvilinear probe and the phased-array probe (**Table 4-2**). High-frequency US probes include the linear probe and the endocavitary probe (**Table 4-2**). More than one probe may be required for some procedures. Another factor in selecting the US probe is its footprint or surface area. A larger footprint is recommended to get a larger scan image unless specific anatomic barriers (e.g., ribs) dictate a smaller footprint. The types of US probes recommended for specific procedures are listed in **Table 4-2**.

TABLE 4-2 Recommendations for the US Probe Type to Use for Specific Procedures

Probe type	Procedure
Curvilinear	Endotracheal intubation
	Lumbar puncture
	Paracentesis
	Pericardiocentesis
	Suprapubic bladder aspiration
	Suprapubic bladder catheterization
	Transcutaneous cardiac pacing
	Transvenous cardiac pacing
Endocavitary	Peritonsillar abscess incision and drainage
Linear array	Abscess incision and drainage
	Endotracheal intubation
	Fracture identification
	Fracture reduction
	Lumbar puncture
	Peripheral nerve blocks
Phased array	Pericardiocentesis
	Thoracentesis
	Transvenous pacing

ORIENTATION OF THE NEEDLE AND THE US PROBE

Two orientations or approaches are used for US guidance during procedures. The longitudinal or long-axis approach refers to placing the long axis of the needle in-line with the long axis of the US probe

FIGURE 4-1. The longitudinal or long-axis approach of the US probe to the needle.

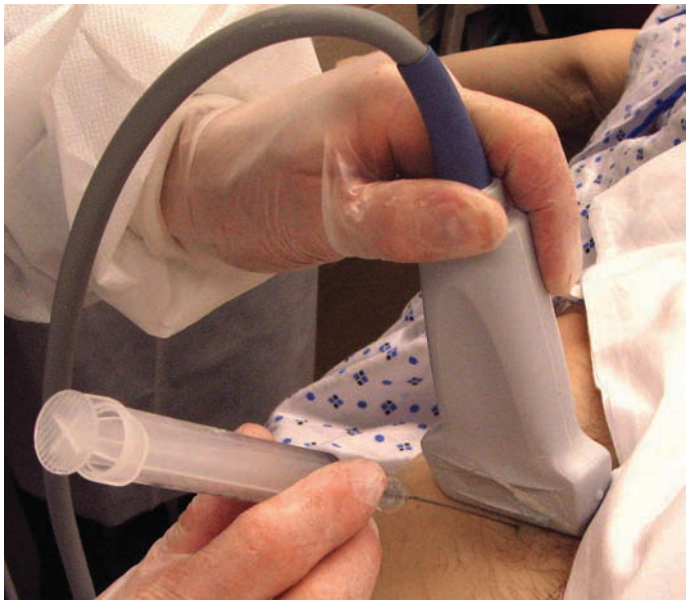

FIGURE 4-2. The transverse or short-axis approach of the US probe to the needle.

(**Figure 4-1**). The transverse or short-axis approach refers to placing the long axis of the needle 90° to the long axis of the US probe (**Figure 4-2**). **It is paramount for the sonographer to keep sight of the needle regardless of which approach is used during the procedure.** It is helpful to have the US probe indicator facing the same side as the marker on the top of the US screen to maintain left-to-right alignment.

The long-axis approach allows the entire length of the needle to be visualized as it approaches the target (**Figure 4-3**). Depth perception is better with this approach. This is a more intuitive approach for some ultrasonographers. The main disadvantage of the long-axis approach is the poor lateral resolution. A needle located to the side of a structure may appear in the same plane as the structure when actually it is not. This approach requires precise alignment of the US probe with the needle, otherwise the sonographer can lose sight of the needle. The one procedure best performed with the long-axis approach is a peripheral nerve block.

The short-axis approach requires the sonographer to center the target of interest on the US screen. The long axis of the needle is positioned 90° to the long axis of the US probe, at the center of the long axis of the US probe (**Figure 4-2**). The short-axis view of the needle is visible on the US monitor, resulting in better lateral resolution (**Figure 4-4**). One disadvantage of this approach is the challenge to maintain sight of the needle tip. The sonographer must move the US probe forward along with the needle tip as it is advanced. The depth of the needle tip can be misjudged if one is not careful. This can sometimes result in the inadvertent puncture of the anterior and/or posterior wall of the target structure or vessel, or of another adjacent structure.

MECHANICAL NEEDLE GUIDES

Needle guides are attachments to the US probe that keep the needle in a predictable path during the procedure. They are often utilized by radiologists for aspiration or biopsy of deep structures. The benefit of using a needle guide is that less hand-to-eye coordination is required to keep the needle aligned with the US probe during the procedure. The disadvantage of a needle guide is that the path angle is fixed and cannot be changed in the midst of the procedure. A needle guide is not necessary for the vast majority of Emergency Medicine procedures. It may actually be disadvantageous since it does not allow "on-the-fly" corrections of the needle path.

FIGURE 4-3. Long-axis US view of the needle (arrows).

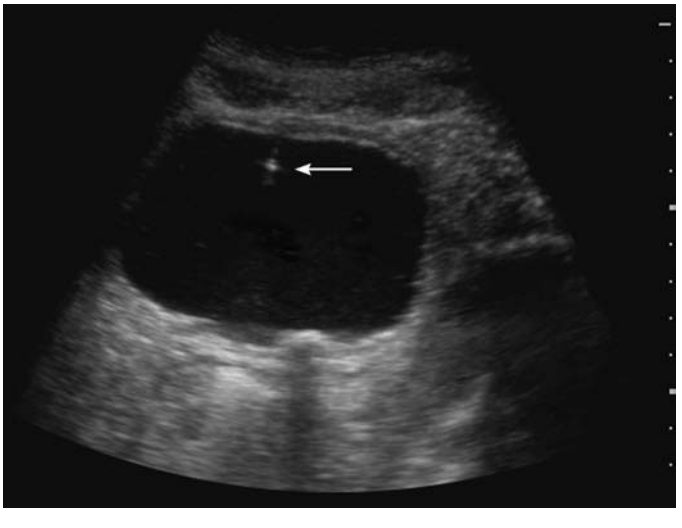

FIGURE 4-4. Short-axis US view of the needle (arrow).

FIGURE 4-5. An example of a good setup with the US machine in relation to the sonographer and the patient.

GENERAL TIPS WHEN USING US GUIDANCE

Always ensure that there is a direct line of sight from the procedural field to the US machine (**Figure 4-5**). The sonographer should not need to turn their head to the side during the procedure to view the US screen. This will greatly improve the sonographer's comfort during the procedure and increase the likelihood of success. Having to turn your head back-and-forth can result in the needle or the US probe moving, an unsuccessful procedure, puncture of incorrect structures, and potential morbidity. Hold the US probe comfortably in the nondominant hand using a pencil-like grip and maintaining light contact with the patient. It is best to use short controlled movements to maintain visualization when manipulating a needle or other instrument under US guidance.

Misalignment of the US probe and the needle is the most common reason for the needle tip not being visualized during the procedure. Stop advancing the needle if it is not visible on the US screen. Reposition the US probe by dragging or fanning it back and forth over the area of the needle until the needle can be seen. Gently rocking or bouncing the needle within the soft tissue can sometimes assist in determining the location of the needle tip.

Indirect clues can help determine the location of the needle tip if it cannot be seen directly. These include the ring-down artifact (**Figure 4-6**) and the needle shadow artifact (**Figure 4-7**). The ring-down artifact is a bright hyperechoic streak due to reverberation of the US beam from the highly reflective interface of the needle. The shadow artifact is a hypoechoic line below the needle due to the needle blocking the US beam. Follow either artifact until the needle can be visualized on the US screen. Continue to follow the needle until the tip is found.

Other factors can affect the ability to visualize the needle. Consider these when preparing to perform a procedure. Use the appropriate probe and depth of field for the procedure. Smaller gauge needles produce smaller artifacts and are more difficult to visualize, especially in cross section. It is easier to visualize needles perpendicular, or in the short axis, to the US beam. Consider using needles specific for ultrasonography that are extra reflective. The costs of these needles are hard to justify, but may be acceptable for teaching. Normal needles are appropriately reflective and it is difficult to justify these specific needles clinically. The beveled tip of the needle is easier to visualize than the shaft. The irregular surface of the bevel will reflect the US beam better than the shaft. Insert and advance the needle with a slight "to-and-fro" motion to easily follow the needle path.

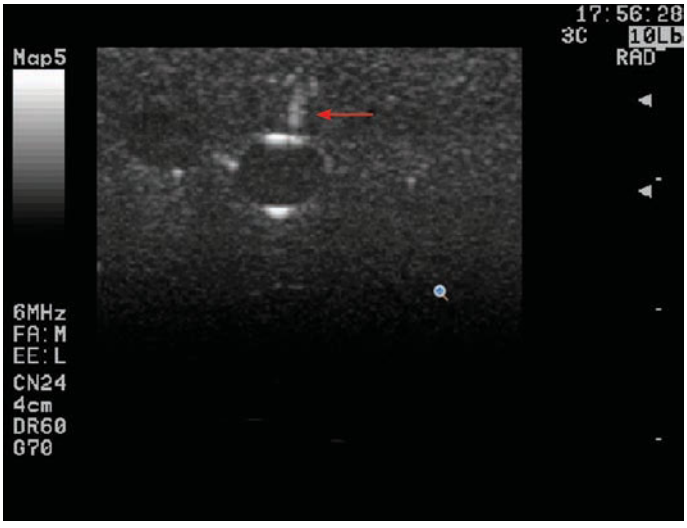

FIGURE 4-6. Ring-down artifact (arrow) showing the hyperechoic vertical line originating from the needle tip.

SUMMARY

The use of US assistance for procedures is an important skill set in the armamentarium of the Emergency Physician. It allows potentially dangerous procedures (e.g., incision and drainage of a peritonsillar abscess) to be performed in a safer manner due to visualization of the surrounding anatomy. It allows for the rapid confirmation of a diagnosis at the bedside, resulting in faster therapeutic interventions (e.g., pericardiocentesis). It usually results in greater patient satisfaction because of fewer attempts being required to successfully complete the procedure. ED ultrasonography can truly be a lifesaving modality when used by trained Emergency Physicians.

ACKNOWLEDGMENTS

The authors would like to thank Linda J. Kesselring, MS, ELS, for copyediting the manuscript and incorporating our revisions into the final document; and Angela Taylor for manuscript preparation.

5 Trauma Ultrasound: The FAST Exam

Wes Zeger

INTRODUCTION

Evaluation of blunt trauma patients with ultrasound (US) has been described for over 30 years.[1,2] Its use in the United States in the early assessment of blunt abdominal trauma patients rapidly increased in the 1990s.[1] It is currently taught as an adjunct to the secondary survey in the Advanced Trauma Life Support (ATLS) course.[1,3] US evaluation of the trauma patients decreases the time to operative care, resource utilization, and the costs of blunt trauma patients.[4,5] The focused assessment with sonography in trauma exam, also known as the FAST exam, can be completed within 5 minutes.[1] It has essentially replaced the need for a diagnostic peritoneal lavage in the initial assessment of all but a few trauma patients.[6,7] This chapter reviews the technique and interpretation of the FAST exam.

ANATOMY AND PATHOPHYSIOLOGY

The FAST exam evaluates four anatomical areas or potential spaces for the presence or absence of intraperitoneal fluid. These include the hepatorenal recess (Morrison's pouch), the splenorenal recess, the rectovesical or rectouterine space, and the pericardial space. The assumption is that fluid represents blood in the setting of trauma. The presence of ascites, urine, and bowel fluid can appear similar. These spaces represent the most dependent areas in the supine patient (**Figure 5-1**). The volume of fluid accumulation required for visualization by US ranges from 250 to 620 mL.[8,9] More experienced sonographers are able to visualize volumes closer to 250 mL.[8]

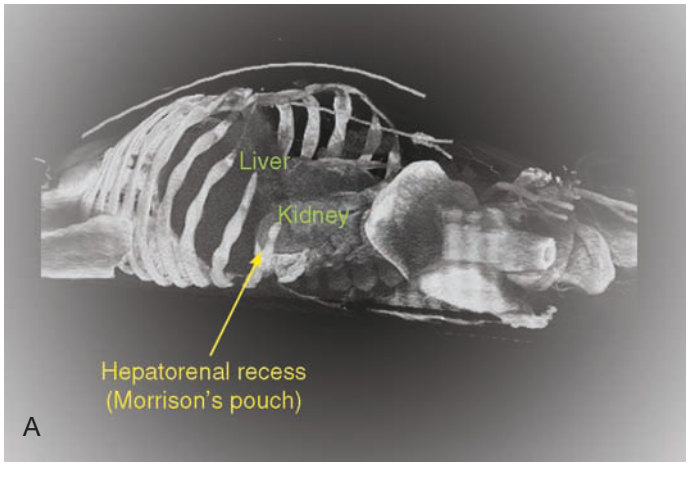
INDICATIONS

The FAST exam is performed after the primary survey. It can be performed in conjunction with ongoing resuscitative efforts. It is indicated when evaluating for the presence of intraperitoneal or pericardial blood in the setting of acute thoracoabdominal trauma. It is useful in determining resource allocation in the setting of multipatient trauma scenarios.[1]

BLUNT THORACOABDOMINAL TRAUMA

The most studied use of the FAST exam has been in adult patients with blunt abdominal trauma. The early diagnosis of hemoperitoneum and/or hemopericardium in the setting of blunt trauma is critical in the management of these patients. The sensitivity and specificity for the presence of hemoperitoneum varies depending on the comparison "gold standard," and is generally reported between 78% to 90% and 98% to 100%, respectively.[7,10–14] It has been reported to approach 100% sensitivity and 100% specificity in hypotensive patients.[6,10] One study by Miller et al. reported a sensitivity of 42% and a specificity of 98%.[15] The difference between these studies was how CT was utilized as the gold standard. Pediatric blunt trauma patients have been less well studied, but the FAST exam has shown a similar sensitivity and specificity.[16–19] When used to predict the need for operative intervention in pediatric trauma patients, its sensitivity approached 90%, but its specificity dropped.[20] Current guidelines recommend evaluation of the pericardial space in patients with blunt thoracoabdominal trauma.[21]

PENETRATING THORACOABDOMINAL TRAUMA



Decreased mortality using US in the assessment of trauma was first described in relation to penetrating chest trauma.[22] Its application in patients with penetrating abdominal trauma is less clear. The sensitivity ranges from 48% to 100%, but its specificity remains high at 98% to 100%.[13,14,23,24] Assessment of the pericardial space can be helpful in guiding operative intervention in the unstable patient.

CONTRAINDICATIONS

US is a noninvasive diagnostic modality. In the setting of trauma, it is contraindicated only if it would delay and negatively impact a clinically obvious need for emergent operative intervention. The FAST exam should not be performed unsupervised by providers who have not been adequately trained.[21]

EQUIPMENT

- US machine
- US gel
- Abdominal US probe
- US probe cover or glove

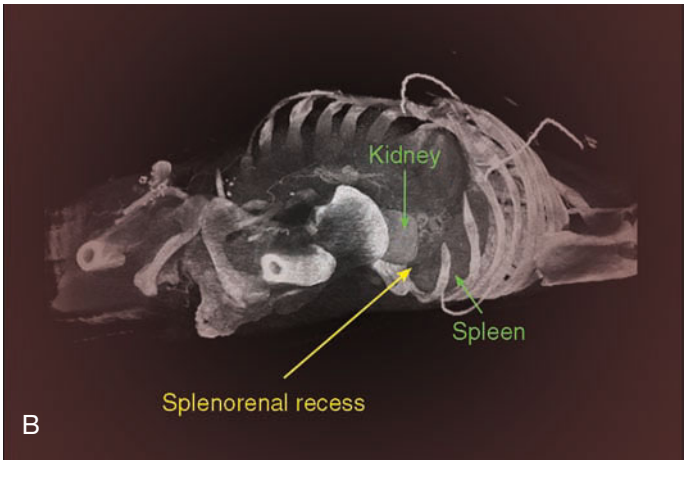


FIGURE 5-1. The posterior reflection of the peritoneum is where blood initially layers in the supine patient. The hepatorenal (**A**) and splenorenal (**B**) recesses represent the posterior peritoneal reflections between the inferior pole of the kidney and the liver or spleen, respectively.

A complete discussion of US equipment is beyond the scope of this chapter. Decisions regarding machines and probes depend on the user, cost, and intended applications. The FAST exam can be performed with a good-quality general abdominal probe. Probes with smaller footprints allow for easier viewing between the ribs.

The US probe is generally used directly against the patient's skin, with gel between them. Place the probe in a probe cover or glove to prevent contamination of the probe if the patient's skin is covered with blood, urine, feces, or other substances. Place US gel in the probe cover or glove before inserting the probe. Squeeze out any air in the space between the tip of the probe and the probe cover or glove.

PATIENT PREPARATION

Little to no preparation is required to perform the FAST exam. Wipe any debris and liquids from the patient's skin in the areas to be scanned. Place the US probe in a probe cover or glove, as described above, if the patient's skin is contaminated with blood, vomit, other body fluids, or other substances that may contaminate or damage the probe.

TECHNIQUE

Performance of any US exam assumes the probe marker orientation is generally cephalad or toward the right relative to the patient. The FAST exam traditionally demonstrates two-dimensional grayscale images of four views reflective of their anatomic potential spaces. These are the hepatorenal recess (Morrison's pouch), the splenorenal recess, the rectovesical or rectouterine space, and the pericardial space. View the rectovesicle space, the area between the rectum and the bladder, in the male patient. View the rectouterine space, the area between the rectum and the uterus, in the female patient.

The overall exam time should be less than 5 minutes, and frequently can be completed in 1 or 2 minutes. If complete views of either the liver or spleen are not visualized with a single image, more than one image of the area is required. The order of image acquisition depends on the mechanism of injury. In blunt trauma, Morrison's pouch is generally imaged first (the area where fluid will most likely first accumulate), followed by the splenorenal view, the rectovesical or rectouterine view, and then the pericardial space. In penetrating trauma, the pericardial space is often imaged first followed by Morrison's pouch, then the remaining two views.

HEPATORENAL RECESS (MORRISON'S POUCH)

The hepatorenal recess is located between the inferior margin of the liver and inferior pole of the right kidney (**Figure 5-1A**). Place the probe on the midaxillary line at the level of the 8th to 11th ribs (**Figure 5-2A**). The liver and kidney should be visualized from the diaphragm to the inferior tip of the liver (**Figure 5-2B**). **It is important to visualize the space between, and including, the inferior liver tip and the inferior pole of the right kidney as fluid tends to accumulate near the tip of the liver first.** A black, echolucent, stripe between the liver and the kidney represents blood and a positive FAST exam (**Figure 5-3**). Rib shadows obscuring portions of the image may be prevented by a slight counter-clockwise rotation of the probe so it lies between the ribs.

SPLENORENAL RECESS

The splenorenal recess is located between the inferior margin of the spleen and the inferior pole of the left kidney (**Figure 5-1B**). Place the probe on the posterior axillary line at the level of the sixth to ninth ribs (**Figure 5-4**). **The spleen and kidney should be visualized from the diaphragm to the inferior tip of the spleen.** A black, echolucent, stripe between the spleen and the kidney represents blood and a positive FAST exam (**Figure 5-5**). Rib shadows obscuring portions of the image may be prevented by a slight clockwise rotation of the probe so it lies between the ribs.

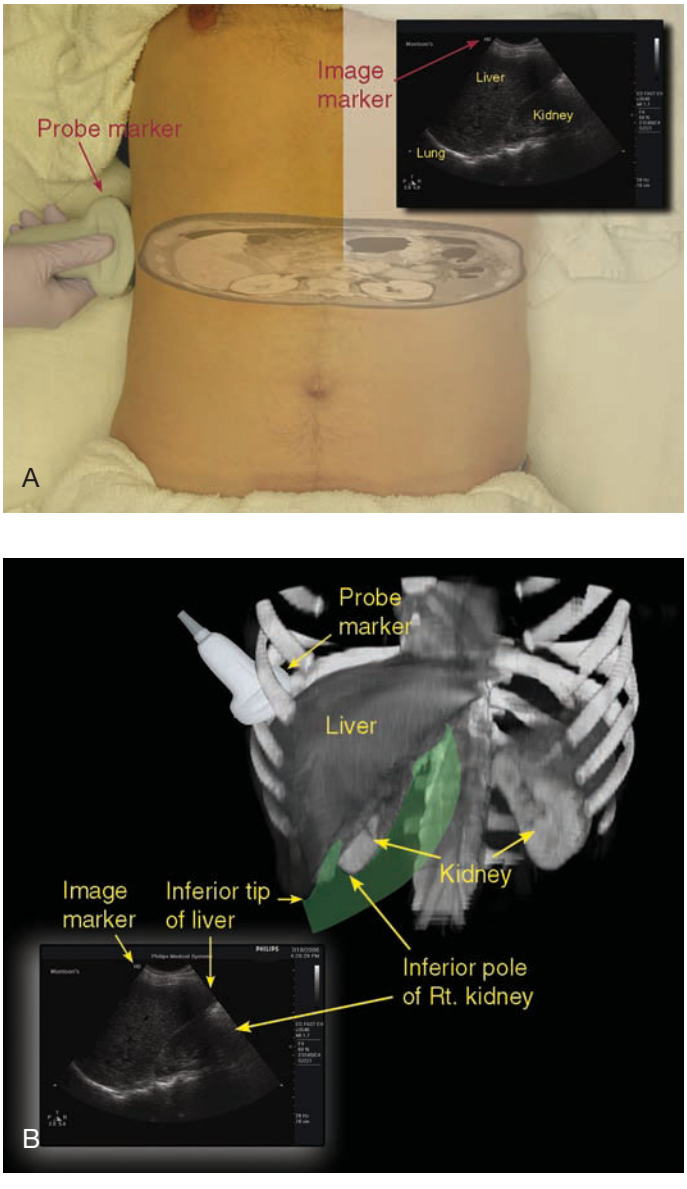

FIGURE 5-2. Imaging of the hepatorenal recess. **A.** US probe placement with the corresponding US screen image. **B.** A view of the US beam (green) as it passes through the liver and kidney with the corresponding US image.

RECTOVESICAL OR RECTOUTERINE SPACE

The rectovesical or rectouterine space represents the most inferior–posterior reflection of the peritoneum. Place the probe just superior to the pubic ramus (**Figure 5-6**). The probe can be oriented in either the sagittal or transverse plane. View the rectovesicle space (**Figures 5-6A & B**) or the rectouterine space (**Figures 5-6C & D**) in both the sagittal and transverse planes. A black, echolucent, stripe in either space represents blood and a positive FAST exam (**Figures 5-7 & 5-8**).

PERICARDIAL SPACE

In the supine trauma patient, fluid accumulates initially in the inferior–posterior portion of the pericardial space. The probe and

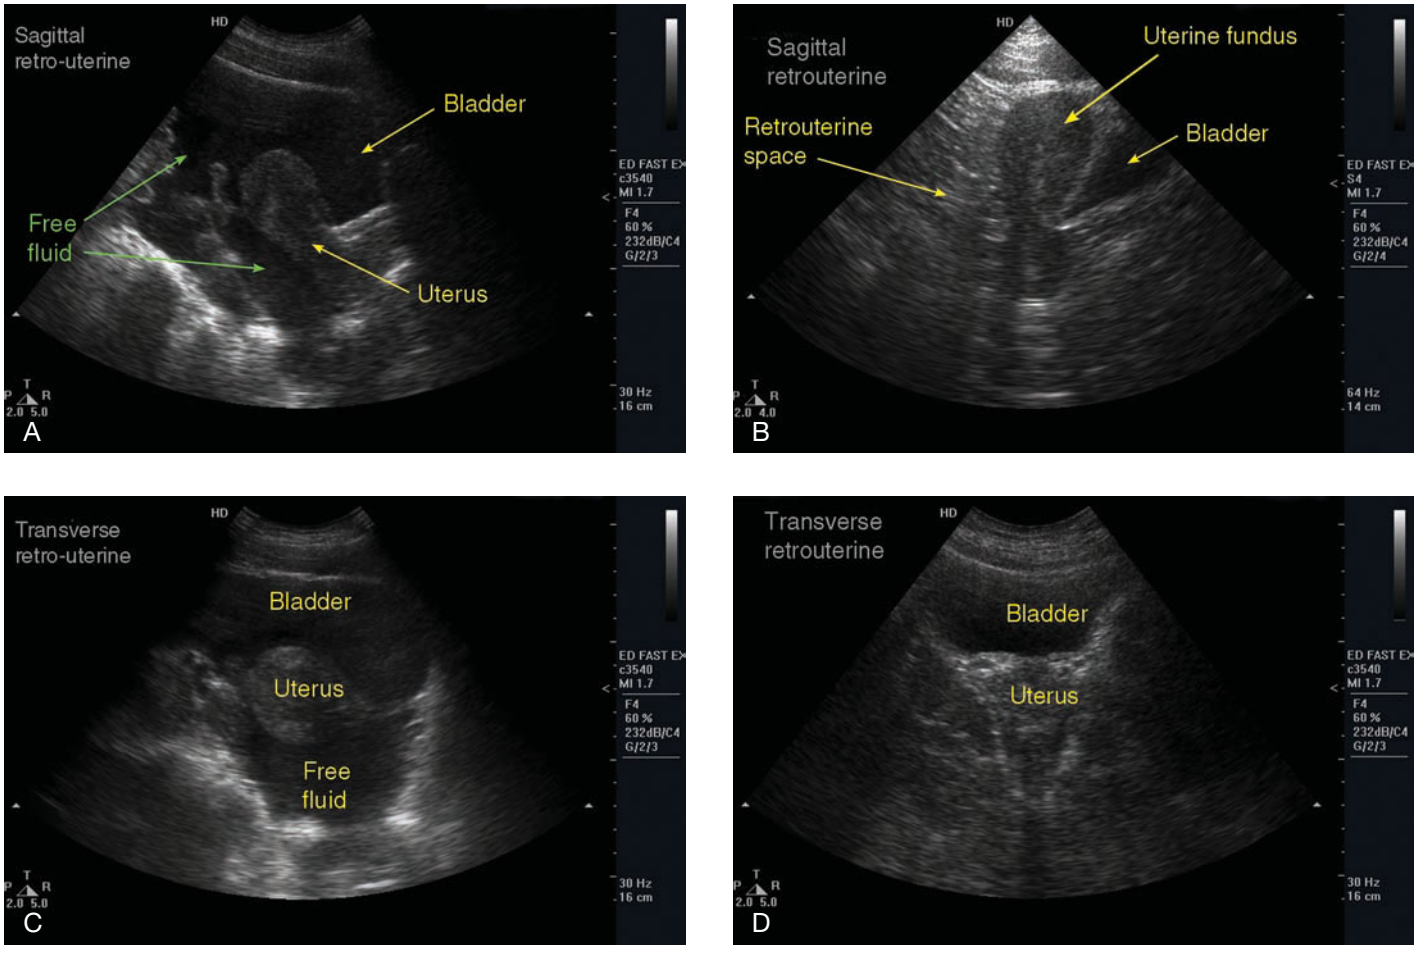

FIGURE 5-8. A positive FAST exam of the rectouterine space. **A.** Sagittal view of an echolucent fluid area. **B.** A normal sagittal exam for comparison. **C.** A transverse view of an echolucent fluid area. **D.** A normal transverse exam for comparison.

screen image orientation are different than traditional echocardiographic views. Place the probe with the marker oriented toward the patient's right and the tip of the probe aimed toward the patient's left shoulder (**Figure 5-9**). Use the liver as an acoustic window and increase the depth of the US beam to increase image quality. Fluid will initially accumulate near the top of the US image, representing the inferior portion of the pericardial space (**Figure 5-9 inset**). Visualize both the inferior and superior areas of the pericardial space. A black, echolucent, stripe in either the inferior or superior areas of the pericardial space represents blood and a positive FAST exam (**Figure 5-10**).

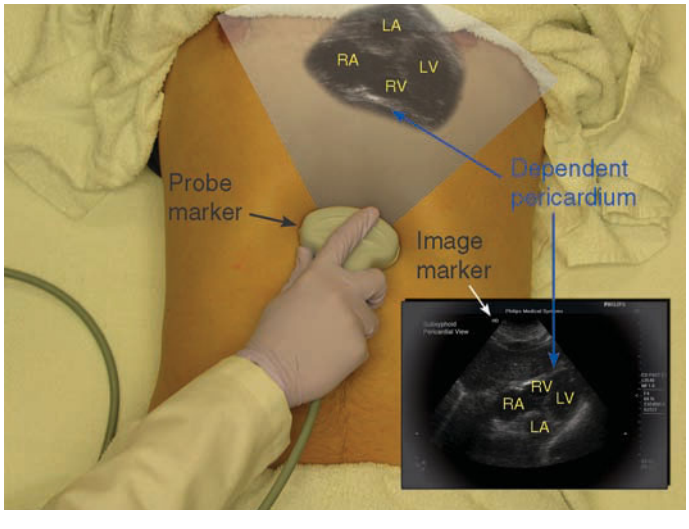

FIGURE 5-9. Imaging of the pericardial space. US probe placement for the subxyphoid view with the corresponding US image. (RV, right ventricle; RA, right atrium; LV, left ventricle; LA, left atrium).

ALTERNATIVE TECHNIQUES

The incorporation of thoracic imaging coupled with the traditional FAST exam has been referred to as an extended FAST or EFAST exam. This additional imaging assesses for the presence of a hemothorax or a pneumothorax. A hemothorax is best assessed by visualizing the inferior–posterior aspect of the plural cavity in the supine patient (**Figure 5-11**). This area is often visualized in routine views of Morrison's pouch, but moving the US probe superior one rib interspace may be required. The lung edges are not normally visualized on US. However, the lung can be seen "floating" in fluid in the presence of a hemothorax (**Figure 5-11B**). Another sign suggestive of a hemothorax is the "spine" sign (**Figure 5-11B**). In the presence of a hemothorax, the portion of the thoracic spine above the diaphragm can be visualized with US. The thoracic spine is not normally well visualized on US superior to the diaphragm (**Figure 5-11C**).

A pneumothorax is best assessed in the supine patient with either a linear or a curvilinear probe. Place the probe on the anterior chest wall in the area bounded by the clavicle, sternum, nipple, and anterior

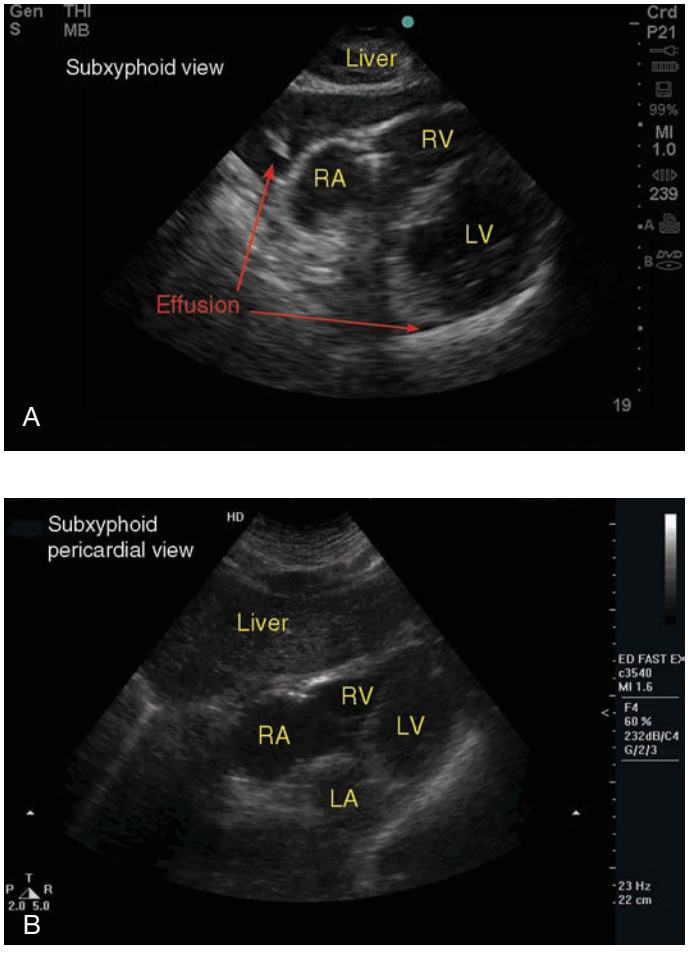

FIGURE 5-10. A positive FAST exam of the pericardial space. **A.** A large echolucent area of fluid in the inferior–posterior aspect of the pericardial space and a small amount of fluid in the more superior area of the pericardial space. **B.** A normal exam for comparison.

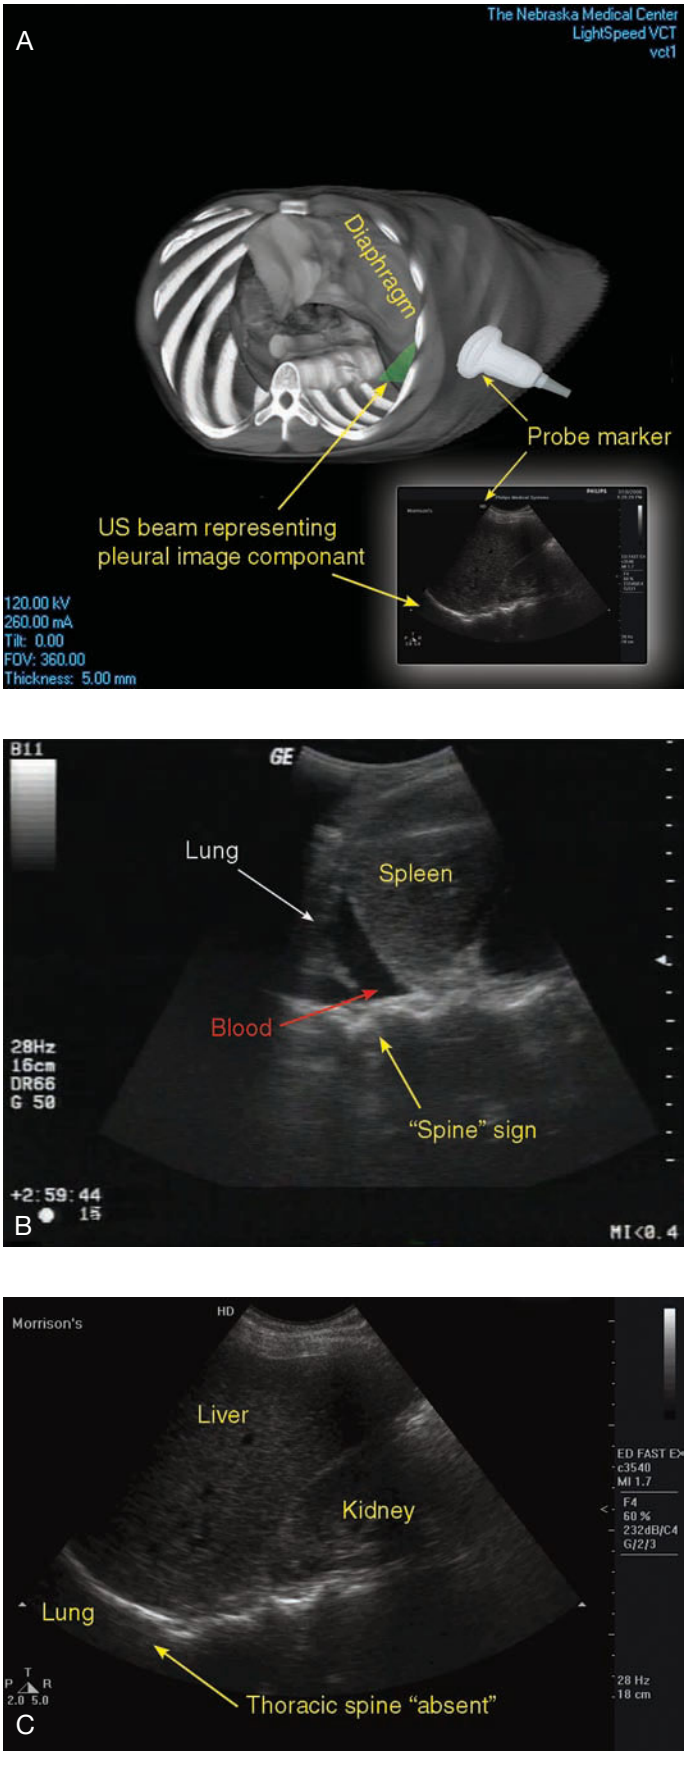
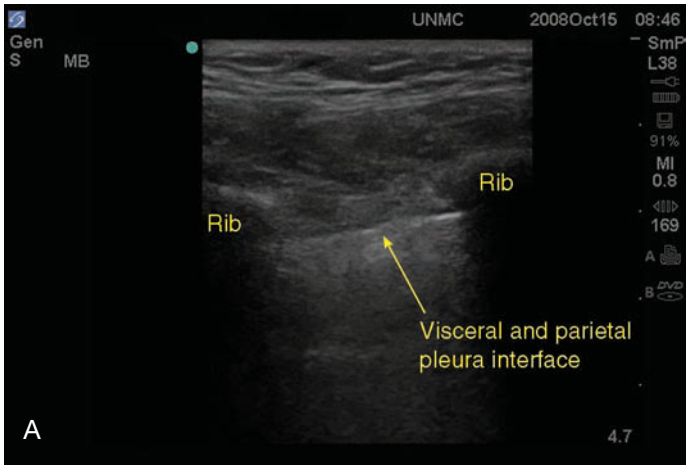
axillary line. Start with the probe on the midclavicular line between the nipple and the clavicle. It may be moved within the area to obtain the best image possible. Position the probe perpendicular to two adjacent ribs to visualize the intercostal space (**Figure 5-12**). The normal sliding of the visceral pleura against the parietal pleura during respiration can be visualized (**Figure 5-12A**). This interface between the two pleura is known as the "sliding-lung" sign and is absent in a pneumothorax.

Use M-Mode to visualize the "sea-shore" sign (**Figure 5-12B**). This is visualized as slightly wavy parallel lines from the thoracic wall over an echogenic line (the pleural line), under which is a sandy pattern produced by the lung parenchyma. The parallel lines at the top of the screen represent the waves of the "sea." The sandy pattern at the bottom of the screen represents the "shore." Together they form the "sea-shore" sign. The echogenic line between the "sea" and the "shore" represents the pleural lines. The "sea-shore" sign indicates a normal chest wall–lung interface. Air interposed between the chest wall and lung forms parallel, horizontal echogenic lines and the loss of the "sea-shore" sign (**Figure 5-12C**).

ASSESSMENT

The interpretation of each of the four views, and of the overall FAST exam, is classified into one of the three categories: positive, negative, or indeterminate. Positive exams demonstrate echolucent





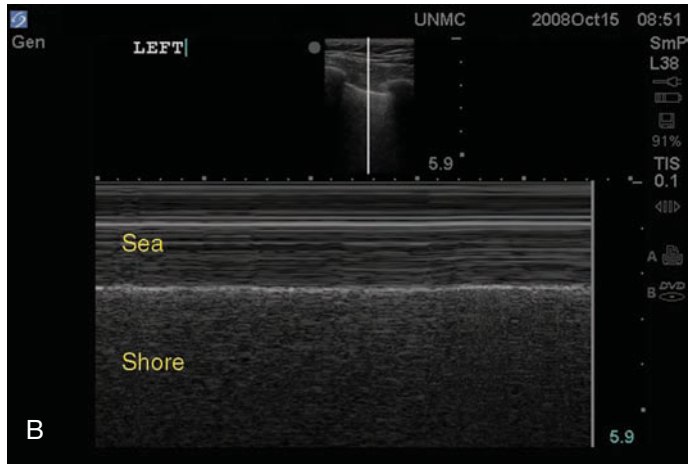


FIGURE 5-11. Imaging a hemothorax. **A.** The patient and US probe position. The US beam path (green) generates the pleural component (inset). **B.** Blood in the pleural space provides an acoustic window to visualize the thoracic spine ("spine sign"). **C.** A normal exam for comparison.

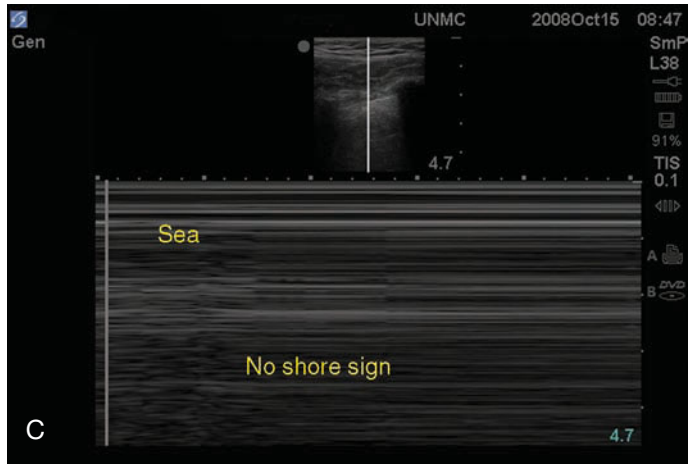

FIGURE 5-12. Imaging a pneumothorax. **A.** Rib shadowing is seen on both sides of the intercostal space. The echoic interface of the parietal and visceral pleura demonstrates the "sliding-lung" sign. **B.** The "sea-shore" sign. It is visible when the lung and chest wall are in contact with each other. Note the bright echogenic stripe of the pleural interface between the chest wall ("sea") and the lung ("shore"). **C.** The "sea-shore" sign and the pleural interface are absent when a pneumothorax is present.

(seen as black on the image) fluid accumulations in any one of the four views. Negative exams and scans demonstrate no fluid with complete visualization of all structures of each view. Indeterminate exams are uncommon but may occur when fat or bowel cannot be distinguished from peritoneal fluid, or if there is incomplete visualization of any of the four views. Women and children may normally have a small amount of physiologic fluid in their pelvis. This finding may lead to an indeterminate exam in the setting of trauma.

AFTERCARE

Multiple algorithms exist for the management of trauma patients.[1,3] In general, these are differentiated into blunt trauma versus penetrating trauma and hemodynamically stable versus unstable. In the hemodynamically stable blunt trauma patient, a positive FAST exam is typically followed with an abdominal cat exam. In the hemodynamically unstable adult blunt trauma patient, a positive FAST exam indicates the need for emergent operative intervention without further imaging. In adult patients with penetrating trauma, a positive FAST exam has good correlation with need for a therapeutic laparotomy.[23] Management of these patients may vary between institutions. An unstable pediatric patient with a positive FAST exam may not necessarily proceed to laparotomy as the indications for operative management differ between adults and children.[3]

A negative FAST exam needs to be evaluated within the patient's clinical context (history, exam findings, vitals, etc.). In the hemodynamically stable or unstable penetrating trauma patient, a negative FAST exam is a reliable screen for the presence of intrapericardial blood. It is not a reliable screening test for the presence of abdominal injury. In the unstable patient, its use is not well defined. In the hemodynamically stable blunt trauma patient, a negative FAST exam should be followed by serial clinical exams and a repeat FAST exam.[25] A negative FAST exam in the presence of hemodynamic instability has a high sensitivity, and an extraperitoneal source of bleeding or the instability should be considered. Indeterminate FAST exams require a follow-up alternative diagnostic modality, usually a CAT exam.

COMPLICATIONS

Performance of the actual FAST exam has no associated complications. However, inaccurate interpretation or inappropriate application of US findings in clinical decision making may complicate its use.

SUMMARY

The FAST exam is a useful adjunct in the management of blunt and penetrating trauma patients. It can be performed rapidly, it is very specific, and it can positively impact patient outcomes. Proper training is required to ensure good-quality images and appropriate interpretation.

SECTION 2

Respiratory Procedures

6 Essential Anatomy of the Airway

Ned F. Nasr, Serge G. Tyler, Gennadiy Voronov, and Isam F. Nasr

INTRODUCTION

A thorough understanding of anatomy is essential for the performance of any medical procedure.[1–10] Untoward events due to a procedure are usually the result of inexperience and/or an inadequate understanding of the regional anatomy. The anatomy of the airway and airway procedures are no exception. From the evaluation of external anatomic landmarks to the performance of nerve blocks for fiberoptic intubation, an understanding of the anatomy of the airway will result in fewer attempts at intubation and improved success with fewer iatrogenic misadventures.

GENERAL ANATOMY

The upper airway comprises the nasal and oral cavities, the pharynx, and the larynx. The lower airway consists of the subglottic larynx, the trachea, and the bronchi.[8] Airway management typically involves the upper airway, the focus of this chapter. The anatomy of the pharynx, larynx, and trachea are depicted in **Figure 6-1**.

The nares serves as the functional beginning of the airway, namely warming and humidification of air.[4] The mucosa of the nasal passage is extremely vascular and fragile and therefore susceptible to trauma. The nasal blood supply originates from branches of the internal and external carotid arteries. It is wise to consider the use of a vasoconstricting agent, when appropriate, to help avoid epistaxis which may obscure further attempts at securing the airway. Although patients tolerate nasal intubation better than oral intubation for a longer period of time, it is more important in an emergency to definitively secure the airway using a straightforward oral intubation if possible.

The sensory innervation of the upper airway is provided by branches of several cranial nerves. The mucous membrane of the nose is innervated anteriorly by the anterior ethmoid nerve (ophthalmic division of the trigeminal nerve) and posteriorly by the sphenopalatine nerve (maxillary division of the trigeminal nerve). The tongue is innervated by the lingual nerve on its anterior two-thirds (a branch of the facial nerve) and by the glossopharyngeal nerve posteriorly. The glossopharyngeal nerve also innervates the adjacent areas, including the palatine tonsils, the undersurface of the soft palate, and the roof of the pharynx.[1] The anatomy of the oropharynx is discussed further under the "Airway Evaluation" section and the anatomy of the larynx is covered in the next section.

The trachea measures 10 to 16.5 cm in an average adult.[4] The trachea is a tubular structure that begins at the level of the fifth or sixth cervical vertebrae and bifurcates at the level of the fifth thoracic vertebra into two primary bronchi. The posterior aspect of the trachea is flat and membranous, while its anterior and lateral aspect is lined by 16 to 20 horseshoe-shaped cartilaginous rings. The primary bronchi subsequently branch into three secondary bronchi on the right and two secondary bronchi on the left. The angle between the primary bronchus and the trachea on the left is more acute than on the right. This is due to the heart being located on the left side. This is clinically significant during aspiration and endobronchial intubations. **Because of the more direct path on the right side due to the obtuse angle of the primary bronchi, objects (food, fluid, and foreign bodies) are more likely to enter the right lung.** The tracheal mucosa removes waste products by producing and moving mucus toward the pharynx via ciliary action. The trachea has a rich innervation from the vagus nerve, which permits a vigorous cough reflex (accompanied by hypertension and tachycardia) if a foreign body is aspirated.

The inner diameter of the trachea varies between normal adult males and females. It ranges from about 15 to 20 mm.[4] Since the external diameter of a 7.5 mm internal diameter (ID) endotracheal tube is 11.0 mm, the size must be taken into consideration in selecting an endotracheal tube. These considerations usually preclude using tubes much larger than 7.5 mm ID for normal adult females or larger than 8.0 or 8.5 mm ID for normal adult males.

ANATOMY OF THE LARYNX

The innervation of the larynx is relatively simple. The internal branch of the superior laryngeal nerve provides sensation above the vocal cords (vocal folds). The recurrent laryngeal nerve supplies sensation below the vocal cords. The recurrent laryngeal nerve provides the motor input to all of the intrinsic muscles of the larynx except to the cricothyroid muscle, which is supplied by the external branch of the superior laryngeal nerve. Bilateral injury to the recurrent laryngeal nerve will result in total airway closure due to unopposed stimulation of the vocal cord adductor, the cricothyroid muscle.[1]

There are three paired and three unpaired cartilages of the larynx.[2] The paired cartilages are the smaller arytenoid, corniculate, and cuneiform cartilages (**Figure 6-2**). The unpaired cartilages are the larger thyroid, cricoid, and epiglottic cartilages. Although not part of the larynx, the hyoid bone has many ligamentous and muscular attachments to the larynx. The cricoid cartilage is signet ring-shaped, as opposed to the C-shaped cartilages of the trachea (**Figure 6-2**). Because it forms a complete circle, depression of the cricoid cartilage will put pressure on structures located posteriorly (i.e., the esophagus). **The application of posteriorly directed pressure on the cricoid cartilage during intubation is known as the Sellick maneuver (Figure 6-3). The Sellick maneuver will not prevent regurgitation from active vomiting. It has been shown to be effective in the prevention of passive regurgitation and subsequent aspiration.**[3] However, the Sellick maneuver can impair insertion of the laryngoscope or an airway introducer, and can cause airway obstruction.

The cricoid cartilage is also an important landmark for locating the cricothyroid membrane, which lies inferior to the thyroid cartilage and superior to the cricoid cartilage (**Figure 6-2**). The

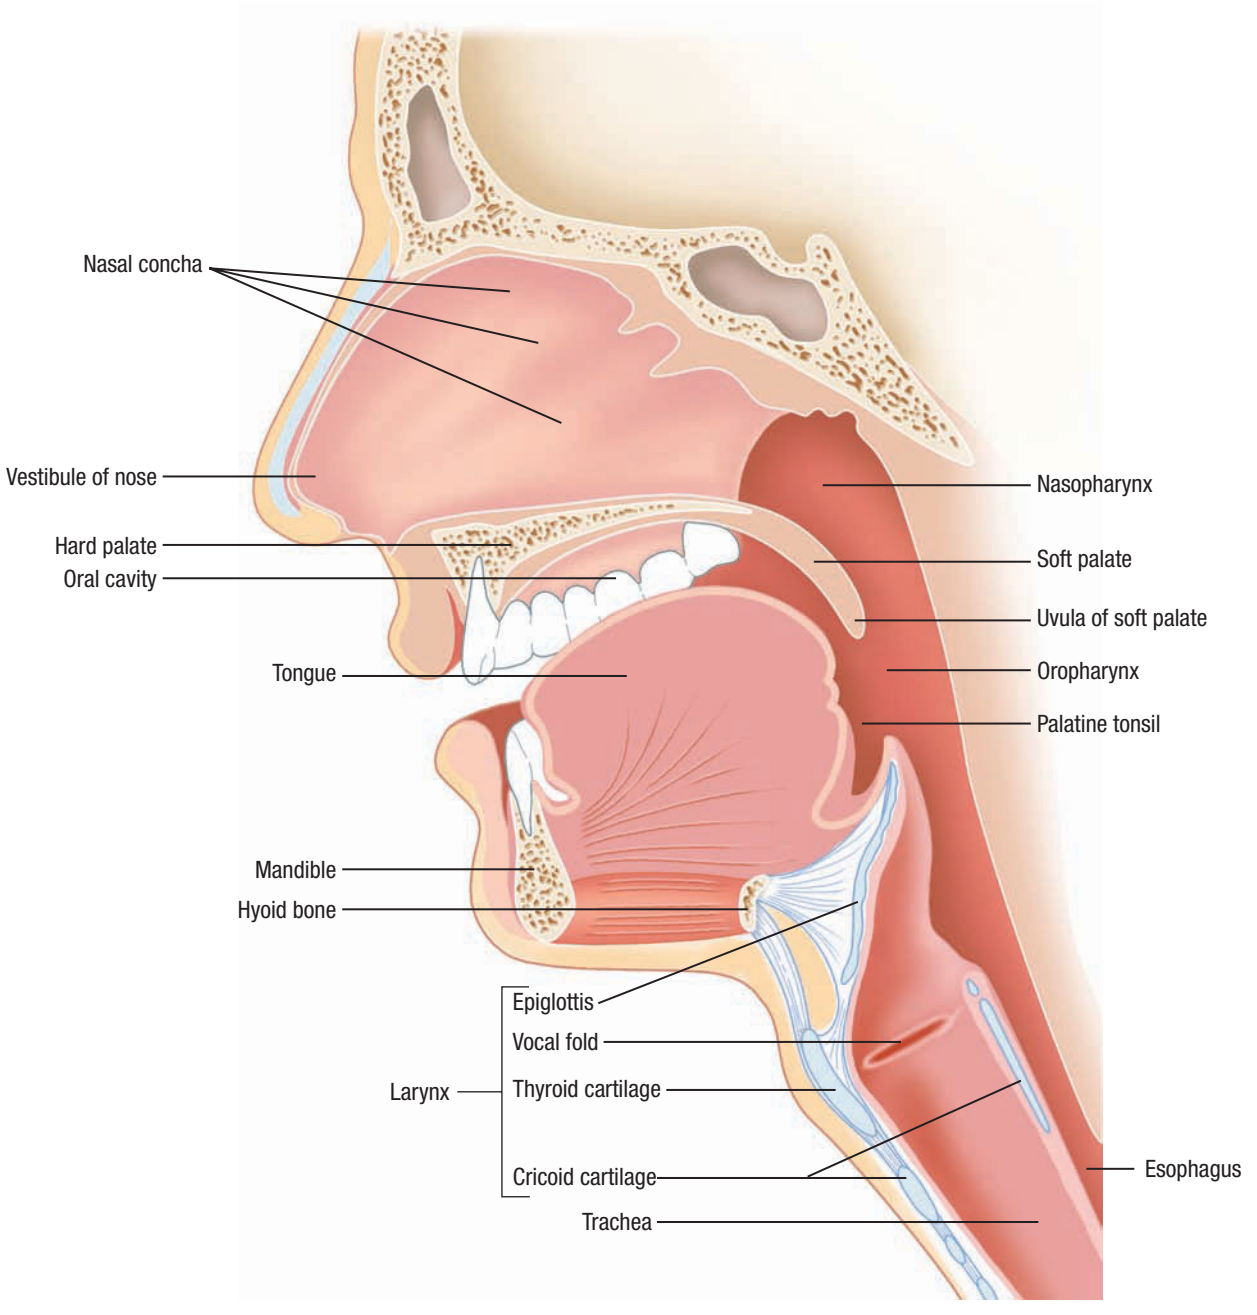

FIGURE 6-1. Anatomy of the airway as visualized in a midsagittal section through the head and neck.

cricothyroid membrane is usually located at the level of the sixth cervical vertebra. It is the anatomic location where emergency cricothyroidotomies and recurrent laryngeal nerve blocks are performed.

The three paired cartilages are located on the posterior aspect of the larynx (**Figure 6-2**). This position renders them vulnerable to injury during intubation.[2] By maintaining an anterior insertion of the laryngoscope blade and by not inserting it too deeply during intubation attempts, it is less likely that these cartilages will become dislocated or otherwise injured. This is particularly true if a straight laryngoscope blade is used.

The hyoid bone is an important supporting structure of the upper airway. One of the attachments of the hyoid bone to the larynx is the hyoepiglottic ligament located at the base of the vallecula (**Figure 6-4**). This ligament is important because it is where the tip of the curved Macintosh laryngoscope blade is placed to move the epiglottis anteriorly and out of the path of vision during intubation. Another attachment of the hyoid bone to the larynx is the thyrohyoid membrane (**Figure 6-2**). As its name implies, it runs from the inferior border of the hyoid bone to the superior aspect of the thyroid cartilage. Just inferior to the lateral border of the hyoid bone, the internal branch of the superior laryngeal nerve passes through the thyrohyoid membrane (**Figure 6-2**). At this point, the internal branch of the superior laryngeal nerve is superficial and very easily anesthetized with an injection of local anesthetic solution.

AIRWAY EVALUATION

The evaluation of the airway should always start with a thorough history. **An airway history should be conducted, when feasible, prior to the initiation of airway management in all patients.** It

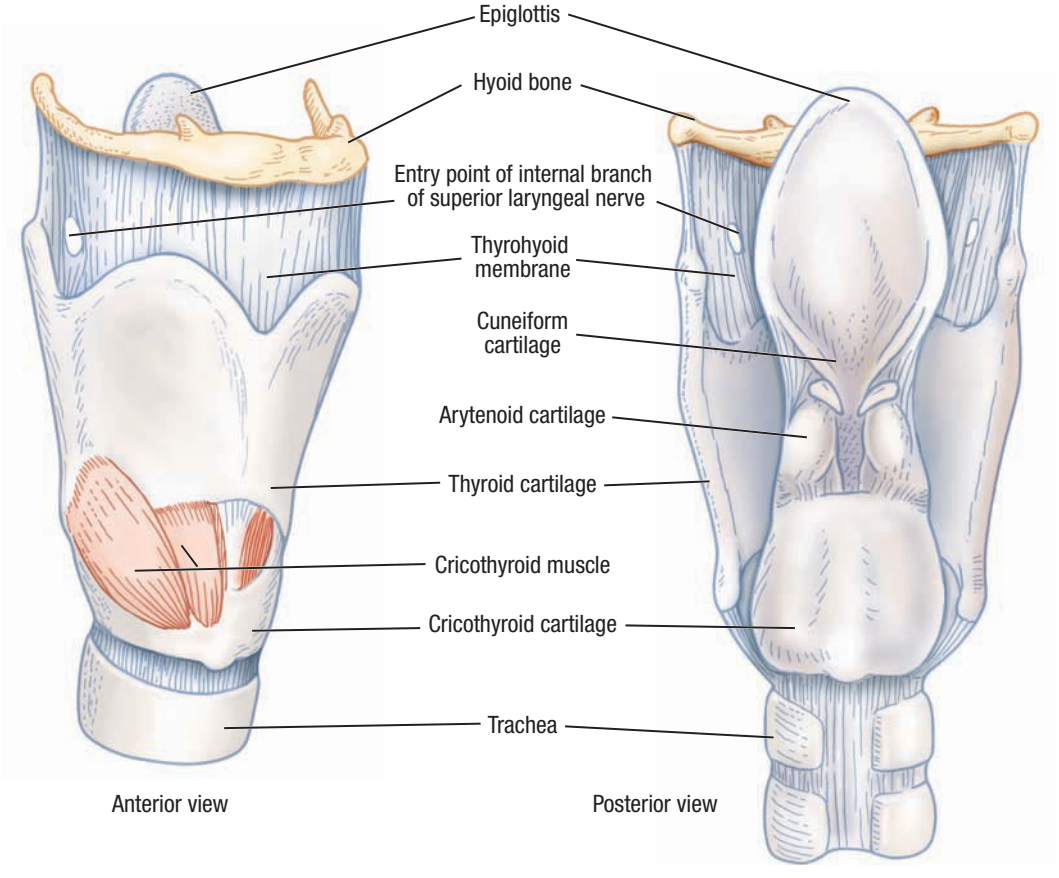

FIGURE 6-2. Right anterolateral and posterior views of the skeleton of the larynx. The thyroid cartilage shields the smaller cartilages of the larynx.

should include whether the patient has ever required intubation and if there was any difficulty. Additional history should focus on the patient's dentition and any surgery on or near the airway. There are many congenital syndromes (**Table 6-1**) and acquired conditions (**Table 6-2**) that can complicate airway management. These should be kept in mind when performing the airway history and physical examination.

External evaluation of the airway is a critical step to a successful intubation. These brief evaluations are helpful in predicting a difficult intubation. External inspection should identify some obvious problems that may interfere with airway management. These include as facial hair which prevents a good mask seal, cervical collars which restrict neck movement, face and/or neck trauma, severe micrognathia, or obesity.

The next steps in evaluating the airway may help to identify patients with potentially difficult airways. In adults, the distance between the thyroid cartilage ("Adam's apple") and the inside of the

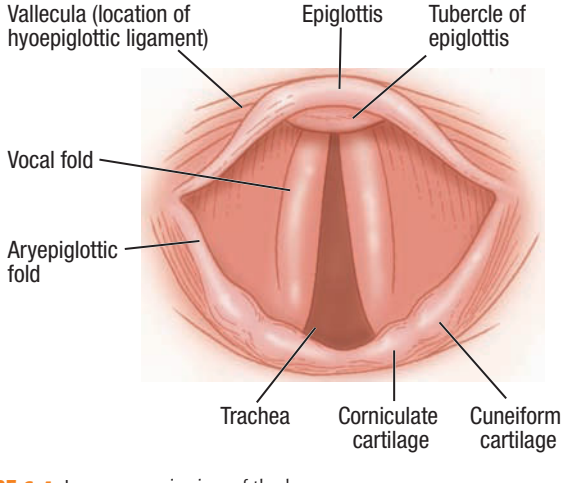

FIGURE 6-4. Laryngoscopic view of the larynx.

TABLE 6-1 Selected Congenital Syndromes Associated with Difficult Endotracheal Intubation

Syndrome	Description
Down's	Cervical spine spondylolisthesis; large tongue, small mouth make laryngoscopy difficult; small subglottic diameter possible; frequent laryngospasm
Goldenhar (oculoauriculovertebral anomalies)	Mandibular hypoplasia and cervical spine abnormality make laryngoscopy difficult
Klippel–Feil	Neck rigidity because of cervical vertebral fusion
Pierre Robin	Small mouth, large tongue, mandibular anomaly; awake intubation essential in neonate
Treacher Collins (mandibulofacial dysostosis)	Laryngoscopy difficult
Turner	High likelihood of difficult intubation

Source: Data from Barash et al.[1]

TABLE 6-2 Acquired Conditions Affecting the Airway and Associated with Difficult Endotracheal Intubation

Condition	Principal pathologic clinical features of the airway
Acromegaly	Macroglossia; prognathism
Acute burns	Edema of airway (worsens with time, secure airway early!)
Angioedema	Obstructive swelling renders ventilation and intubation difficult
Arthritis	
Rheumatoid arthritis	Temporomandibular joint ankylosis, cricoarytenoid arthritis, deviation of larynx, restricted mobility of cervical spine
Ankylosing spondylitis	Ankylosis of cervical spine; less commonly ankylosis of temporomandibular joints; lack of mobility of cervical spine
Benign tumors	Stenosis or distortion of airway
Cystic, hygroma, lipoma, adenoma	
Diabetes mellitus	May have reduced mobility of atlantooccipital joint
Foreign body	Airway obstruction
Hypothyroidism	Large tongue, abnormal soft tissue (myxedema) make ventilation and intubation difficult
Infectious	
Supraglottitis	Laryngeal edema
Croup	Laryngeal edema
Abscess (intraoral, retropharyngeal)	Distortion and stenosis of airway and trismus
Ludwig's angina	Distortion and stenosis of airway and trismus
Malignant tumors	Stenosis or distortion of airway; fixation of larynx or adjacent tissues secondary to infiltration or fibrosis from irradiation
Carcinoma of tongue, larynx, or thyroid	
Morbid obesity	Short, thick neck, and large tongue are likely to be present
Pregnancy	Edema of airway
Sarcoidosis	Airway obstruction (lymphoid tissue)
Scleroderma	Tight skin and temporomandibular joint involvement make mouth opening difficult
Temporomandibular joint syndrome	Severe impairment of mouth opening
Thyromegaly	Goiter may produce extrinsic airway compression or deviation
Trauma	Cerebrospinal rhinorrhea, edema of airway; hemorrhage; unstable fracture(s) of maxillae and mandible; intralaryngeal damage; dislocation of cervical vertebrae
Head, face, or cervical spine injury	

Source: Modified from Miller.[4]

anterior aspect of the mandible is known as the thyromental distance. It should be at least 5 cm or about three large finger breadths.[1] A lesser distance suggests that the patient's vocal cords are positioned more anteriorly than normal. **Distances less than 5 cm may indicate that visualization of the larynx during intubation may be difficult or impossible due to a lack of space in which to displace the tongue.** The next evaluation requires the patient to open his or her mouth maximally. Ideally, the patient will be in a seated or semisitting position. The distance between the maxillary and mandibular incisors in an average adult is 3 to 5 cm or about two large finger breadths.[5] Limited mouth opening may impair visualization of the airway as well as expose the teeth to damage during intubation. Adults should be able to flex their cervical spine 35° and extend the cervical spine (atlantooccipital joint) 80° from a neutral position.[6] This range of neck movement allows for the alignment of the oral, pharyngeal, and laryngeal axes during orotracheal intubation (**Figure 6-5**). This alignment of the axes provides the greatest chance for a successful intubation. Recent evidence suggests that slight head extension in infants and young children by placing a rolled towel behind their shoulders better aligns the vision of the glottic and laryngeal axes.[10] Observe the patient's neck for length and thickness. A short, excessively long, or thick neck may indicate difficulty in placing the patient in the "sniffing position" and align the airway axes.

The internal examination should evaluate the patient's dentition, palate, and tongue. Note any protuberant incisors, loose teeth, broken teeth, dental work, and dental devices. Prominent upper incisors may complicate the insertion of the laryngoscope blade, make laryngoscopy difficult, and predispose the patient to dental trauma. Assess the relation of the maxillary and mandibular incisors during normal jaw closure. Lack of an overbite forces the laryngoscope blade to enter the mouth in a more cephalad direction than normal. This can result in difficulty visualizing the airway. Observe the maxillary and mandibular incisors during voluntary protrusion of the mandible to determine the degree of temporomandibular joint mobility. Determine if the palate is normal, high and arched, or cleft. Determine if the tongue is elevated, larger, or wider than normal in comparison to the oral cavity. Any abnormality can make the procedure of orotracheal intubation more difficult.

A common classification used by Anesthesiologists to grade the difficulty of laryngoscopy and intubation involves the identification of the size of the tongue in relation to the tonsillar pillars, the fauces, the soft palate, and the uvula.[7] It is important to perform this evaluation by first instructing patients to open their mouths and protrude their tongues maximally in the sitting position. The patient should not say "ahhh," as this distorts the anatomy and may falsely improve the airway classification. The Mallampati classification, named after its author, has four grades or classes.[7] The anterior and posterior tonsillar pillars, the fauces, the soft palate, and the uvula can be fully visualized in class I (**Figure 6-6A**). The fauces, the soft palate, and the uvula can be visualized in class II (**Figure 6-6B**). The anterior and posterior tonsillar pillars are covered by the base of the tongue and not visible. Only the soft palate and the base of the uvula are visible in class III (**Figure 6-6C**). None of the structures are visible in class IV (**Figure 6-6D**). The predictive value of this classification is that during direct laryngoscopy, the entire glottis can be exposed in 100% of class I airways, 65% of class II airways, 30% of class III airways, and 0.1% of class IV airways.[7]

The airway evaluation is imperfect in predicting potential problems and an airway strategy (combination of plans) should be drawn up for each patient. Additional evaluation may be indicated in some

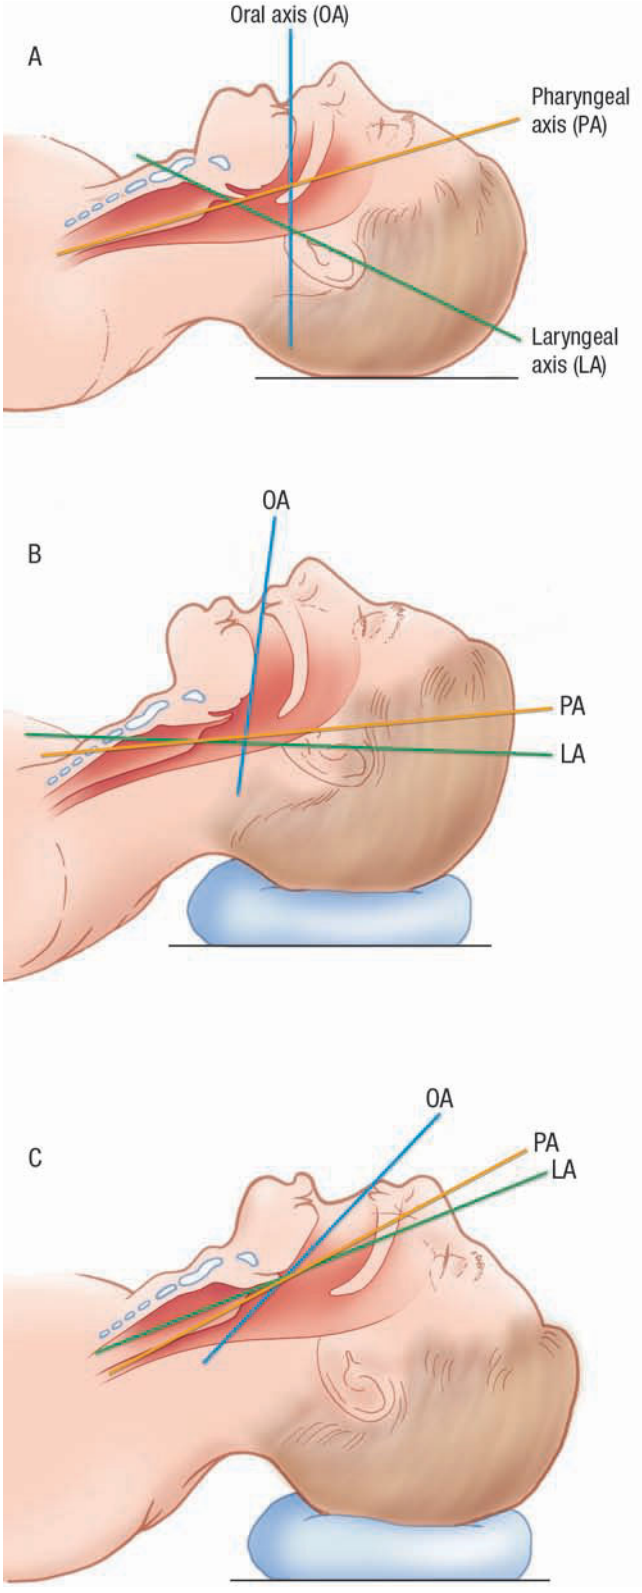

FIGURE 6-5. Schematic diagram demonstrating head positioning for endotracheal intubation. **A.** The normal alignment of the oral, pharyngeal, and laryngeal axes. **B.** Elevation of the head about 10 cm with pads below the occiput, while the shoulders remain on the table, aligns the laryngeal and pharyngeal axes. **C.** Subsequent head extension, at the atlantooccipital joint, serves to create the shortest distance and most nearly a straight line from the incisor teeth to glottic opening.

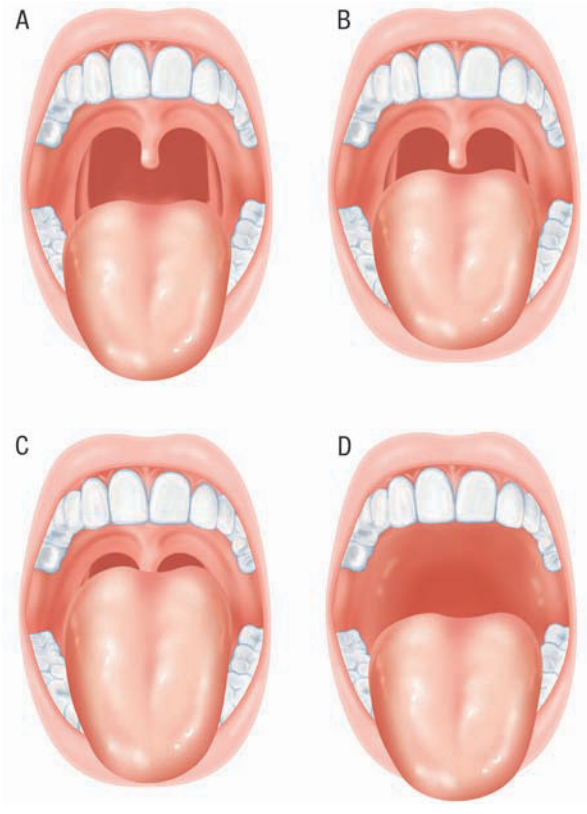

FIGURE 6-6. The Mallampati classification. **A.** Class I. **B.** Class II. **C.** Class III. **D.** Class IV.

patients to characterize the likelihood or nature of the anticipated airway difficulty. The findings of the airway history and physical examination may be useful in guiding the selection of specific diagnostic tests and consultation.

ANATOMIC DIFFERENCES BETWEEN THE ADULT AND THE YOUNG CHILD

There are numerous differences between the airway of an adult and that of a child. The head-to-body ratio is larger in the child. This causes the neck to be flexed when the child is supine. Placing a rolled towel under the child's shoulders will correct the flexion. A child has a small mouth with a relatively large tongue as compared to an adult. This can make orotracheal intubation difficult. The presence of adenoidal tissue in the child makes nasotracheal intubation difficult and orotracheal intubation the preferred method.

The anatomic differences between the larynx of an adult and that of a young child are summarized in **Table 6-3** and **Figure 6-7**.[1] The vocal cords are more obliquely inclined in the child. The cricothyroid membrane is very small and narrow. **The most important difference is that the narrowest portion of the infant or young child's airway is below the level of the vocal cords at the level of the cricoid cartilage. In an adult, the narrowest point of the airway is at the level of the vocal cords.** The cricoid cartilage is the only complete cartilaginous ring and the narrowest part of the trachea. An endotracheal tube may therefore pass through the vocal cords of a young child but might not advance past the cricoid cartilage due to normal anatomy. Forcing an endotracheal tube past the vocal cords in a young child may result in trauma to the airway and subsequent tracheal stenosis. Because the child's larynx is located more cephalad at the level of the third or fourth cervical vertebrae and

TABLE 6-3 Anatomic Differences Between the Child's and the Adult's Larynx

	Child's larynx	Adult's larynx
Size	Smaller	Larger
Shape	Lumen is funnel shaped with the narrowest part below the vocal cords and within the cricoid ring	Narrowest part of lumen is at the vocal cords
Location	Higher, closer to the tongue base; vertical extent is opposite C3, C4, C5 vertebrae; more anterior	Vertical extent is lower, opposite C4, C5, C6 vertebrae
Epiglottis	Longer, narrower, and "U" shaped; the angle between glottis and epiglottis is more acute; increased chance of airway obstruction (see Figure 6-7)	Shorter and wider
Vocal cords	Angled in relation to the axis of trachea; shorter; more cartilaginous; more distensible; more likely to be injured	Perpendicular to the axis of trachea
Rigidity	The laryngeal cartilages are softer and more pliable	More rigid
Response to trauma	Mucous membrane is more loosely attached and swells more readily when traumatized or infected	Less vulnerable to trauma and infection

angulated anterior to the glottis, blind nasal intubation in the case of airway emergencies is not possible. The child's laryngeal inlet is narrow and more susceptible to obstruction. The U-shaped epiglottis and a more acute angle between the epiglottis and glottis cause the aryepiglottic folds to be more in the midline (**Figure 6-7B**).

Differences also exist in the trachea. Children have a relatively shorter trachea. This makes both right main bronchial intubation and accidental extubation much easier. The narrower diameter of the trachea with smaller spaces between the cartilaginous rings makes a tracheostomy more difficult to perform. To avoid injury and subsequent subglottic stenosis, uncuffed endotracheal tubes should be used in children less than 28 days of age.[11] A correctly sized endotracheal tube should have a leak at 15 to 25 cm water. Using the uncuffed endotracheal tube with high leak pressure more than 25 cm of H_2O or the cuffed endotracheal tube can not only cause croup after extubation, but also create an erosion of the mucosa and subglottic stenosis. A cuffed endotracheal tube is recommended for anyone above the age of 28 days.[10–13]

The differences also continue into the chest. The infant thoracic cage is more compliant than the older child and adult. This can lead to more effective ventilation. The child's diaphragm is shorter and flatter than the adult, and thus has a decreased excursion during respiration. The child's relatively narrower airways result in an increased resistance to inspiratory and expiratory airflow. They are also more susceptible to airway edema and mucous plugs obstructing their narrow airway. Children have smaller and fewer alveoli. This results in less surface area for gas exchange compared to adults.

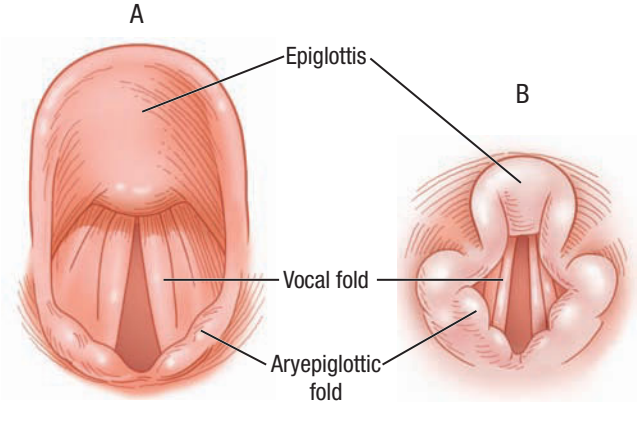

FIGURE 6-7. Differences between the adult's larynx (**A**) and the child's larynx (**B**).

SUMMARY

It is essential for Emergency Physicians to know the anatomy of the airway, especially the differences found in the young child. The airway assessment is an essential element in the preparation to intubate a patient. Unfortunately, there may be limited information and time available to perform the full assessment in an emergent setting. Performing the airway assessment in every patient before orotracheal intubation will allow one to perform it quickly in an emergency.

7 Basic Airway Management

Christopher J. Russo and Zach Kassutto

INTRODUCTION

Airway management is one of the most basic and important aspects of Emergency Medicine. The concepts and techniques described in this chapter can be applied in a variety of environments. Understanding the following concepts and having an opportunity to practice them will allow one to provide the most fundamental of all medical care, support of a patient's airway.

Airway management remains crucial. Without oxygen, the brain begins to die within minutes.[1] The primary purpose of airway management is to facilitate the transport of oxygen to the lungs. The secondary purpose is to protect the airway from contamination with blood, fluids, or food. Airway management can be as simple as lifting a snoring patient's chin or as involved as awake, fiberoptic-guided endotracheal intubation.

The fundamental importance of airway management is reflected by the fact that two-thirds of basic life support taught by the American Heart Association is concerned with this vital function.[2] **The mission of airway management is to ensure a patent airway, provide supplemental oxygen, and institute positive-pressure ventilation when spontaneous breathing is inadequate or absent.[3] These three key aspects of airway management warrant repeating. Ensure a patent airway. Provide supplemental oxygen. Provide positive-pressure ventilation.**

Time is always critical when a patient needs airway support. The body's limited oxygen stores are rapidly exhausted once breathing stops. A healthy individual having maximally breathed 100% oxygen will begin to desaturate and have brain injury after 5 minutes of apnea. However, a sick patient breathing room air will desaturate almost immediately upon becoming apneic.[1]

Oxygenation and ventilation remain the essential goals of airway management. Inadequate ventilation may occur for a variety of reasons. Spontaneously breathing patients may develop an airway obstruction due to food, blood, secretions, or tissue obstruction from the loss of normal pharyngeal tone. The conscious patient with airway obstruction will be in obvious distress and is more likely to have obstruction due to a foreign body, tissue swelling from an infection, laryngeal edema, tumor, or laryngospasm. The unconscious patient,

despite spontaneous respiration, is at risk for aspiration of gastric contents. Unconscious patients should have their airway secured as well as receive mechanical ventilation.

ANATOMY AND PATHOPHYSIOLOGY

The "upper airway" includes the nasal, oral, pharyngeal, and laryngeal anatomy and physiology. This highly complex system is responsible for conveying warmed and filtered air to the trachea and lungs while simultaneously allowing for passage of liquids and solids to the esophagus. Phonation is a secondary physiologic function of the larynx.[4] This highly sophisticated system allows us to drink liquid, eat food, breathe, and talk simultaneously. However, if a small drop of liquid or a particle of food enters the airway, a profound system of reflexes is activated to protect its integrity.[5]

The nasal cavity and the nasopharynx is the area from the tip of the nose to the palate. The nasal cavity is bounded laterally by the bony framework of turbinates and medially by the nasal septum. This area is highly innervated by the ophthalmic and maxillary branches of the trigeminal nerve. The mucosa of the nasal cavity and the nasopharynx is highly vascular. It is this high degree of vascularity that allows cool air from the environment to be warmed and humidified prior to entering the lungs. It also dictates that care be taken when nasal airways are placed. It takes very little trauma to the nasal mucosa to cause significant epistaxis. Polyps or mucus can obstruct the nasopharynx, as can congestion due to an upper respiratory infection. The nasopharynx is oriented in an anteroposterior plane. In the supine patient, nasal airways or nasogastric tubes should always be passed perpendicular to the horizontal axis and not in a cephalad direction.

The oropharynx extends from the palatoglossal fold down to the epiglottis. The primary structure contained within the oropharynx is the base of the tongue. The anterior two-thirds of the tongue is innervated by the lingual nerve, a branch of the facial nerve. The posterior one-third of the tongue, the tonsils, and the palate are innervated by the glossopharyngeal nerve.[6] Salivary glands located in the oropharynx can produce a significant volume of saliva, creating potential problems for mask ventilation or intubation. Loose teeth can be inadvertently dislodged into the oropharynx, becoming potentially hazardous foreign bodies in the airway.

Edentulous patients present a unique set of problems for mask ventilation.[7] The lack of a maxillary alveolar ridge allows the face mask to collapse into the airway. Redundant tissue, due to lack of teeth, tends to collapse into the airway as well, making mask ventilation without an oral or a nasal airway extremely difficult. An appropriately sized and placed oral airway is the best way to overcome the problem of upper airway obstruction in the unconscious and edentulous adult patient.

The laryngopharynx extends from the epiglottis to the inferior border of the cricoid cartilage. The piriform recesses lie in the pharynx, on either side of the larynx, and the esophagus resides posteriorly. The larynx is positioned at the entrance to the trachea, acts as the sphincter of the pulmonary system, and is made up of nine cartilages to support this function.[6] There are three paired and three unpaired cartilages. The unpaired cartilages are the epiglottis, the thyroid cartilage, and the cricoid cartilage. The paired cartilages are the arytenoids, the corniculates, and the cuneiforms. **The cricoid cartilage is the only complete ring in the entire airway.** This presents a unique opportunity for the practitioner to help prevent gastric aspiration. **The cricoid cartilage can be firmly pressed posteriorly to pinch the esophagus against the cervical spine and prevent the passive regurgitation of gastric contents. This is known as the Sellick maneuver.**[8] The cricoid cartilage is the narrowest point of the airway in the pediatric patient while the glottic narrowing is the most narrow point in adults. The cricoid and thyroid cartilages are the landmarks for identifying the cricothyroid membrane, which is essential in obtaining an emergent surgical airway.

TABLE 7-1 Indicators that Warrant Respiratory Assistance

$PaCO_2$ > 55 mmHg
Vital capacity < 15 mL/kg
A-a gradient > 350 mmHg on 100% O_2

Source: Data from Shapiro et al.[10]

The sensory and motor innervation of the larynx is derived from the vagus nerve.[6] The superior laryngeal nerve is a branch of the vagus nerve and gives rise to the internal branch, which provides the sensory innervation of the upper larynx. The superior laryngeal nerve also gives rise to the external branch, which provides the motor innervation to the cricothyroid muscle (a vocal cord adductor). The recurrent laryngeal nerve provides the sensory innervation to the larynx below the vocal cords and motor innervation to all other laryngeal muscles.[6]

The trachea is approximately 15 cm long in an adult. It is composed of 17 or 18 C-shaped cartilaginous rings.[6] The rings are essential to prevent the trachea from collapsing during the negative intrathoracic pressures generated on inspiration.

INDICATIONS

The decision to institute airway support must often be made very quickly and frequently without the aid of laboratory results, radiographic studies, or pulmonary function tests. **The decision to institute emergent airway support is usually based on clinical judgment and the signs and symptoms of inadequate oxygenation and ventilation.** The signs of impending respiratory failure are tachypnea, dyspnea, cyanosis, agitation, and the use of accessory muscles.[9] In the case of a partial airway obstruction, the patient will demonstrate extreme anxiety, audible wheezing or stridor, as well as aggressive attempts to clear the obstruction. If the obstruction is complete, there may be no audible breath sounds at all.

If time permits, a more formal evaluation of the indicators that warrant respiratory assistance should be performed (**Table 7-1**). The ultimate signs indicating the necessity for airway assistance are hypoxia and hypercarbia. The most common etiologies resulting in the need for airway support are cardiopulmonary arrest, drug overdoses, toxic reactions, and airway obstruction (food, vomit, or foreign body). Impending ventilatory failure due to congestive heart failure, severe asthma, or pneumonia are also common indications for endotracheal intubation.

CONTRAINDICATIONS

There are no absolute contraindications for basic airway management. The contraindications for the various methods of endotracheal intubation are discussed in subsequent chapters.

EQUIPMENT

- Bag-valve-mask device
- Oxygen source
- Clear face masks, various sizes and shapes
- Oropharyngeal airways, various sizes
- Nasopharyngeal airways, various sizes
- Head strap

- Yankauer suction catheter
- Suction source
- Pulse oximeter
- Tongue blades or tongue depressors
- Water-soluble lubricant or anesthetic jelly

TECHNIQUES

PATIENT POSITIONING

The first goal of airway management, regardless of a patient's ability to breathe spontaneously, is the establishment of a patent airway. This may be all that is required in a patient who has an upper airway foreign body or a patient who has suffered a loss of consciousness with loss of pharyngeal tone. **The importance of proper positioning cannot be overemphasized.** The success of airway management is predicated on this very basic but often overlooked issue. Placing the patient in the "sniffing" position, or lateral decubitus position, may correct many upper airway obstructions due to soft tissue impingement.[11] **The "sniffing" position is achieved by flexing the cervical spine approximately 15° and extending the atlantooccipital joint maximally (Figure 7-1)**. This is the position one subconsciously adopts in order to sniff and smell. Head extension in this manner must be omitted in the patient for whom cervical spine precautions are in effect. **This position can also be achieved with the chin-lift and/or jaw-thrust maneuvers.**

If the patient is obese or has large breasts, they often cannot be effectively managed in a supine position. The normal sniffing position in an obese person is often not sufficient to relieve an airway obstruction (**Figure 7-2A**). Place a ramp or shoulder roll under the patient's upper back to achieve the sniffing position (**Figure 7-2B**).

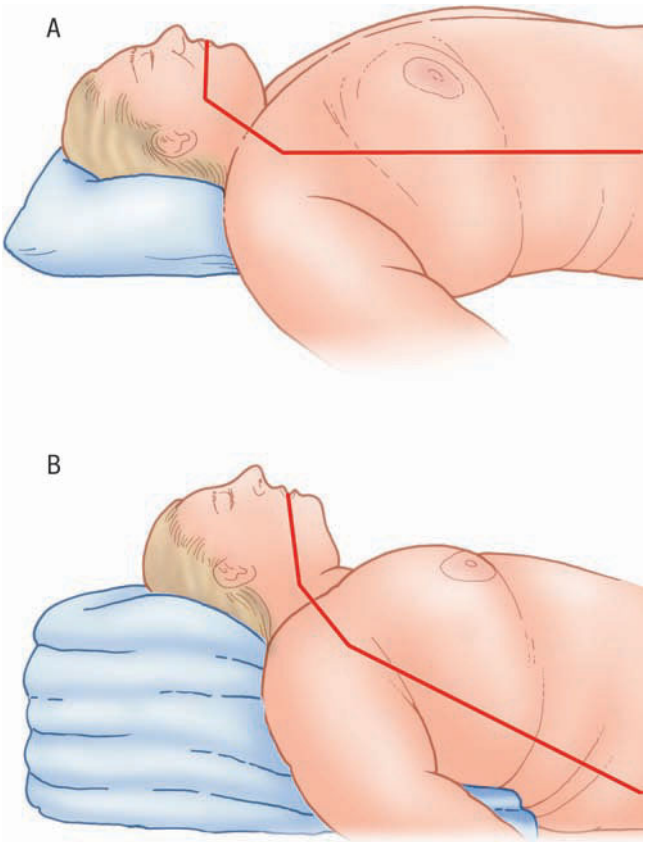

FIGURE 7-2. Airway management in the obese patient. **A.** The normal "sniffing" position is inadequate to open the airway. The dotted line represents the axis of the airway. **B.** A ramp placed under the head and shoulders will achieve the "sniffing" position.

JAW-THRUST MANEUVER

The jaw thrust is one of the most basic maneuvers and an initial method of establishing a patent airway.[12] The tongue is attached to the mandible and falls into the pharynx in the supine patient. **The goal of the jaw-thrust maneuver is to move the tongue away from the palate and posterior pharyngeal wall.** The jaw-thrust maneuver is a two-handed technique that can also be used with the face mask and a second person to provide positive-pressure ventilation. The operator is positioned at the head of the patient and places their fingers on the angles of the patient's mandible bilaterally, then displaces the mandible anteriorly (**Figure 7-3**). This maneuver elevates the tongue from the pharynx and allows air to flow unobstructed and posterior to the tongue.

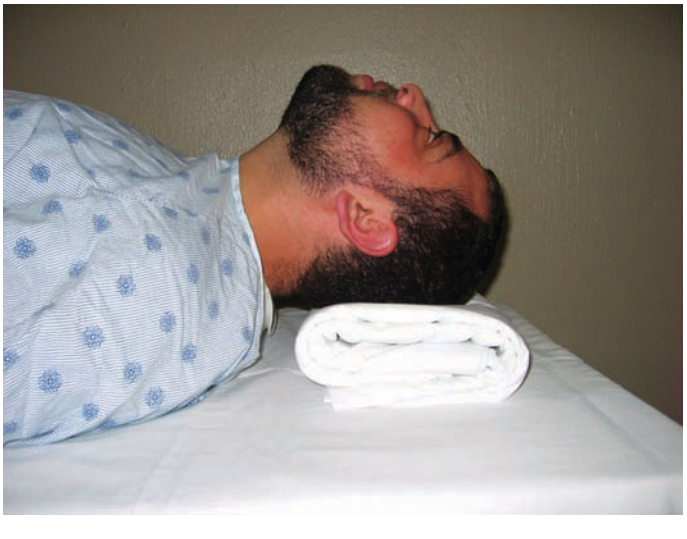

FIGURE 7-1. The "sniffing" position for successful airway management.

CHIN-LIFT MANEUVER

The chin lift is also one of the most basic maneuvers and an initial method of establishing a patent airway.[12] The chin lift is performed by the operator placing their fingers on the inferior surface of the patient's mandible (**Figure 7-4**). **Do not place any of the fingers on**

FIGURE 7-3. The jaw-thrust maneuver.

FIGURE 7-4. The chin-lift maneuver.

the soft tissues of the submandibular space, as this will elevate the tongue and cause further obstruction. Lift the chin in an anterior and cephalic direction. The head may also be tilted slightly posterior to aid in opening the airway.

NASOPHARYNGEAL AIRWAYS

The majority of airway obstructions occurs in the region of the pharynx.[13] In addition to proper positioning, one can use various aids to overcome this site of obstruction and facilitate effective ventilation. The most commonly used devices are oropharyngeal (oral) and nasopharyngeal (nasal) airways. Regardless which device is chosen, it is important to place a large enough airway to bridge the area of soft tissue impingement on the pharynx.

Nasal airways are soft rubber or plastic tubes that are inserted through the nostril and into the oropharynx, just above the epiglottis. Nasal airways are available in numerous sizes (**Figure 7-5**). The proximal end has an enlarged flange that rests against the patient's nares and prevents the nasal airway from slipping backward into the nose and becoming a foreign body in the patient's airway. The larger the inner diameter, the longer the tube. Once positioned, the

FIGURE 7-5. Nasopharyngeal airways.

FIGURE 7-6. Insertion of the nasopharyngeal airway.

nasal airway is more comfortable for the patient than an oral airway, but nasal airways carry the significant risk that their placement may result in epistaxis.[3,10] A size 30 or 32 French nasal airway is appropriate for most adults. It can be safely placed in the conscious, semiconscious, or unconscious patient, and can also be used when an oral airway cannot be placed (e.g., oral trauma, braces, seizures, trismus, etc.). **It is imperative to also perform the jaw thrust and/or chin lift to prevent the tongue from obstructing the patient's airway when using a nasal airway.**

Insertion of a nasal airway is a rapid procedure. Choose the proper size nasal airway by placing the flared end of the airway near the tip of the patient's nose. The distal end of the nasal airway should be at the external auditory canal. Liberally apply a water-soluble lubricant or an anesthetic jelly to the nasal airway. If not contraindicated, apply a vasoconstrictor to the patient's nasal mucosa. Gently insert and advance the nasal airway with the beveled tip against the nasal septum (**Figure 7-6**). This will prevent any epistaxis from the tip of the nasal airway getting caught on the inferior or middle turbinate. Also insert it along the floor of the nasal cavity adjacent to the septum. Continue to advance the nasal airway completely until the flared end is against the patient's nostril. Rotate the nasal airway 90° so it is concave upward. If resistance is encountered during insertion, slight rotation will often facilitate the passage of the nasal airway. If resistance is still encountered, insert the nasal airway into the other nostril or use a smaller nasal airway. Supplementary oxygen or positive-pressure ventilation with a bag-valve-mask device can be started after insertion of the nasal airway.

Insertion of a nasal airway may be associated with complications. If the device is too long, it may cause laryngospasm and vomiting. It may also be placed with its tip in the esophagus, resulting in gastric distention and subsequent aspiration. Nasal mucosal injury upon insertion can result in epistaxis and aspiration of blood.

OROPHARYNGEAL AIRWAYS

The oropharyngeal (oral) airway is a semicircular plastic device that holds the tongue up and away from the posterior pharyngeal wall (**Figure 7-7**). Oral airways cause less trauma and are more easily placed than nasal airways. **Oral airways must be used only in unconscious patients. They may result in laryngospasm and vomiting if placed in a conscious or semiconscious patient.**[14] An 8.0, 9.0, or 10.0 cm oral airway is appropriate for most adults.

Oral airways have many uses. The primary indication is to maintain a patent airway. It will prevent the patient from biting,

FIGURE 7-7. Oropharyngeal airways.

occluding, and lacerating an endotracheal tube. It facilitates oropharyngeal suctioning by removing the tongue from the airway, and will also protect the tongue from bites during seizure activity.

Insertion of the oral airway is a quick and simple procedure. Choose the proper size oral airway. The correct size is estimated by placing the proximal flange of the oral airway next to the patient's mouth. The distal tip should lie just above the angle of the mandible. Clear the mouth and oropharynx of any blood, secretions, or vomit with a Yankauer suction catheter. Open the patient's jaw with the nondominant hand. Separate the patient's jaws with a "scissors-like" action of the thumb on the lower teeth and the index or middle finger on the upper teeth. Insert the oral airway curved side down (**Figure 7-8A**). The tip will slide along the hard palate. Insert it until the plastic flange on the proximal end is at the patient's lips. Rotate it 180° so that the curve of the oral airway follows the curvature of the tongue.

An alternative method is to use a tongue blade to depress the tongue and then insert the oral airway as described above. If the tongue blade is used, the oral airway may also be inserted with the curve side upward (**Figure 7-8B**). Supplementary oxygen or positive-pressure ventilation with a bag-valve-mask device can be started after the insertion of the oral airway.

Insertion of an oral airway is not a benign procedure. If the oral airway is not inserted properly, it can push the tongue posteriorly and further obstruct the oropharynx. Significant lacerations can occur if the lips or tongue are caught between the teeth and the oral airway. If the oral airway is too long, it can force the epiglottis closed against the vocal cords and produce a complete airway obstruction. Too small of an oral airway will force the tongue against the pharynx and produce an obstruction.

MASK VENTILATION

The likelihood of success in airway management is often predictable, given enough time to fully assess a patient's history and anatomy (please refer to Chapter 6).[15] The ease of mask ventilation and intubation is directly related to anatomy. Anesthesiologists rely on a series of evaluations and classification criteria to help predict the success of airway management. The most widely used classification is the Mallampati classification (**Figure 6-6**).[16] This evaluation—coupled with an examination of the patient's body habitus, thickness of the patient's neck, temporomandibular joint function, ability to fully open the mouth, dental structures, cervical range of motion, and thyromental distance—can help predict the ease or difficulty of airway management.[15–21]

FIGURE 7-8. Insertion of the oropharyngeal airway. **A.** It is inserted with the curve toward the tongue. After insertion, it is rotated 180°. **B.** It is inserted with the curve toward the palate. A tongue blade is used to depress the tongue and facilitate insertion.

A distinction must be made between ease of mask ventilation and ease of oral endotracheal intubation. The two are often correlated but can, at times, be completely unrelated. For example, a patient with a normal body habitus who is in a cervical halo may be very easy to ventilate by mask but impossible to intubate orally via direct laryngoscopy. Conversely, the patient who is obese, suffers from sleep apnea, but has a Mallampati class 1 airway may be very easy to intubate but virtually impossible to ventilate by mask.

After achieving the proper positioning, the presence of spontaneous respirations must be evaluated. If the patient is not breathing and there is no evidence of a foreign body, positive-pressure ventilation must be initiated. In the awake patient with complete airway obstruction due to a foreign body, the Heimlich maneuver is the method of choice.[2] If the patient has become unconscious and the foreign body is clearly visible, remove it. **However, caution must be used to prevent forcing the object further into the airway.** Instrument removal of airway foreign bodies with a McGill forceps is possible if the foreign body is visible and within reach of the forceps.

Once the airway is patent, the options for positive-pressure ventilation include mouth-to-mouth, mouth-to-mask, and bag-valve devices (mask ventilation). The remainder of this section will review the latter, as the other two options are not used in Emergency Departments or hospitals. **The key to effective mask ventilation is ensuring a continually patent airway. This is initially achieved by placing the patient in the sniffing position, coupled with**

FIGURE 7-9. The one-handed, one-person mask ventilation technique.

FIGURE 7-10. The two-handed, two-person mask ventilation technique.

a combination of chin lift and jaw thrust. Neglect of this key maneuver leads to an excessive use of positive-pressure ventilation in an attempt to compensate for an obstructed upper airway. Improper patient positioning associated with positive-pressure ventilation will force gas into the stomach, increasing intraabdominal pressure and resulting in the need for ever-increasing positive pressure on the airway. Rising intraabdominal pressure will eventually make ventilation difficult or impossible, and significantly increase the risk of gastric aspiration. When called upon to mask ventilate a patient, **always keep in mind the importance of proper positioning and the use of an appropriately sized oral or nasal airway as an adjunct.**

Face masks should be made of clear plastic and/or silicone, have a soft seal, and have an anatomic shape that conforms to the contours of the patient's face. Typical adult sizes are 3, 4, and 5. **The mask must be large enough to completely cover the nose, mouth, and chin but not so large as to allow a leak.** It should not cover any part of the patient's eyes. There are two ways to properly hold a face mask. The one-handed technique is performed with the nondominant hand (**Figure 7-9**). The operator should be positioned at the top of the bed looking down at the patient's head. Place the little, ring, and middle fingers under the patient's mandible. Place the index finger and thumb on the bottom and top portions of the mask. **This technique allows the operator to simultaneously lift the mandible and extend the atlantooccipital joint while applying enough downward pressure on the face mask to create an airtight seal.** An elastic head strap is a very helpful device to aid in sealing the mask tightly. The dominant hand is used to ventilate the patient through the bag-valve device.

A two-handed technique may be necessary in patients with facial hair and those who are obese, elderly, or edentulous. Two people are required to perform this technique, in which both of the operator's hands are applied to the face mask to aid in the creation of a tight seal and align the airway properly (**Figure 7-10**). Place the face mask on the patient's face. Place the index, middle, ring, and small fingers of the left hand on the body of the left side of the patient's mandible. Position the right hand similarly on the right side of the patient's mandible. Apply both thumbs to the mask and apply pressure to create a seal. Anteriorly elevate the mandible to perform the jaw-thrust maneuver. This is the two-person technique and makes it necessary to have an assistant apply positive pressure through the bag-valve device attached to the face mask. It is preferable, whenever possible, to use the two-person technique which allows for improved bag-valve-mask ventilation.[25]

THE NuMask™

A relatively new device can be used to assist in ventilation instead of a traditional face mask. The NuMask™ (NuMask Inc., Woodland Hills, CA) solves the problem of having to create an airtight face mask seal in patients. This device is an intraoral mask for teenagers and adults that connects to a bag-valve device and eliminates the need for a face mask (**Figure 7-11A**). It is especially useful in patients whom it is difficult to get a good face mask seal (e.g., obese, facial hair, and facial trauma) or for the one-person bagging technique. The company makes a retention shield that wraps around the patient's head to secure the device and seal the patient's nostrils. This allows for easy one-person bagging.

The NuMask™ is simple to insert into the patient's mouth. Place the device into the patient's mouth. It should sit between the patient's teeth/gums and the cheeks/lips (**Figure 7-11B**). Use the thumb and index finger of the nondominant hand to pinch the patient's nostrils closed (**Figures 7-11C & D**). Use the hand and remaining fingers to wrap around the external tube portion and to seal the patient's lips over the intraoral portion of the device (**Figures 7-11C & D**). The moisture in the patient's oral cavity maintains the airtight seal. Attach the bag-valve device and begin ventilations. If ventilation is difficult, remove the NuMask™, insert an oral airway, replace the NuMask™, and begin ventilations.

There are numerous advantages of using the NuMask™ over the traditional face mask. It is ideal for operators with small hands who have difficulty grasping and maintaining a seal with a face mask. While initially cumbersome to use, it is easier to maintain a seal than a face mask. Ventilation is easier when only one person is available to bag and ventilate the patient. It can be used in patients in whom a good face mask seal is difficult. The device can be used in both conscious and unconscious patients as it should not cause a gag reflex. Finally, the one size available will fit most teenagers and adults. A pediatric version is not available.

THE BAG-VALVE DEVICE

A bag-valve device is used to provide positive-pressure ventilation. It consists of a self-inflating bag connected to oxygen on one end and a one-way (nonrebreathing) valve on the other. They are available in several sizes depending on the age of the patient (**Figure 7-12**). The valve end is connected to the face mask, or other airway device, to allow one-way flow of oxygen. The other end has tubing to attach the bag to an oxygen source. This device can also force air into the esophagus and stomach and place the patient at risk for aspiration if not used properly.

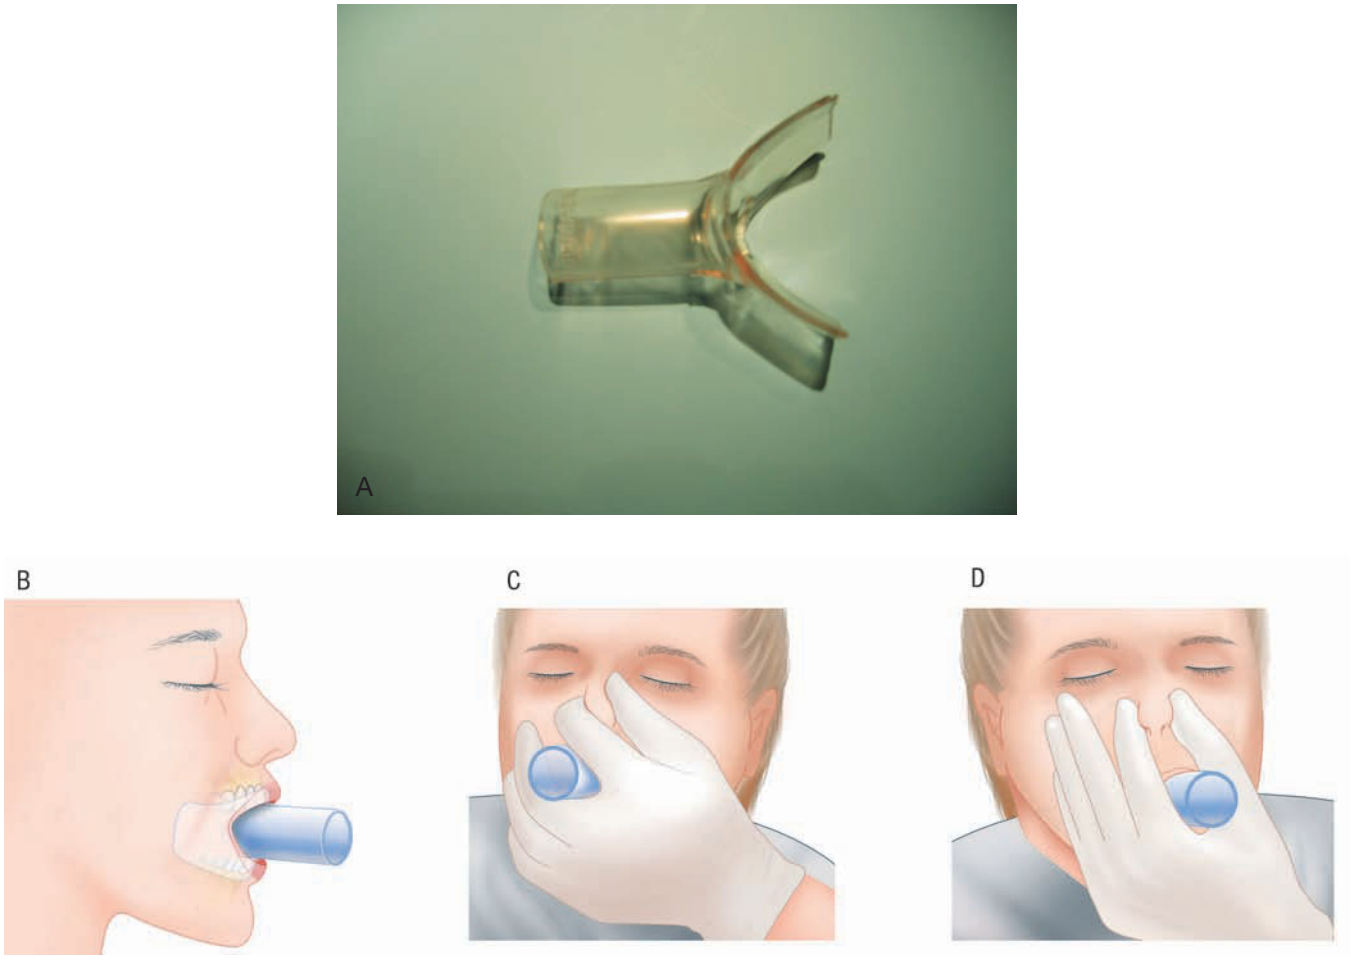

FIGURE 7-11. The NuMask™ intraoral mask. **A.** The device. **B.** The device is inserted between the patient's teeth/gums and their lips/cheeks. **C.** Proper hand positioning to seal the patient's nostrils and lips. **D.** An alternative hand positioning.

It may be difficult to provide adequate ventilatory volumes through the bag-valve device attached to a face mask. This is often due to an inadequate seal of the face mask on the patient while maintaining an open airway. It can also result from inadequate squeezing of the bag to generate an appropriate volume of air flow. Consider using the two-person technique to resolve these issues. If ventilation is difficult in a child, change the face mask from the standard teardrop shaped mask to a circular-shaped face mask.

FIGURE 7-12. The bag-valve-mask device. From left to right: adult size, child size, and infant size.

Stand above the patient's head. Place the patient in the sniffing position. Apply a face mask. Attach the bag-valve device to the face mask and begin positive-pressure ventilation. Begin ventilations at a rate of 10 to 12 per minute, or squeeze the bag every 5 to 6 seconds. If ventilation is difficult, apply the jaw-thrust and/or chin-lift maneuvers. If ventilation is still difficult, insert an oral or nasal airway. If ventilation is still difficult, the patient requires an invasive airway device immediately.

The American Society of Anesthesiologists has published an algorithm to facilitate decision making in the face of airway management problems. A detailed discussion of the various intubation options is presented in following chapters.

PEDIATRIC CONSIDERATIONS

Significant differences exist between the adult and pediatric airway as described in Chapter 6. The ratio of head-to-body size is greater in infants and young children. Care must be taken to achieve proper positioning for optimal airway angulation. A towel may be placed under an infant's shoulders, while younger children may be optimally positioned while lying flat on the stretcher. Older children may require a towel under the head to achieve ideal positioning.[23] Despite proper head positioning, loss of tone in the muscles

supporting and protecting the upper airway may still result in an airway obstruction. This may be corrected by the use of a jaw thrust, chin lift, nasal airway, or oral airway.

Infants and children have a higher minute ventilation and cardiac output than adults, as well as higher basal oxygen consumption. They also have a lower functional residual capacity which leads to oxygen desaturation more rapidly than in adults when apnea occurs. When oxygenation and ventilation are provided in an effective and efficient fashion, hypoxic bradycardia can be prevented or reversed.[23]

Properly sized equipment remains crucial to the success of airway management, and can be addressed by the use of the Broselow tape. It should be noted that there is insufficient evidence for or against the routine use of laryngeal mask airways during pediatric cardiac arrest. While an acceptable adjunct in the hands of experienced providers, it is associated with a higher incidence of complications in young children.[24]

COMPLICATIONS

The most serious complication of basic airway management is aspiration of gastric contents. The aspiration of acidic gastric contents can result in an acute chemical pneumonitis. This phenomenon is known as the Mendelson syndrome and has an associated 50% mortality.[22] It is a significant risk when airway management is needed emergently or routinely in the pregnant, trauma, diabetic, or obese patient.

Less serious complications include soft tissue trauma to the lips, tongue, oral cavity, and eyelids. Tooth fractures or avulsions are uncommon but possible. A dermatitis or allergic reaction to the plastic material is rarely seen. Facial nerve dysfunction due to pressure effects of the mask are transient. Corneal abrasions, conjunctival chemosis, and increased intraocular pressure are common with masks that are too large.

SUMMARY

Basic airway management is a fundamental skill that must be mastered by all caregivers. With an oxygen source, a means to deliver positive-pressure ventilation, attention to detail in positioning, and the use of airway adjuncts, it is usually possible to prevent hypoxia and hypercarbia in the apneic patient. The ultimate measure of the efficacy of ventilation and oxygenation is a normal $PaCO_2$ and PaO_2. The various methods of securing the airway are discussed elsewhere in this text.

8 Pharmacologic Adjuncts to Intubation

Ned F. Nasr, David W. Boldt, and Isam F. Nasr

INTRODUCTION

Oral endotracheal intubation without pharmacologic assistance should be reserved for the unresponsive and apneic patient. Unconscious patients capable of resisting laryngoscopy or those with spontaneous respiratory effort should be intubated with the assistance of pharmacologic adjuncts. A rapid sequence induction optimizes intubation conditions while minimizing the risk of aspiration for the patient. It can be performed with a high rate of success and minimal complications.[1] Rapid sequence intubation requires the use of several pharmacologic adjuncts (**Tables 8-1 & 8-2**). This includes a potent anesthetic agent to induce unconsciousness and a neuromuscular blocking agent to produce paralysis.

TABLE 8-1 Recommended Anesthetic Doses of Pharmacologic Agents Used for Rapid Sequence Induction

Medication	Adult dose (mg/kg)	Pediatric dose (mg/kg)	Onset (sec)	Duration (min)
Thiopental	2–5	2–6	<30	5–10
Methohexital	1–3	1–2	<30	5–10
Etomidate	0.2–0.3	0.2–0.3	15–45	3–12
Ketamine	1–2	1–3	45–60	10–20
Propofol	1.5–2.5	2.5–3.5	15–45	5–10
Midazolam	0.2–0.4	0.5–1.0	30–90	10–30
Fentanyl	0.005–0.015	0.005–0.015	15–45	30–60

INDUCTION AGENTS

The ideal induction agent has an extremely rapid onset of action, produces predictable deep anesthesia, has a short duration of action, and has no adverse effects.[2] Unfortunately, such an agent does not yet exist. However, there are at least six drugs that can safely be used for induction of anesthesia and intubation. These include thiopental, methohexital, etomidate, ketamine, and propofol. Midazolam and fentanyl may also be used alone or in conjunction with the above agents.[2] **The decision as to which induction agent is the most suitable is largely dependent on the Emergency Physician's experience and his or her understanding of each drug's properties.** In this section, each of these drugs is briefly detailed as to its pharmacokinetics, mechanism of action, pharmacodynamics, administration, and adverse effects.

BARBITURATES

For more than 50 years, barbiturates have been a mainstay in the induction of anesthesia. They rapidly produce sedation and hypnosis in a dose-dependent fashion. They are also less expensive than many of the newer induction agents.[3] Because of their high potency, rapid onset, and short duration of action, the most commonly used barbiturates are thiopental (Pentothal™) and methohexital (Brevital™).

PHARMACOKINETICS

When injected intravenously, these ultra-short-acting barbiturates can produce effects in one arm-brain circulation time, or less than 30 seconds.[4] The onset of central nervous system (CNS) depression is primarily due to the rapid distribution of thiopental and methohexital to the well-perfused, low-volume central compartment,

TABLE 8-2 Recommended Neuromuscular Blocking Agents for Intubation and Rapid Sequence Induction

Medication	Adult dose (mg/kg)	Pediatric dose (mg/kg)	Onset (min)	Duration (min)
Succinylcholine	0.6–1.0	1–2	1	2–3
Succinylcholine for RSI	1.5	2	1	3–5
Pancuronium	0.1	0.07–0.10	2–5	40–60
Atracurium	0.5	0.5	3	20–35
Vecuronium	0.1	0.05–0.10	3	30–40
Vecuronium for RSI	0.3–0.5	0.3–0.5	1	45–60
Rocuronium	0.6	1.0	4–6	15–85
Rocuronium for RSI	0.9–1.2	1.0–1.2	1.0–1.5	30–110

consisting mainly of the brain and liver. Approximately 15% of these lipid-soluble drugs remain unbound and free to diffuse across the blood–brain barrier at high initial concentrations. Brain levels peak in about 1 minute. The duration of a single dose of thiopental is approximately 5 to 10 minutes, while an equipotent dose of methohexital lasts approximately 4 to 6 minutes.[5] The short duration of action is due to the redistribution of the drugs from the small-volume central compartment to the large-volume peripheral compartment, which is predominantly made up of lean muscle.

Both thiopental and methohexital are metabolized in the liver and excreted by the kidneys. Methohexital has a substantially higher hepatic extraction ratio, which may account for its shorter duration of action. Clearance of the drugs has little to do with the cessation of CNS effects in single or multiple small doses. If barbiturates are given in multiple high doses or in an infusion, the concentration in the peripheral tissue approaches the plasma concentration and the rate of redistribution is greatly diminished.[6] This prolongs their anesthetic effects.[6]

MECHANISM OF ACTION

Barbiturates, along with other common intravenous (IV) anesthetic agents, are postulated to act on the γ-aminobutyric acid (GABA) receptor complex. Specifically, these drugs work on the $GABA_A$ receptor.[7] GABA is the principal inhibitory neurotransmitter in the CNS. The GABA receptor complex forms a transmembrane chloride channel when activated. The influx of chloride ions causes hyperpolarization and functional inhibition of the postsynaptic neurons. Barbiturates can act on the GABA receptor in two ways. At lower doses, they may potentiate the action of endogenously produced GABA by decreasing the rate of its dissociation from the receptor complex. At higher doses, barbiturates may directly activate the chloride ion channels and inhibit neuronal activity.[3] **It is important to note that barbiturates do not inhibit sensory impulses and therefore have no analgesic effect.** In fact, they may produce hyperalgesia (increased response to painful stimuli) when given in subhypnotic doses.[3]

PHARMACODYNAMICS

Barbiturates produce dose-dependent depression of cerebral oxygen metabolism ($CMRO_2$), cerebral blood flow (CBF), and electroencephalogram (EEG) activity. A flat EEG tracing correlates to a maximal barbiturate suppression of $CMRO_2$ to 55% of normal.[3] The diminished $CMRO_2$ and CBF lead to a decrease in intracranial pressure (ICP). Since barbiturates lower mean arterial pressure less than they lower ICP, cerebral perfusion pressure (CPP) is usually enhanced. Barbiturates are commonly used in neuroanesthesia and in treatment of acute brain injury.

The cardiovascular effects of barbiturates include decreased cardiac output, decreased systemic arterial pressure, and a direct negative inotropic effect on the myocardium. Barbiturates decrease cardiac output primarily by depressing the vasomotor center, causing peripheral vasodilatation, and decreasing venous return to the heart. Both thiopental and methohexital have a positive chronotropic effect on the heart. Methohexital produces a greater increase in heart rate, which may explain why an equipotent dose of methohexital produces significantly less hypotension than does thiopental.[3] Although the increase in heart rate mitigates the drop in blood pressure, myocardial oxygen demand is increased while coronary vascular resistance is decreased. If the aortic pressure remains stable, coronary blood flow will increase to meet the increased demand. **Therefore, barbiturates must be used cautiously in any patient whose condition is sensitive to tachycardia or a decrease in preload (e.g., hypovolemia, congestive heart failure, ischemic heart disease, or pericardial tamponade).** Methohexital has less cardiovascular depressant effects and a shorter duration of action, likely making it more useful than thiopental in the Emergency Department setting.

Barbiturates cause dose-dependent central respiratory depression characterized by diminished tidal volume and minute ventilation. The rate and depth of respiration may be suppressed to the point of apnea. The physiologic response to hypercarbia and hypoxemia may also be blunted, even after the hypnotic effects have dissipated. All these effects may be greatly exaggerated with the concomitant use of opioids and in patients with chronic obstructive pulmonary disease.[8]

ADMINISTRATION

Thiopental and methohexital are available as sodium salts and should be dissolved in 0.9% saline. The recommended dose of thiopental is 3 to 5 mg/kg in adults, 5 to 6 mg/kg in children, and 6 to 8 mg/kg in infants IV given over 1 minute. The recommended dose of methohexital is 1 to 3 mg/kg IV over 30 seconds. The induction dose should be reduced in patients premedicated with fentanyl or midazolam. Doses may have to be adjusted in patients with known hepatic or renal disease because decreased plasma albumin levels leave a greater fraction of barbiturate available to cross the blood–brain barrier. A 30% to 40% reduction should be made in the geriatric population since their diminished muscle mass slows the rate of redistribution and lengthens the duration of CNS effects.[3]

ADVERSE EFFECTS

The most significant complications of barbiturate therapy stem from their cardiopulmonary depressant effects. As stated above, these agents should be used with caution in patients who are hypovolemic, have significant cardiovascular disease, or have reactive airway disease. Thiopental can raise plasma histamine levels, which may be associated with a transient skin rash and bronchospasm. Its use should be avoided in patients with a history of hypersensitivity to barbiturates. Severe anaphylactic reactions are extremely uncommon.[3] Laryngeal reflexes appear to be more active with thiopental than with propofol. Thiopental should be avoided in people with asthma.[3] Laryngospasm following induction with thiopental is more likely the result of airway manipulation in a "lightly anesthetized" patient.[3] Methohexital has known epileptogenic effects and is frequently associated with myoclonic tremors and other CNS excitatory side effects, such as hiccups.[3] Barbiturates stimulate the production of porphyrins and thus are contraindicated in patients with acute intermittent porphyria, variegate porphyria, and hereditary coproporphyria.[3] Pain at the site of intravenous injection is more common with the administration of methohexital than thiopental. Due to their high alkalinity (pH 10), extravascular or intraarterial injection of these drugs may cause severe pain, tissue necrosis, and thrombosis, leading to potential nerve damage and gangrene.

Intraarterial injection should be treated promptly by initially diluting the barbiturate with saline injected through the catheter in the artery. Next, intraarterial injections of heparin, papaverine, lidocaine, or phenoxybenzamine may be administered to cause vasodilation and prevent vessel thrombosis.[3] Lastly, sympathectomy of the involved upper extremity by a stellate ganglion or brachial plexus block can be performed by an Anesthesiologist to relieve the vasoconstriction.

An additional concern relating to the high alkalinity of these solutions is that if they are injected rapidly through the same intravenous line along with highly acidic drugs, such as neuromuscular blockers, precipitation will occur. This may lead to permanent blockage of the line at a time when intravenous access is crucial. It

is recommended that the line be flushed thoroughly both before and following the administration of barbiturates, and before the administration of the next agent.

ETOMIDATE

Etomidate (Amidate™) is an ultra-short-acting hypnotic unrelated to any other intravenous anesthetic agent. Like barbiturates, it is highly potent and produces a rapid onset of anesthesia. It lacks the barbiturates' cardiodepressant side effects. Given its favorable profile, etomidate has become a popular induction agent and, in many Emergency Departments, is now the induction agent of choice for rapid sequence intubation.[9]

PHARMACOKINETICS

Etomidate is a carboxylated imidazole agent that undergoes a molecular rearrangement at physiologic pH, which grants it greater lipid solubility. Approximately 75% of the drug is plasma protein bound. The free fraction accumulates readily in the CNS. Unconsciousness is produced within one arm-brain circulation time. Peak brain concentration is achieved within 1 minute. Redistribution of the drug is quite rapid. A single bolus dose produces hypnosis in 10 seconds and lasts approximately 3 to 5 minutes. Since it has a high extraction ratio and undergoes rapid hydrolysis by the liver, clearance of etomidate is dependent on hepatic blood flow, with inactive metabolites excreted in the urine.[10]

MECHANISM OF ACTION

By modulating GABA receptors to produce hyperpolarization and functional inhibition of the postsynaptic neurons, etomidate (like barbiturates, propofol, and benzodiazepines) produces dose-dependent CNS depression. GABA antagonists, such as flumazenil, may attenuate its effects. **Etomidate has no analgesic properties.**[11]

PHARMACODYNAMICS

Etomidate produces dose-dependent depression of $CMRO_2$, CBF, and EEG activity analogous to that of the barbiturates. Since it does not affect mean arterial pressure, **etomidate decreases ICP with minimal effect on CPP.** It is useful in patients with elevated ICP, especially those who are hemodynamically unstable.[12] **Etomidate causes minimal cardiovascular depression, even in the presence of significant cardiac disease.** Heart rate, blood pressure, and cardiac output are all adequately maintained. The respiratory depressant effects of etomidate appear to be substantially less than those of thiopental or propofol, making it a safer choice than barbiturates in patients with diminished pulmonary function. **Etomidate is therefore considered to be the induction agent of choice in patients with severe cardiopulmonary disease and high-risk patients in whom maintenance of blood pressure is crucial.**[13] Because it does not blunt the sympathetic response to laryngoscopy and intubation, etomidate should be combined with an opioid analgesic in patients who would be at risk from a transient elevation of blood pressure or heart rate.[14] **Etomidate is the only available intravenous anesthetic that does not induce the release of histamine and thus is safe for patients with reactive airways.**[15]

ADMINISTRATION

Etomidate is formulated in a 0.2% solution with 35% propylene glycol. The standard induction dose is 0.3 mg/kg IV. There is virtually no accumulation of the drug. Emergence time is dose-dependent but remains short, even after repeated boluses.[16] Dose adjustments for elderly patients or those with hepatic or renal disease may be required.

ADVERSE EFFECTS

The most common side effects of etomidate are nausea, vomiting, and myoclonus during the induction phase, and injection site pain. Myoclonic activity has been reported in about one-third of cases and is attributed to interruption of inhibitory synapses in the thalamocortical tract rather than CNS excitation.[2] Pretreatment with an opioid analgesic or a benzodiazepine has been reported to diminish the frequency of myoclonic movements.[11] Vein irritation and pain at the intravenous site can be attributed to the propylene glycol diluent. Use of a large vein with simultaneous analgesic and saline infusion reduces the incidence of injection pain.[17]

Etomidate causes a dose-dependent suppression of adrenal corticosteroid synthesis by inhibiting the enzyme 11-β-hydroxylase.[74] A single induction dose of etomidate suppresses adrenocortical hormone synthesis for more than 5 hours.[75] In critically ill patients on an etomidate infusion, increased mortality has been attributed to this reduction of endogenous steroids leading to acute adrenocortical insufficiency.[18] **There is currently conflicting evidence, however, as to whether a single induction dose of etomidate has an effect on overall mortality in critically ill patients.**[76–81] Until significant randomized, controlled clinical trials can be performed, the use of etomidate for the induction of patients in early sepsis or septic shock should be cautioned.

KETAMINE

Ketamine (Ketalar™, Ketaject™) is a phencyclidine derivative that is unique among induction agents. **It produces a dissociative anesthetic state characterized by profound analgesia and amnesia.** Patients may appear awake with their eyes open, revealing a nystagmic gaze. They may make spontaneous nonpurposeful movements. **Protective reflexes are usually maintained,** which is fortunate considering that increased salivation is a common side effect. Ketamine is fast acting and has a brief duration of action. Although the likelihood of emergence delirium limits the usefulness of this drug, it has been widely used since 1970.[19]

PHARMACOKINETICS

Ketamine has a p*K*a of 7.5. Approximately 12% is plasma protein bound. Therefore, roughly half of the unbound fraction is available to accumulate rapidly in the CNS. A single induction dose produces anesthesia within 30 seconds and brain concentration peaks at 1 minute. Like barbiturates and etomidate, ketamine follows the three-compartment model, with rapid redistribution to the peripheral tissues.[19] Its CNS effects last approximately 10 to 15 minutes. Recovery of full orientation and function may take an additional 60 minutes. Ketamine is readily metabolized by hepatic microsomal enzymes to norketamine. Norketamine is one-fourth as potent as its precursor. The active metabolite may explain the prolonged recovery time. Norketamine is hydroxylated and excreted by the kidneys. Ketamine has a high extraction ratio, and its clearance is dependent on hepatic blood flow.[2]

MECHANISM OF ACTION

Ketamine acts by binding to the *N*-methyl-D-aspartate (NMDA) receptors on postsynaptic neurons. This receptor is a gated ion channel that allows depolarization and initiation of an action potential when activated by glutamate or NMDA. Ketamine blocks the flux of ions through this channel and inhibits the stimulatory effects of these neurotransmitters. Ketamine depresses neuronal activity in the cerebral cortex and the thalamus. It also stimulates the limbic system. Analgesia is produced by interrupting the association pathways responsible for the interpretation of painful stimuli that run from the thalamocortical and limbic systems.[20]

PHARMACODYNAMICS

Although ketamine produces dose-dependent CNS depression, it increases $CMRO_2$ and CBF, leading to an increase in ICP. Ketamine has a potent sympathomimetic effect. Its use often produces an increase in heart rate and arterial blood pressure. It has a direct negative inotropic effect on the myocardium, which is evident in the critically ill patient with depleted catecholamines. Ketamine produces minimal to no respiratory depression and has a potent bronchodilatory effect. It increases both bronchial and oral secretions. In contrast to other anesthetic agents, ketamine is likely to preserve protective airway reflexes. Skeletal muscle tone is also increased, resulting in the occurrence of random movements.[19]

ADMINISTRATION

Ketamine is available in 1% and 5% aqueous solutions for intravenous administration and a 10% aqueous solution for intramuscular (IM) injection. The induction dose of ketamine is 1 to 2 mg/kg IV over 1 minute or 5 to 10 mg/kg IM.[2]

In the Emergency Department, ketamine is indicated for the intubation of asthmatic patients due to its bronchodilatory properties. Ketamine may also be therapeutic for these patients, because the increase in bronchial secretions may decrease the incidence of mucous plugging.[21] Due to its cardiostimulatory effects, ketamine may be useful in the hemodynamically unstable patient. **Ketamine should not be used in those with suspected head trauma or intracranial pathology because it may increase ICP. It should not be used in patients with ischemic heart disease because it can increase blood pressure, heart rate, and myocardial oxygen demand.**

ADVERSE EFFECTS

The most significant side effect of ketamine is the occurrence of postanesthetic emergence reactions. Up to 30% of patients treated with ketamine have reported unpleasant sensations, agitation, hallucinations, restlessness, or nightmares.[2] Those most affected were elderly, females, and patients receiving more than 2 mg/kg. Children seem less adversely affected than adults. These reactions can be attenuated or eliminated by the coadministration of a benzodiazepine (midazolam) or propofol. Other side effects include hypersalivation, random movements, nystagmus, and increased intraocular and intracranial pressure. The hypersalivation may be limited by the administration of atropine or glycopyrrolate. Ketamine may activate epileptogenic foci in patients with a seizure disorder.[19]

PROPOFOL

Introduced in 1989, propofol (Diprivan™) is a sedative-hypnotic agent used for procedural sedation, induction, and maintenance of anesthesia. Although unrelated to any of the other induction agents, it has a profile similar to that of thiopental. Despite its cardiopulmonary depressant effects, the use of propofol has greatly expanded. It is well suited for ambulatory surgery performed on relatively healthy outpatients. Recovery after propofol anesthesia is rapid and is accompanied by less residual sedation, fatigue, and confusion than any other induction agent. Propofol is associated with a low incidence of postanesthetic emesis.[22] While the role of propofol as an adjunct to emergency airway management in the Emergency Department is still unfolding, it is commonly used for procedural sedation (Chapter 129) or postintubation sedation.

PHARMACOKINETICS

Propofol is an alkyl-phenol compound that is insoluble in water. It is 98% plasma protein bound. Since it is highly lipophilic, any unbound drug rapidly accumulates in the brain and liver. A single bolus produces hypnosis in as little as 15 to 45 seconds. Its duration of action, like that of thiopental, is 5 to 10 minutes and reflects a rapid redistribution to lean muscle mass. Propofol is cleared from the central compartment by hepatic metabolism. Its metabolites are water soluble and excreted in the urine.[2]

MECHANISM OF ACTION

Propofol produces CNS depression by modulating the $GABA_A$ receptor by the same mechanism as barbiturates.[2]

PHARMACODYNAMICS

Propofol produces a dose-dependent CNS depression without analgesia. It does have a strong amnestic effect. It decreases $CMRO_2$, CBF, and ICP. Since its cardiodepressant effects are greater than those of thiopental, CPP may be affected at high doses. Propofol is a myocardial depressant and potent vasodilator that lowers blood pressure and cardiac output. These effects attenuate the hemodynamic pressor response to laryngoscopy and intubation. Propofol blunts the baroreflex, so that the heart rate does not increase in proportion to a drop in blood pressure. Decreased respiratory rate and tidal volume are seen with propofol, and ventilatory response to hypercarbia is diminished. Propofol may produce bronchodilation in patients with chronic obstructive pulmonary disease (COPD).[23] Propofol appears to have a strong anticonvulsant effect and may be used to terminate status epilepticus.[24]

ADMINISTRATION

Propofol is prepared as a 1% oil-in-water emulsion that contains egg lecithin, soybean oil, glycerol, and EDTA. The adult dose for induction is 2.0 to 2.5 mg/kg IV. For sedation, an infusion rate of 25 to 75 μg/kg/min is titrated to effect. Dosages should be reduced to 1.0 to 1.5 mg/kg IV in the elderly, in high-risk patients, and in anyone premedicated with an opioid or a benzodiazepine.[23] Propofol supports bacterial growth, and any unused portion should be discarded.

ADVERSE EFFECTS

Propofol produces pain on injection in up to 75% of patients. This may be reduced or prevented by pretreatment with an opioid or the addition of 0.01% lidocaine to the emulsion. Propofol may cause mild CNS excitation in the form of myoclonus, tremors, or hiccups.[2]

BENZODIAZEPINES

Benzodiazepines are a large class of drugs with anxiolytic, sedative, hypnotic, and amnestic properties without any analgesic properties. Of these, diazepam (Valium™), lorazepam (Ativan™), and midazolam (Versed™) are most used to facilitate intubation. They have a relatively short time of onset when given intravenously. Compared to midazolam, diazepam and lorazepam have longer times of onset, less predictable dose–effect relationships, and longer elimination half-lives. They are also insoluble in water and are formulated in a propylene glycol diluent, which can produce a high rate of venous irritation as well as unpredictable absorption after intramuscular injection.[25] Midazolam, on the other hand, is water soluble at a low pH and therefore does not require propylene glycol. This decreases the incidence of erratic absorption after intramuscular injection and pain on injection.

Midazolam is the newest of the three drugs. It has become the standard choice for preinduction anxiolysis, sedation, and amnesia. Midazolam is well suited and widely used as an induction agent.[26] It may be administered alone or in combination with an opioid. There is considerable hypnotic synergy when midazolam is used in

combination with an opioid. The opioids provide excellent analgesia, which is a property lacking in midazolam.[2] When midazolam is used as the sole induction agent, recovery of consciousness takes longer than with thiopental, methohexital, etomidate, or propofol as a single agent. Midazolam is often used as a coinduction agent with ketamine or propofol, as it facilitates the onset of anesthesia without prolonging emergence times.[2] When combined with ketamine, midazolam attenuates ketamine's cardiostimulatory side effects as well as the incidence, severity, and recall of emergence reactions.[27]

PHARMACOKINETICS

Midazolam is formulated at a pH of 3.5, as it is water soluble in an acidic environment. At physiologic pH, it undergoes a molecular rearrangement that makes it highly lipophilic. It is 94% protein bound in the plasma. Unbound midazolam rapidly accumulates in the CNS, where it produces dose-dependent sedation or unconsciousness in 30 to 90 seconds. The drug redistributes less rapidly than many of the other hypnotics. This is reflected in the 10 to 30 minute duration of its CNS effects.[28] Midazolam is oxidized by the liver and excreted in the urine. Changes in hepatic blood flow can influence the clearance of midazolam.[29] Age has little effect on the elimination half-life.[29] Fentanyl has been shown to competitively inhibit the hepatic metabolism of midazolam in vitro and to decrease its clearance.[30]

MECHANISM OF ACTION

Benzodiazepines bind to a specific site on the alpha subunit of the $GABA_A$ receptor and enhance inhibitory neurotransmission. Midazolam has the greatest affinity for the receptor when compared to other benzodiazepines.[2] It has been proposed that the percentage of benzodiazepine receptor occupancy accounts for its effects. A 20% occupancy provides anxiolysis. A 30% to 50% occupancy causes sedation. Greater than 60% occupancy produces unconsciousness. It is unknown how the benzodiazepines produce amnesia.[2]

PHARMACODYNAMICS

Like thiopental and propofol, midazolam decreases $CMRO_2$ and CBF. Midazolam has a ceiling effect with respect to cerebral metabolism. The cerebrovascular response to carbon dioxide is unaffected by midazolam. It is also a potent anticonvulsant. Midazolam is a mild cardiodepressant and can decrease systemic vascular resistance.[28] The cardiac output and coronary blood flow are usually not affected by midazolam.[31] The drop in blood pressure is often masked by the sympathetic response to laryngoscopy. However, it may be pronounced in hypovolemic patients or in those who were given large doses.

Midazolam's respiratory effects also have a ceiling. It produces a mild and dose-dependent respiratory depression. In relatively healthy patients, the respiratory depression is insignificant. The respiratory depression is enhanced in patients with pulmonary disease. Hypoxemia is more frequent in patients who receive midazolam in combination with an opioid, such as fentanyl, than with either drug alone.[32]

ADMINISTRATION

An induction dose of midazolam is 0.2 to 0.4 mg/kg IV. When used as a coinduction agent, the dose of midazolam is reduced to 0.1 to 0.2 mg/kg. For sedation, the dose is 0.04 to 0.1 mg/kg IV. It can also be administered intramuscularly at a dose of 0.07 to 0.1 mg/kg when rapid onset is not required.[2] Doses may have to be lowered in older patients because sensitivity to the hypnotic effects of midazolam increases with age, independent of pharmacokinetic factors.[33]

ADVERSE EFFECTS

Midazolam has relatively few adverse effects. It is a mild cardiorespiratory depressant. When it is combined with an opioid, a synergistic respiratory depressant effect may result in hypoxemia, apnea, and death. Those patients receiving this combination should be monitored with pulse oximetry while being given supplemental oxygen.[32] Unlike diazepam, midazolam produces little venous irritation and pain upon injection. It may precipitate a psychotic episode in patients taking valproate. It does cross the placenta and is associated with birth defects, especially involving the lip and palate, when administered in the first trimester.[28]

OPIOIDS

Opioids produce dose-dependent analgesia, sedation, and respiratory depression by mimicking the effects of endogenous opiopeptins.[34] Morphine is the standard to which all opioids are compared. However, fentanyl (Sublimaze™) is the opioid of choice for use in the Emergency Department due to its rapid onset and short duration of action.[35] It has been in use since 1968 and its effects are well documented. **Unlike morphine, fentanyl is rarely associated with a significant release of histamine.**[36] Fentanyl has a remarkable hemodynamic stability profile.[36] If given in a large dose, fentanyl will produce anesthesia adequate for intubation. It is more often used as a sedative-analgesic or as a pretreatment adjuvant with one of the previously mentioned induction agents. Fentanyl is a synthetic opioid that is 50 to 100 times more potent than morphine. Structurally related to the phenylpiperidines, it is highly lipophilic and produces excellent short-term analgesia and sedation.[37]

Alfentanil (Alfenta™) is a structural derivative of fentanyl. It has a more rapid onset of action than fentanyl and half the duration of effect. Alfentanil is between one-sixth and one-ninth as potent as fentanyl. Its uses are analogous to those of fentanyl. It has been in use in the United States since 1982.[38] Recent data show alfentanil to be safe and effective for use in emergent rapid sequence intubation.[39] In cardiac patients, it was associated with a greater degree of cardiovascular depression than fentanyl.[40] Alfentanil is associated with a greater incidence of nausea and vomiting than fentanyl.[41] There are no data to suggest that alfentanil is more efficacious than fentanyl for use in the Emergency Department.

PHARMACOKINETICS

Upon intravenous injection, plasma fentanyl is 85% protein bound. Its lipophilic nature allows it to enter highly perfused tissues rapidly, including the brain, heart, and lungs. After a single bolus dose of fentanyl, effects may be seen in as little 10 seconds, and they peak in 3 to 5 minutes. Morphine's effects peak in 20 to 30 minutes. Fentanyl has a high affinity for adipose tissue and redistribution accounts for the cessation of effects, which can take up to 30 to 60 minutes. An equipotent dose of morphine has a duration of 3 to 4 hours. Redistribution of fentanyl from peripheral tissues to the central compartment after large or repeat doses may prolong its effects. Clearance of morphine and fentanyl is by hepatic metabolism. These drugs have a high extraction ratio, and changes in hepatic blood flow can influence the clearance of fentanyl.[38]

MECHANISM OF ACTION

Fentanyl binds to the μ (mu) opioid receptor found throughout the CNS. Activation of the opioid receptor causes hyperpolarization and inhibition of neurotransmitter release.[34] It has been suggested that fentanyl may also be a low-affinity NMDA receptor antagonist.[42]

PHARMACODYNAMICS

Fentanyl decreases CBF and cerebral oxygen consumption. In patients with head trauma, a relatively small dose (3 μg/kg) produced an elevation of ICP.[43] Although fentanyl has little effect on cardiac contractility, it may produce a mild reduction in the heart rate. Systemic vascular resistance and blood pressure may be slightly reduced, but they are usually unaffected in patients without cardiac pathology.[44] Respiratory depression induced by fentanyl is dose dependent. The respiratory rate first decreases, followed by the tidal volume and subsequent apnea. The patient's response to hypercarbia is blunted when sedated with fentanyl.[45]

ADMINISTRATION

Fentanyl can be used in several ways to facilitate emergency intubation. Given purely for analgesia, as little as 3 to 5 μg/kg IV over 2 minutes may allow for an awake intubation. For adults, incremental doses of fentanyl from 25 to 50 μg can be titrated to produce the desired effect.[37] Fentanyl has a more stable hemodynamic profile during rapid sequence induction than either thiopental or midazolam.[35] In hemodynamically unstable patients and those with poor cardiac reserve, 5 to 15 μg/kg of fentanyl may be used as the sole induction agent.[35]

The most prudent role for fentanyl is as an adjunct to an induction agent. Three minutes prior to intubation, premedication with 2 to 4 μg/kg of fentanyl IV over 2 minutes provides excellent analgesia and attenuates the transient hypertension and tachycardia associated with laryngoscopy and intubation.[46] Although lidocaine and β-blockers have also been shown to blunt the pressor response, opioids are more effective and reliable and do not produce rebound hypotension and bradycardia.[47,48]

ADVERSE EFFECTS

Other than the respiratory depression that is common to all opioids, fentanyl has relatively few adverse side effects. Although it may produce nausea and vomiting, this side effect is relatively uncommon when compared to other opioids such as morphine.[37] Fentanyl is not associated with a significant release of histamine, which is reflected in its hemodynamic stability. Muscular rigidity involving the chest wall and diaphragm may occur, making ventilation difficult. This happens more often at higher doses, typically greater than 15 μg/kg, and may be prevented or relieved by neuromuscular blockade or by opioid antagonism with naloxone.[49] Myoclonic movements may occur, but these do not reflect seizure activity on the EEG. As with all opioids, biliary colic and urinary retention are associated with fentanyl administration.[37]

NEUROMUSCULAR BLOCKING AGENTS

Neuromuscular blockade is an integral part of the rapid sequence induction and intubation protocol. The combination of a paralytic agent and a sedative or an analgesic is superior to the use of any single agent. The use of a neuromuscular blocking (NMB) agent to facilitate intubation provides for control of the airway and better visualization of the vocal cords than does sedation without paralysis.[50] It is also well documented that, in the Emergency Department setting, rapid sequence induction with an NMB agent allows for faster intubations with fewer complications than sedation alone.[1] **The use of a sedative without a NMB should be reserved for the awake oral intubation of a patient with a difficult airway.**

NMBs are classified as either depolarizing or nondepolarizing, depending on their action at the nicotinic acetylcholine receptor of the motor end plate. The optimal NMB agent has a rapid onset of action, a predictably short duration of action, and no side effects. As with induction agents, the optimal NMB agent has yet to be found. Until a better agent is developed, succinylcholine (Anectine™) remains the standard NMB agent for Emergency Department intubations.[51]

SUCCINYLCHOLINE

Succinylcholine is the only depolarizing NMB agent in clinical use. Introduced in 1952, it is a chemical combination of two acetylcholine molecules. **It is the most widely used NMB in the Emergency Department because its onset of action is faster and its duration of action is shorter than that of any other NMB agent. This is particularly important in patients who cannot be intubated after neuromuscular blockade and where the resumption of spontaneous respirations is vital.**

PHARMACOKINETICS

After a paralytic dose of succinylcholine, adequate intubating conditions are usually achieved in 60 seconds.[53] The duration of apnea following a single dose of succinylcholine is 3 to 5 minutes and reflects the rapid degradation of the drug by pseudocholinesterase, also known as plasma cholinesterase or butyrylcholinesterase.[53] Repeated doses or infusion of succinylcholine may produce tachyphylaxis, prolonged paralysis, and repolarization of the neuromuscular membrane, a condition referred to as phase II block.[53] If this condition develops, it can be partially reversed by administration of an anticholinesterase agent, similar to the reversal of a nondepolarizing block. **If paralysis of greater than 3 to 5 minutes is desired, a nondepolarizing agent can be administered after the patient is intubated.**

MECHANISM OF ACTION

The structure of succinylcholine allows it to bind noncompetitively to acetylcholine receptors, causing depolarization of the postjunctional neuromuscular membrane. This initial depolarization is seen as a brief period of muscle fasciculation following the administration of the drug. Unlike acetylcholine, which is hydrolyzed within milliseconds, succinylcholine remains intact for several minutes. It produces paralysis by occupying the acetylcholine receptors, and making the motor end plates refractory, so that muscle contraction cannot occur. Muscle relaxation proceeds from the distal muscles to the proximal muscles, and thus the diaphragm is one of the last muscles to become paralyzed.[52]

PHARMACODYNAMICS

Succinylcholine is rapidly hydrolyzed by plasma pseudocholinesterase to succinylmonocholine. Only a small fraction of the IV administered dose reaches the neuromuscular junction. Succinylmonocholine, which also has some neuromuscular blocking properties, is further hydrolyzed to succinic acid and choline. These end products are rapidly taken up by cells and reused in various biochemical molecules. The rapid degradation of succinylcholine provides a concentration gradient that causes the diffusion of succinylcholine away from the acetylcholine receptors and allows repolarization of the myocyte membrane.

In patients with atypical pseudocholinesterase enzyme, a genetic variant with autosomal semidominant transmission, the duration of action of succinylcholine is markedly prolonged due to decreased enzyme activity. In patients homozygous for the atypical allele, a condition that occurs with an incidence of 1 in 3200, a single intubating dose of succinylcholine may last up to 8 hours.[53]

ADMINISTRATION

The recommended dose of succinylcholine to produce optimal intubating conditions is 1.0 to 1.5 mg/kg IV bolus in adults and 1.5 to 2.0 mg/kg in infants, with the twofold increased dose in this

population explained by their higher volume of distribution.[53,83] This dose should be increased by 50% in patients who have received a defasciculating dose of a nondepolarizing neuromuscular blocker (see below under "Adverse Effects" section) prior to the administration of succinylcholine.[53] Intramuscular administration is also possible, which may become important for use in an emergency when control of the airway is necessary and the patient has no IV access. The intramuscular dose is two to four times the IV dose.[54]

ADVERSE EFFECTS

Although relatively uncommon, a number of potential adverse effects are associated with the administration of succinylcholine. These include muscular fasciculations and myalgia, autonomic stimulation, histamine release, prolonged apnea, elevated intracranial and intraocular pressure, hyperkalemia, and malignant hyperthermia.[53] **The use of succinylcholine is recommended for rapid sequence induction and intubation as the risk of a compromised airway far outweighs the potential harm from these side effects.**

The fine, chaotic muscle contractions that are often observed at the onset of paralysis are associated with several side effects, most commonly myalgia, but also increased intraocular pressure (IOP), increased intracranial pressure (ICP), and increased intragastric pressure. Muscle pain 24 to 48 hours after the administration of succinylcholine is most prominent in young, muscular men, while it is unlikely in children, the elderly, and those with undeveloped or diminished muscle mass. Muscle fasciculations may be prevented by the administration of a defasciculating dose (10% of the paralytic dose, a phenomenon known as "precurarization") of a nondepolarizing NMB agent given 3 to 5 minutes prior to the succinylcholine.[55]

Increased ICP may also occur with the use of succinylcholine. While the magnitude and clinical significance of this increase remains unclear, defasciculation with a nondepolarizing NMB agent has been shown to prevent this rise in ICP.[58]

To omit the use of a paralyzing agent entirely during the rapid sequence induction of patients with penetrating eye injuries or intracranial pathology for fear of the potential increase in IOP or ICP is a decision that must be made for each individual patient. Any attempt to intubate a nonparalyzed, lightly anesthetized patient could result in gagging or "bucking," which has been shown to increase both IOP and ICP far more than that which would be achieved from an intubating dose of succinylcholine. In most patients, muscle fasciculations are benign and precurarization is unnecessary. In patients with eye injuries or suspected intracranial pathology, however, it is prudent to either use a nondepolarizing NMB agent or utilize precurarization with succinylcholine to prevent worsening of an injury to these areas.[56] Rocuronium is a nondepolarizing agent that has been shown to significantly decrease IOP during rapid sequence induction.[57] Its use may be indicated in patients with penetrating eye injuries.[57]

Increased intragastric pressure, which is also lessened by precurarization, may increase the risk of aspiration. On the other hand, succinylcholine favorably increases the tone of the lower esophageal sphincter, which may mitigate the risk of aspiration.[59] Regurgitation of stomach contents during intubation is more likely the result of distention from overzealous mask ventilation.

Succinylcholine binds to acetylcholine receptors throughout the body, including those of the autonomic ganglia. Succinylcholine may have direct muscarinic effects on the heart. It is difficult to characterize a specific cardiovascular effect typical of succinylcholine. It may produce tachycardia, bradycardia, or dysrhythmias.[53] Children are particularly susceptible to bradycardia following succinylcholine administration. It is recommended that all children be given 0.01 mg/kg IV of atropine prior to administration of succinylcholine.[54]

Prolonged apnea following succinylcholine is a sign of decreased plasma pseudocholinesterase levels. This may occur in patients with hepatic disease, anemia, renal failure, cancer, connective tissue disorders, pregnancy, cocaine intoxication, genetically deficient enzyme activity, or taking cytotoxic drugs. In most cases, apnea rarely exceeds 20 minutes.[60]

Succinylcholine may produce an increase in serum potassium level, which is typically less than 0.5 meq/L. It should be used with caution in patients with significant hyperkalemia. Its use is not contraindicated in patients with renal failure, but caution must be taken if their serum potassium level is elevated. It has been associated with cases of massive hyperkalemia (>5 meq/L) and cardiac arrest in patients who have had digoxin toxicity, myasthenia gravis, massive muscle trauma, crush injuries, severe burns, and major nerve or spinal cord injury at least 1 week prior to receiving succinylcholine.[53] In such patients, succinylcholine should not be used starting 24 hours after the insult.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia (MH) is an extremely rare and life-threatening autosomal dominant condition that can develop following exposure to certain inhaled anesthetics and/or succinylcholine in genetically susceptible individuals. It is characterized by intense, sustained skeletal muscle contraction leading to severe acidosis, rhabdomyolysis, hyperthermia, hyperkalemia, arrhythmias and, if left untreated, death. The triggering exposure is not dose-dependent, can occur following any single dose or combination of offending agents, and may occur even in individuals who have been exposed to the agents in the past without an adverse effect. The incidence of MH during anesthesia is estimated to be 1 in 15,000 in children and 1 in 50,000 in adults.[82] **Although it is most notoriously characterized by a rapid elevation in temperature, the earliest signs of the condition are usually profound tachycardia, tachypnea, and generalized skeletal muscle rigidity.** Laboratory blood analysis reveals severe respiratory and metabolic acidosis, hyperkalemia, and elevation of serum creatine kinase.

Early and aggressive treatment is the key to patient survival. This involves active cooling measures, volume resuscitation, correction of acid–base and electrolyte disturbances, and rapid administration of dantrolene (2 to 3 mg/kg IV bolus with additional increments up to 10 mg/kg).[53,82] Dantrolene sodium is a muscle relaxant that is supplied as a lyophilized powder in 20 mg vials. Prior to administration, each vial must be reconstituted with 60 mL of water.[82] **It is emphasized that rapid and early administration of dantrolene is important to abort the reaction and greatly increases the chance of survival.** Dantrolene administration should be continued until all signs of MH have stabilized. Admit the patient to the intensive care unit for observation of any recurrence following the acute phase.

Isolated masseter muscle rigidity is a benign side effect in most cases. It has been reported mainly in children receiving succinylcholine. In several reported cases of fatal malignant hyperthermia, however, masseter muscle rigidity was the first sign of an abnormal reaction.[61] **Masseter rigidity occur following the administration of succinylcholine requires the patient to be closely monitored for other signs of MH.**

Patients of families with MH, those with suspected reactions, and other selected high-risk patients can undergo a muscle biopsy test known as the caffeine-halothane contracture test, which carries a 100% sensitivity and 85% to 90% specificity for MH susceptibility.[82] Patients who develop suspected MH reactions should be referred immediately to their primary physicians for testing and follow-up, as documented positive susceptibility and patient education could prevent a future potentially lethal exposure to offending agents.

Despite the lengthy list of potential adverse effects, the benefits of intubation with a rapidly acting and short-lasting paralytic agent such as succinylcholine provide the safest conditions for

intubation in the Emergency Department. If prolonged paralysis is required in an agitated patient, a nondepolarizing agent should be administered for maintenance following intubation with succinylcholine.

NONDEPOLARIZING AGENTS

Nondepolarizing NMB agents act by competitive inhibition of the acetylcholine receptors at the motor end plate. They weakly bind to the receptor and block the binding site for acetylcholine without producing any effect on the postsynaptic neuromuscular membrane. Following the kinetics of competitive inhibition, this blockade is dependent on the relative concentrations of acetylcholine and NMB available in the synaptic cleft. As the ratio returns in favor of acetylcholine, normal neuromuscular transmission is restored. Thus, return of muscle function can be hastened by the use of a cholinesterase inhibitor such as neostigmine or edrophonium, but only after some muscular contraction can be observed. Nondepolarizing agents have not only the potential for reversal, but also for fewer side effects than succinylcholine. Their longer time to onset and much longer duration of action make them less useful for rapid sequence induction, especially in the Emergency Department.[53]

Nondepolarizing NMB agents can be grouped by chemical structure. The steroid-based agents include pancuronium, vecuronium, and rocuronium. The oldest nondepolarizing agent, d-tubocurarine, is a benzylisoquinoline, as are atracurium, cisatracurium, and mivacurium.[53] Pancuronium, vecuronium, and rocuronium have been extensively studied for use in rapid sequence intubation.[62] Of these, rocuronium (Zemuron™) has become established as the nondepolarizing NMB of choice for rapid sequence induction in situations where succinylcholine is contraindicated. For this reason, rocuronium is discussed separately from the other nondepolarizing NMB agents.

ROCURONIUM

When succinylcholine is contraindicated, rocuronium has been used at a dose of 1.2 mg/kg. This dose is twice the standard intubating dose to yield an onset of action in approximately 60 seconds and intubating conditions that are comparable to succinylcholine.[72] This has been demonstrated both in adult and pediatric populations.[72,84] It should be noted, however, that at this increased dosage, the duration of action is also prolonged to greater than 1 hour, which far exceeds the 3 to 5 minutes provided by succinylcholine.[53,63] The nondepolarizing, competitive blockade produced by rocuronium cannot be immediately reversed by anticholinesterases such as neostigmine until a partial competitive antagonism by acetylcholine has taken place naturally at the motor end plate. This may take an average of 20 minutes to occur, and must be measured by the return of muscular twitch using a neuromuscular twitch monitor, a device often used by anesthesia personnel in the operating room to monitor the level of intraoperative motor blockade.[84] Therefore, should unexpected difficulties with intubation or ventilation be encountered, it is recommended that the practice of using high-dose rocuronium during rapid sequence induction be limited in the Emergency Department as much as possible. Should all attempts at intubation and ventilation fail, staff experienced in the attainment of a surgical airway must be immediately available.

PHARMACOKINETICS

Rocuronium is eliminated primarily by the liver and <10% by the kidneys.[53] Its duration of action, therefore, is significantly prolonged in liver failure and only slightly in renal failure. There are no active metabolites, making it a good choice for prolonged infusions. Nondepolarizing NMB agents as a class are highly ionized, water-soluble compounds that cannot easily cross lipid membranes such as the blood–brain barrier and the placenta. As a result, they have no central nervous system effects and do not affect the fetus when administered to pregnant women.[53]

MECHANISM OF ACTION

Rocuronium binds nicotinic acetylcholine receptors at the neuromuscular end plate and, once bound, it is unable to induce the conformational change necessary to open the ion channels and allow subsequent depolarization. This results in a competitive and antagonistic block.

PHARMACODYNAMICS

Several drugs including volatile anesthetics, aminoglycosides, magnesium, lithium, dantrolene, and certain antiarrhythmics will augment the neuromuscular blockade produced by nondepolarizers. In contrast, corticosteroids, certain anticonvulsants, and calcium will diminish their effect. Patients with myasthenia gravis, Lambert–Eaton myasthenic syndrome, and Duchenne's muscular dystrophy exhibit varying sensitivity to nondepolarizing neuromuscular blockers. Burn patients, on the other hand, are resistant to their effects. Careful titration of dosages, dosing intervals, and infusion rates are necessary in these patient populations.

ADMINISTRATION

Rocuronium is administered at a usual intubating dose of 0.6 mg/kg, providing a clinical duration of roughly 45 minutes. Rapid sequence induction with rocuronium is most rapidly achieved with a dose of 1.2 mg/kg and is associated with an accompanying increase in duration. Following intubation, maintenance of paralysis can be achieved with intermittent 0.1 mg/kg boluses or by infusion rates of 5 to 12 mcg/kg/min, titrated to effect.

ADVERSE EFFECTS

Other than the potential for a severe anaphylactic reaction in allergic patients, rocuronium is essentially devoid of any serious side effects. This should not be taken lightly, however, as neuromuscular blocking drugs are responsible for >50% of all life-threatening anaphylactic or anaphylactoid reactions occurring during anesthesia administration.[53] While succinylcholine is the most common offending agent, the nondepolarizers are the second.

As a class, the steroidal nondepolarizers possess varying degrees of vagolytic activity and, fortunately, are not associated with histamine release. The vagolytic action of rocuronium is weak and rarely of clinical significance. This is in contrast to pancuronium, another steroidal nondepolarizer, which can cause significant tachycardia following administration. Patients may report pain on injection of rocuronium due to venous irritation. This may be reduced by prior administration of IV lidocaine, but is usually not a problem as patients are unconscious or sedated at the time of rocuronium injection.

OTHER NONDEPOLARIZING AGENTS

Pancuronium, in use since 1972, is classified as a long-acting, bisquaternary steroidal nondepolarizing agent. At a dose of 0.08 to 0.12 mg/kg, it produces paralysis in 2 to 5 minutes and lasts approximately 60 to 90 minutes. Following intubation, supplemental doses of 0.02 mg/kg can be given intermittently to maintain paralysis.[53] Its use is associated with an increased heart rate, blood pressure, and cardiac output through a postganglionic vagolytic effect. It is not associated with the release of histamine. An estimated 80% to 85% of a dose of pancuronium is eliminated unchanged in the urine. Therefore, in patients with renal failure its duration may be significantly prolonged.[53] Pancuronium's low cost and familiarity have

made it popular, but its slow onset of action and extended duration limit its usefulness in facilitating emergent endotracheal intubation.

Removing a quaternary methyl group from pancuronium yields vecuronium, a monoquaternary steroidal nondepolarizer. This small change does little to affect potency, but favorably alters the side effect profile of the drug, most notably the vagolytic action. Similar to rocuronium, the vagolytic effects of vecuronium are negligible and do not cause histamine release. This molecular change also alters the metabolism and excretion of the drug when compared with pancuronium. Vecuronium is metabolized to a small extent by the liver and depends primarily on biliary excretion and secondarily on renal excretion. Vecuronium is unstable in solution. It is prepared as a lyophilized powder that must be hydrated prior to use.

The normal intubating dose of vecuronium (0.1 mg/kg) takes 3 minutes to produce adequate paralysis for intubation, and the patient will remain apneic for 30 to 35 minutes. Although it can produce good intubating conditions within 1 minute at 2.5 times the normal dose, this unfortunately results in paralysis for 1 to 2 hours. Maintenance of paralysis can be achieved with boluses of 0.02 mg/kg. The most troublesome side effect of this drug is prolonged paralysis (up to several days) following an infusion, a side effect attributed possibly to accumulation of its active 3-hydroxy metabolite.[53]

Rapacuronium is a newer nondepolarizing NMB agent with onset times and duration of action similar to those of succinylcholine. It was developed as a replacement for succinylcholine in the rapid sequence protocol. Due to reported incidences of fatal bronchospasm in patients, rapacuronium was voluntarily withdrawn from the US market by its manufacturer in March, 2001. At present, succinylcholine is firmly in place as the muscle relaxant of choice for rapid sequence emergency intubations.[64]

MISCELLANEOUS AGENTS

LIDOCAINE

Lidocaine is a local anesthetic agent that, in low doses, has an antiarrhythmic effect on the heart. At a dose of 1 to 2 mg/kg IV, it also attenuates the increase in ICP and the hypertensive and tachycardic response associated with laryngoscopy.[65–68] It does not affect myocardial contractility in therapeutic doses. Lidocaine is usually administered to patients in which the increases in ICP, heart rate, and blood pressure associated with direct laryngoscopy are undesirable.

ATROPINE

Atropine is a rapidly acting muscarinic acetylcholine receptor antagonist with significant vagolytic effect. It is commonly used as part of the Advanced Cardiac Life Support (ACLS) protocol during resuscitation of patients in cardiac arrest and those with symptomatic bradycardia at doses of 1.0 mg and 0.50 mg IV, respectively. During rapid sequence induction of children using succinylcholine, atropine is given to prevent significant bradycardia and possibly asystole, which may occur in this population much more frequently than in adults.[73] The dose is 0.01 mg/kg IV with a minimum dose of 0.10 mg IV and a maximum dose of 0.40 mg IV. Atropine has a secondary antisialagogue effect of reducing secretions produced in the respiratory tract and the salivary glands.

Atropine crosses the blood–brain barrier and overdoses may lead to central atropine intoxication, referred to as the central anticholinergic syndrome. This is characterized by agitation, restlessness, confusion, and hallucinations that may progress to stupor, seizures, and coma. Provide supportive treatment, including seizure prophylaxis and possibly mechanical ventilation. Reversal of this life-threatening condition can be achieved with IV physostigmine, an anticholinesterase agent with the ability to cross the blood–brain barrier.

GLYCOPYRROLATE

Glycopyrrolate is a quaternary amine of the muscarinic anticholinergic class. Compared to atropine, it possesses significantly less of a vagolytic effect, but greater antisialagogue effects. This makes it the drug of choice for premedication to reduce pharyngeal and tracheobronchial secretions. Glycopyrrolate does not easily cross the blood–brain barrier due to its quaternary ammonium structure, making the occurrence of central anticholinergic side effects much less likely. It should not be administered to neonates due to the benzyl alcohol component, which can cause significant adverse effects. The recommended antisialagogue dose of glycopyrrolate is 0.004 mg/kg IM given 30 to 60 minutes prior to the procedure. It may be administered intravenously in boluses of 0.1 mg every 2 to 3 minutes as needed until the desired effect. In the Emergency Department, one or two doses are typically required during procedural sedation as an adjunct to prevent ketamine's effect of increasing respiratory tract secretions.

Glycopyrrolate is routinely administered with anticholinesterase medications during reversal of nondepolarizing neuromuscular blockade to counteract the unwanted side effects of bradycardia, bronchoconstriction, and intestinal hypermotility that accompany the ensuing increase in cholinergic activity. Specifically, it is administered along with neostigmine and pyridostigmine at a dose of 0.2 mg IV of glycopyrrolate for each 1 mg of neostigmine or 5 mg of pyridostigmine. When given IV, the onset is usually within 1 minute and the duration of the vagolytic and antisialagogue effects are 2 to 3 hours and up to 7 hours, respectively.

DEXMEDETOMIDINE

Dexmedetomidine is a new centrally acting alpha$_2$-adrenergic agonist similar to clonidine, but with more selectivity for the alpha$_2$ receptor. It causes dose-dependent sedation and anxiolysis and blocks the sympathetic response to stress and airway manipulation. For this reason, it is increasingly being used with much success as an adjunct to awake fiberoptic intubations. Its main indication, however, is for sedation of intubated and mechanically ventilated patients in the intensive care unit, especially around the time of planned extubation when other IV sedatives have been discontinued. Patients remain calm and sedated when left alone, but are readily arousable when stimulated and follow commands. Dexmedetomidine causes little to no respiratory depression.[70,71] The main side effects of the drug are hypotension and bradycardia. Dosing consists of an initial loading dose of 1 mcg/kg IV over 10 minutes followed by an infusion of 0.2 to 0.7 mcg/kg/h, titrated to the desired level of sedation.[69] Its half-life is about 6 minutes following infusion due to rapid redistribution. This short half-life has the potential for its use in the Emergency Department for awake intubations.

SUGAMMADEX

Sugammadex (Bridion™, Schering-Plough) is a novel agent that can terminate the neuromuscular block associated with rocuronium, vecuronium, and pancuronium.[85–91] It is a cyclodextrin, or a cyclic oligosaccharide carbohydrate, that is formed from the degradation of starch. It has a hydrophobic core surrounded by a hydrophilic outer rim. The hydrophobic core can trap other hydrophobic substances and solubilize them. Cyclodextrins administered intravenously are not metabolized and are excreted by the kidney.

Sugammadex is the first agent of its class. It has an affinity for the aminosteroid nondepolarizing NMB agents. Its affinity is strongest for rocuronium, followed by vecuronium then pancuronium. It binds rocuronium in a 1:1 fashion to decrease rocuronium plasma concentrations. Bound rocuronium cannot gain access to the motor endplate and cause paralysis. The reversal of the neuromuscular

block results from the binding of plasma rocuronium and the rapid movement of rocuronium from peripheral sites to the plasma to maintain an equilibrium. The sugammadex–rocuronium complex is excreted in the urine.

A variety of adverse events have been reported with the use of sugammadex.[86] These include anaphylactic reactions, back pain, bronchospasm, cough, constipation, fever, headache, hypersensitivity reactions, procedural hypotension and hypertension, prolonged QT intervals, and vomiting. It binds to bone and teeth, but the effect of this is not fully known, especially in growing children. There is the possibility that sugammadex binds to and decreases plasma levels of other drugs with a steroid-based structure such as hormones, oral contraceptives, and some antibiotics among others.

Sugammadex has the potential for significant use in the Emergency Department. The biggest concern with using rocuronium for intubation is the length of time a patient is paralyzed if they cannot be intubated. The development of sugammadex can provide a "safety net" to reverse rocuronium's effects if a patient cannot be intubated. This agent may eventually allow rocuronium to become the NMB agent of choice for rapid sequence intubation in the Emergency Department.[88,89]

Sugammadex is currently approved for use in numerous countries. Unfortunately, it is not available in the United States.[92] After an expedited review, the FDA's Anesthetic and Life Support Advisory Committee unanimously recommended approval of sugammadex in March 2008.[86] In August 2008, the FDA rejected approving this drug due to concerns regarding allergic reactions, hypersensitivity reactions, and anaphylactic reactions. At the time of this writing, sugammadex is still not approved by the FDA. Research is continuing on this drug with the hope of FDA approval in the near future.

SUMMARY

Numerous pharmacologic agents are available to sedate, relax, and paralyze a patient in preparation for intubation. These same agents are used in lesser doses to maintain postintubation sedation and paralysis as well as for procedural sedation. There is no ideal sedative or paralytic agent. The combination of lesser doses of several agents, depending on the patient's condition, will maximize the positive effects and minimize the adverse effects of each individual drug. This requires Emergency Physicians to become familiar with several drugs in each class, so that they may choose the appropriate combination for each patient.

9 Endotracheal Medication Administration

Shoma Desai

INTRODUCTION

Healthcare providers are charged with the primary goal of optimizing the oxygenation, ventilation, and the hemodynamic status of the patient during a resuscitation. In most cases, the first definitive intervention is to secure the airway through endotracheal (ET) intubation. The establishment of access to the systemic circulation soon follows. **Vascular access in certain patients can be problematic. In such cases, the ability to administer medications endotracheally can be life saving.**

Bernard first reported the ET route of medication administration in 1857, describing the alveolar absorption of curare in dogs. This discovery was followed by the observation that ET instilled salicylates appeared in the urine (Peiper 1884). In 1897, Washitzky studied the ET application of strychnine, atropine, chloral hydrate, and potassium iodide.[1]

The first suggestion for using the ET route for the therapy of pulmonary disease was in 1915.[2] This idea evolved, culminating in a study in 1937, which recommended the use of inhaled epinephrine in asthmatics.[3] The rapidity of pulmonary absorption was eventually utilized for resuscitation purposes 1967. This study demonstrated the equality of the intratracheal, intravenous (IV), and intracardiac routes of epinephrine administration in resuscitating hypoxia-induced cardiorespiratory arrest in dogs. This study began the utilization of the ET route for medication administration in emergent clinical situations.

ANATOMY AND PATHOPHYSIOLOGY

Most experiments involving ET medication administration are conducted on subjects with normal cardiovascular function. Thus, there are still many questions remaining about the utility of this route in patients with cardiopulmonary arrest. While the alveolar-capillary membrane is a highly absorptive surface, numerous factors can undermine this potential. These include reduced pulmonary blood flow (less than 30% of normal during CPR), ventilation–perfusion mismatch, and compromised alveolar absorption (e.g., pulmonary edema and pneumonia) in cardiopulmonary arrest.[5–7]

During a cardiopulmonary arrest, ET administered medications are absorbed in a protracted manner. This phenomenon, termed the "depot effect", is observed in laboratory and clinical experiments.[5] Studying ET administered lidocaine (2 mg/kg) in nonarrest patients revealed a biphasic pattern of absorption, an initial immediate peak, and a second higher peak approximately 24 minutes later.[8] Plasma lidocaine levels were still measurable 120 minutes postinstillation.[8] In addition to the altered physiologic conditions of cardiopulmonary arrest as described above, local vasoconstriction induced by epinephrine may contribute to this "depot effect."[9] The relatively low initial plasma medication levels and then the subsequent extended plateau of plasma medication levels are also exhibited by the ET administration of atropine, epinephrine, and vasopressin.[5,10]

MEDICATION DOSE

The American Heart Association (AHA) suggests an ET medication dose of 2 to 2.5 times the recommended IV dose (Table 9-1).[11] The optimal dose of ET administered medications is unknown. While there is a consensus that IV doses given endotracheally result in subtherapeutic plasma levels, the equipotent dose ranges from 3 to 10 times the IV dose in the literature.[12–42]

Many studies have noted the inadequacy of the currently recommended dose of epinephrine and atropine in cardiopulmonary arrest models.[27,31,36] Niemann and Stratton retrospectively reviewed 136 adult medical arrests, both primary and secondary asystole, with less than 10 minutes to definitive care. The rates of response (positive rhythm) and return of spontaneous circulation were significantly greater in the IV medication group than both the ET medication group and the no therapy group.[27]

TABLE 9-1 Recommended Endotracheal Medication Doses[2,11]

Medication	Adults	Pediatrics	Neonates
Atropine	2–2.5 mg	0.03 mg/kg	Unknown
Epinephrine	2–3 mg (1:10,000)	0.1 mg/kg (1:1000) (or 0.1 mL/kg)	0.01–0.03 mg/kg (1:10,000)
Lidocaine	2–3 mg/kg	2–3 mg/kg	Unknown
Naloxone	0.8–2 mg	<5 y or ≤ 20 kg: 0.1 mg/kg ≥5 y or >20 kg: 2 mg	0.1 mg/kg
Vasopressin	80 units	Unknown	Unknown

A recent discussion in the literature has drawn attention to the behavior of epinephrine when given at suboptimal doses. Epinephrine is used in arrest situations for its α-adrenergic effects. The β-adrenergic effects predominate when epinephrine is administered in small doses. This can transiently result in potentially harmful hypotension, decreased coronary perfusion pressure, and the diminished likelihood of return of spontaneous circulation.[11] Manisterski et al. documented an early drop in mean arterial blood pressure with prolonged tachycardia after ET epinephrine at doses of 0.02, 0.035, 0.1, and 0.2 mg/kg in healthy dogs.[28] Only the 0.3 mg/kg dose was effective in achieving an increase in blood pressure without a transient drop.[28] Findings such as this have prompted investigations on pretreatment with β-blockers (e.g., propranolol) prior to ET epinephrine administration, which does blunt the early β-effects.[29,30] Although more research is needed in this area, these studies do question the efficacy of the current recommended ET epinephrine dose, calling for higher ET doses.

Despite these results, concerns regarding the "depot effect" have kept the current ET medication dose recommendation at 2 to 2.5 times the IV dose. This is to avoid the prolonged side effects in the critical postresuscitation period.[5] This compromise leads to many uncertainties regarding the effectiveness and reliability of the ET route for medication administration.[9,31,32]

DILUENT

A primary goal in administering ET medications is to achieve rapid absorption. This goal can be reached with larger volumes of diluent, but is tempered by the potentially detrimental effects on pulmonary function.[4] **The current recommended volumes for ET instillation of each medication are dilution to a total volume of 10 mL in adults, 5 mL for children, and 1 mL for neonates.**[11,26]

Another controversy arises with respect to the type of diluent used. Distilled water and 0.9% saline have been utilized for ET medication administration and are currently recommended by the AHA.[11] In theory, water creates a greater osmotic gradient to potentially speed up medication absorption. This could also lead to a greater disruption of pulmonary surfactant, thereby hindering gas exchange.[5] This has been confirmed in nonarrest experiments using dogs.[33] It was later disputed utilizing much smaller volumes (2 and 10 mL) of instilled medication.[34,35] These studies found that distilled water provides more rapid and more effective absorption (higher peak serum medication levels) than 0.9% saline without a physiologically significant drop in PaO_2.

PEDIATRIC CONSIDERATIONS

Much of the debate regarding ET medication administration still exists in pediatrics. While approximately half of pediatric arrests are resuscitated without the use of medications, resuscitation drugs may be required to achieve return of spontaneous circulation. Obtaining vascular access in children, especially in neonates, can be extremely difficult. This makes the ET medication administration route a possible option for early resuscitative efforts.[37] There are no published pediatric or neonatal studies examining the type or volume of diluent, only consensus recommendations.[11,26]

A major difference between adults and children in arrest is the absorptive capacity of the immature lung. In particular, the surface area is smaller, the diffusion coefficient is larger, and there exists the potential for right to left shunts in children.[9,38] These conditions greatly affect an already unreliable absorptive process.

The indications, procedures, and complications are considered to be much the same in pediatrics as in adults. There are very few published studies focused on ET medication administration in pediatrics. Those that studied epinephrine in pediatric arrest agree that it seems to take 10 times the IV medication dose to achieve appropriate serum epinephrine levels and responses in the heart rate and blood pressure.[26,38,39] A retrospective study of neonates who received epinephrine in the delivery room underscores the difficulty of obtaining vascular access.[40] Almost all the neonates (94%, $n = 52$) received their first dose of epinephrine via the ET route. Of these, 32% obtained return of spontaneous circulation while the rest required additional epinephrine through their IV line once it was established. The authors concluded that the currently recommended ET epinephrine dose of 0.01 to 0.03 mg/kg is ineffective.

INDICATIONS

The ET administration of medications is reserved for resuscitations in which vascular access (i.e., IV or intraosseous (IO)) is delayed.[11] This may apply to the resuscitation of any patient with cardiovascular collapse. The ET route may be more frequently encountered in certain patient populations traditionally associated with difficult vascular access such as neonates, the obese, cancer patients, sickle cell patients, IV drug abusers, burn patients, and dialysis patients.[12] **The goal is to increase the probability of successful resuscitation despite a delay in obtaining definitive systemic vascular access.**

The ET route is recommended for the administration of lidocaine, epinephrine, atropine, naloxone, and vasopressin.[11] Other medications that can be administered but are not widely used include flumazenil, diazepam, midazolam, penicillins, sulfonamides, and aminoglycosides.[13–17]

CONTRAINDICATIONS

The absorption of medications given through an ET tube is unpredictable during a cardiopulmonary arrest. The only contraindication to ET medication administration is the patient having IV or IO access. The ET route may be used initially until IV or IO access is established.

EQUIPMENT

- ET tube, standard or specialty ET tube
- Bag-valve device
- Medication to be administered
- Diluent, 0.9% normal saline or distilled water
- 10 mL syringe
- 18 gauge needle
- IV adapter lock
- Water-soluble lubricant
- Optional catheters (suction, feeding, or central venous)

The patient may be intubated with a standard ET tube, an ET tube with a monitoring lumen, or a specialty ET tube with a medication injection port.[18] The EDGAR ET tube (endobronchial drug and gas application during resuscitation, Rusch, Germany) has a separate injection channel that terminates at the tip of the ET tube. This ET tube is currently available in Europe, but not in the United States. The Stat-Med ET tube (Hudson RCI, Temecula, CA) has a separate injection port and channel that terminates distal to the inflated cuff (**Figure 9-1**). These two ET tubes allow the ET administration of medications without interrupting CPR compressions or ventilation.

The LITA ET tube (Hudson RCI, Temecula, CA) is a modification of the Stat-Med ET tube. Like the Stat-Med, it has a separate injection port and channel. The channel has eight openings above the cuff and two below the cuff. This ET tube was designed for use with local anesthetic solutions to anesthetize the tracheal mucosa. It should not be used to administer resuscitation medications. They will mostly pool above the cuff in the trachea and not get properly absorbed.

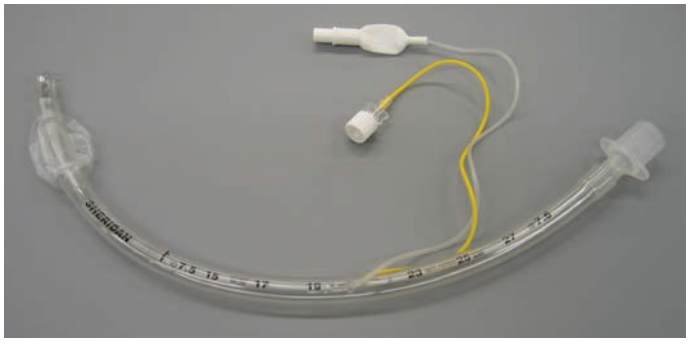

FIGURE 9-1. The Stat-Med tube (Hudson RCI, Temecula, CA).

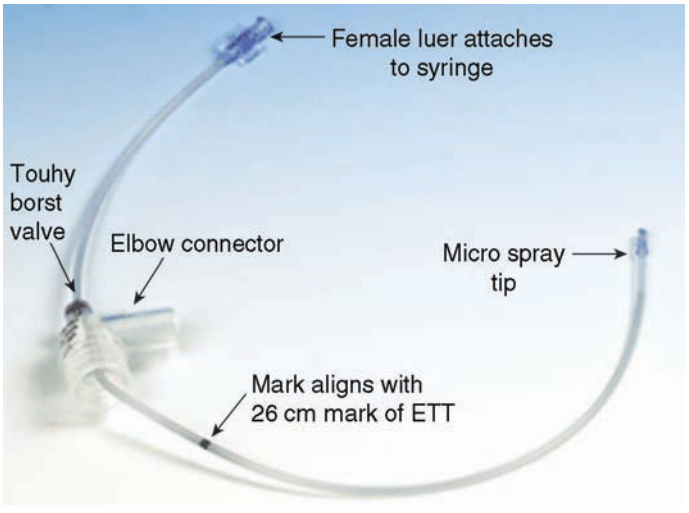

FIGURE 9-2. The MADett™ (Wolfe Tory Medical, Salt Lake City, UT).

Other, optional, equipment may be used depending on the technique used to administer the medications. A catheter may be used to administer the medication. A suction, feeding, or central venous catheter may be introduced into the ET tube to administer medications more distally. An IV adapter lock is required on the proximal end of these catheters to allow the syringe to attach to the catheter. There are no formal guidelines regarding proper catheter size. There are recommendations to use a 16 French (Fr) suction catheter in adults,[19] an 8 Fr feeding catheter in children,[20] and a 5 Fr feeding catheter in neonates.[21]

The administration of drugs through laryngeal mask airways (LMAs, Chapter 19) and combitubes (Chapter 20) as compared with ET tubes has been studied. Medication instilled through a catheter inserted through an LMA and into the trachea achieved the equivalent blood concentrations as through an ET tube.[43] Unfortunately, it is often difficult to successfully pass a catheter through an LMA and into the trachea.[22] Administration of lidocaine through LMAs was unreliable (4 out of 10 reached therapeutic plasma levels) as compared with ET tubes (10 out of 10 reached therapeutic plasma levels) in nonarrest patients.[22] Subtherapeutic plasma medication levels were noted when comparing lidocaine administration via combitubes (placed in the esophagus) versus ET tubes.[23]

The intubating LMA (ILMA) is a modification of an LMA. It is designed to allow the blind passage of an ET tube through it and into the trachea. Insertion of a catheter through an ILMA was only successful in 92% of the attempts.[44] It also required a mean time of 20 seconds (range 11–44 seconds), which is too long by AHA guidelines to discontinue CPR.[11]

An interesting device is the MADett™ or mucosal atomizer device (Wolfe Tory Medical, Salt Lake City, UT, **Figure 9-2**). This device allows ET medication administration without stopping compressions and ventilations of CPR, and no splash back into the face of the person administering the medication. The MADett™ must be used only with an ET tube size greater or equal to 7.0 mm inner diameter and a length of at least 28 cm.

TECHNIQUES

PROXIMAL MEDICATION INSTILLATION

The simplest method for ET medication administration is direct instillation. Prepare the medication or use a prefilled syringe with a needleless adapter. If drawing your own medications, use a syringe with an 18 gauge needle to draw up the medication into the syringe. Draw up sterile water or 0.9% normal saline to dilute the medication to the appropriate volume. Remove the bag-valve-mask device from the ET tube. Briefly interrupt external chest compressions. Remove the 18 gauge needle from the syringe. Inject the diluted medication in the syringe or from the prefilled syringe into the proximal end of the ET tube. Replace the bag-valve-mask device and manually ventilate five times in quick succession. The forced hyperventilation results in bilateral and distal distribution of the medication.[12] Resume chest compressions.

Always remove the needle from the syringe when injecting medication into the ET tube. Some medical personnel may choose to leave the needle attached to the syringe for convenience or to decrease any delays in medication administration. The needle, if loose, can fall off the syringe and into the ET tube. It will then "ride the tube" and can become an airway foreign body in the distal trachea or main bronchus. The needle also slows down medication injection into the ET tube, delaying restarting CPR.

PROXIMAL NEEDLE INJECTION OF MEDICATION INTO THE ET TUBE

An alternative approach is to piercing the proximal end of the ET tube with an 18 gauge needle attached to the medication-filled syringe.[24] Care must be taken to assure that the needle does not damage the ET cuff inflation tube and the tip of the needle is completely within the lumen of the ET tube. Instill the medication during inspiration, when the bag is squeezed. Detach the syringe from the needle. Attach a new medication-filled syringe or refill the used syringe to instill other medications without removing the needle from the ET tube. The remaining hole in the ET tube after the resuscitation and the needle is removed results in a negligible air leak that may be closed with a piece of tape.

DISTAL MEDICATION INSTILLATION

Medications may be administered deeper through a catheter inserted into the ET tube. This technique minimizes medication adherence to the walls of the ET tube. Prepare the medication and catheter. Draw up the appropriate medication and diluent into a syringe or use a prefilled syringe. Choose the appropriate type and size of catheter. Attach an IV adapter lock to the proximal end of the catheter. The proximal end of the catheter may have to be cut off if it is flared, tapered, or too big for the IV adapter lock to fit.[25] After cutting the proximal end, attach the IV adapter lock.

Remove the bag-valve-mask device from the ET tube. Briefly interrupt external chest compressions. Lightly lubricate the catheter with a water-soluble lubricant, so that it will advance easily through the ET tube. Insert the catheter (feeding, venous, and suction) into the ET tube until its tip extends just beyond the distal end of the

ET tube by approximately 1 to 2 cm. Attach the medication-filled syringe to the IV catheter lock if using a feeding or suction tube, or the leur lock if using a central venous catheter. Inject the medication into the catheter followed by 5 mL of air to clear the tube of any residual medication. Replace the bag-valve-mask device and manually ventilate five times in quick succession. The forced hyperventilation results in bilateral and distal distribution of the medication.[12] Resume chest compressions.

TECHNIQUES TO MINIMIZE INTERRUPTION OF VENTILATIONS AND COMPRESSIONS

The goal of CPR is to minimize interruptions of chest compression and ventilation. This can be accomplished using one of the specialized ET tubes discussed in the "Equipment" section of this chapter. These ET tubes may be placed initially in a patient with a cardiopulmonary arrest. If a standard ET tube is initially placed, it can be exchanged for one of these specialized ET tubes. Prepare the medication. Attach the medication-filled syringe to the injection port of the ET tube. Inject the medication into the ET tube injection port during inspiration with the bag-valve-mask device. The diluted drug solution may be followed by the injection of 5 mL of air to clear the tube of any residual medication.

An alternative to using these specialty ET tubes is to attach the MADett™ to a standard ET tube. The MADett™ is quick, simple, and easy to use (**Figure 9-3**). The patient should already be intubated. Stop ventilations, but not compressions, and remove the bag-valve device from the ET tube. Attach the MADett™ adapter onto the ET tube (**Figure 9-3A**). Resume ventilations by attaching the bag-valve device to the side port of the adapter. Advance the

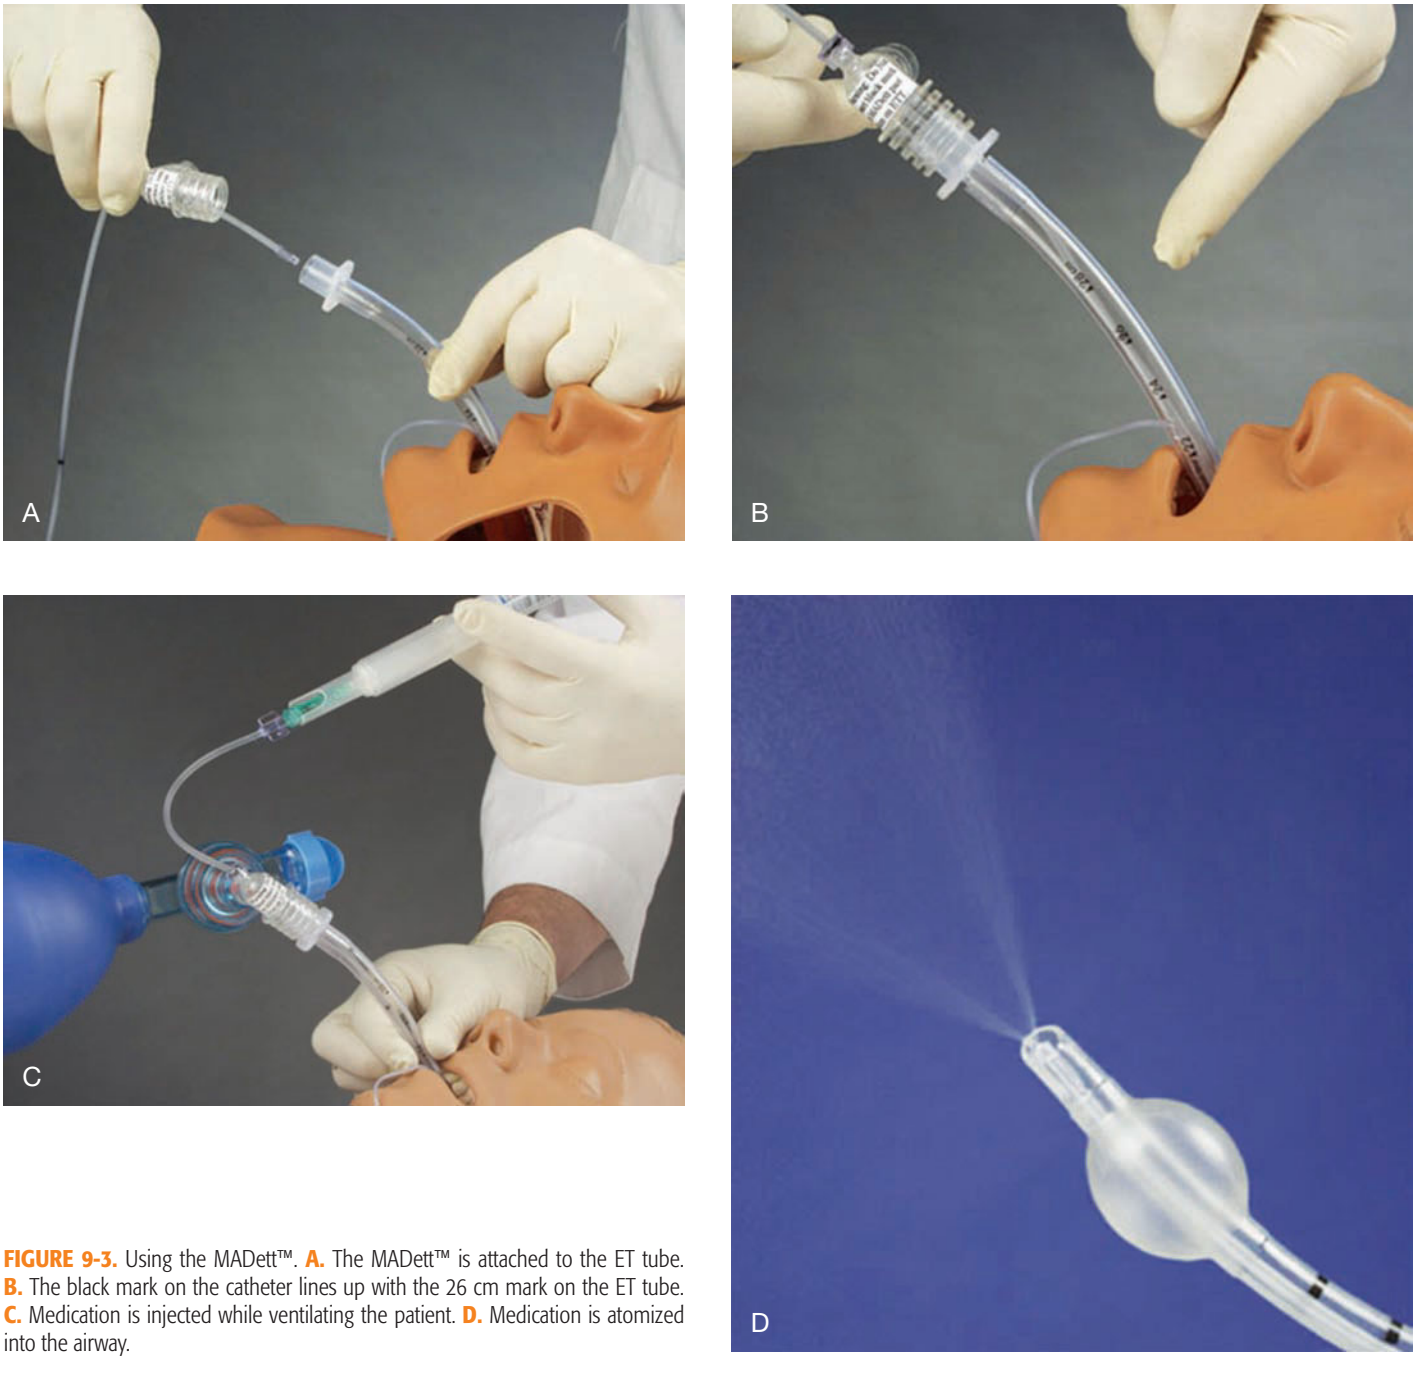

FIGURE 9-3. Using the MADett™. **A.** The MADett™ is attached to the ET tube. **B.** The black mark on the catheter lines up with the 26 cm mark on the ET tube. **C.** Medication is injected while ventilating the patient. **D.** Medication is atomized into the airway.

MADett™ catheter into the ET tube until the black mark on the catheter lines up with the 26 cm mark on the ET tube (**Figure 9-3B**). Tighten the lock nut on the MADett™ adapter to hold the catheter in place, so that it will not be advanced or withdrawn. Attach the medication-containing syringe to the luer lock attachment and inject the medication while ventilating the patient (**Figure 9-3C**). Inject the medication while bagging the patient to allow the atomized medication (**Figure 9-3D**) to penetrate deeply into the respiratory tract.

WHICH IS THE BEST TECHNIQUE?

Mielke et al. studied the time involved to perform each technique by Paramedics and Emergency Physicians.[25] These included direct injection into the ET tube, via suction catheter, via central venous catheter, and use of an EDGAR tube with an injection channel. Overall, both direct injection into the ET tube and use of the EDGAR tube were significantly faster (median 7 and 8 seconds, respectively) than the catheter techniques (median 26 and 30 seconds). In their discussion, a theoretical disadvantage of using a catheter was the instillation of medication unilaterally down one of the mainstem bronchi if the catheter was advanced too far down the ET tube. This would thereby decrease the potential absorptive surface by half. This potential negative was offset, however, by the use of larger volumes of medication and the application of postinstillation hyperventilation.[25]

Studying the same three techniques (direct ET instillation, via a suction catheter, and use of an EDGAR tube) in nonarrest patients, no difference was found in the pharmacokinetic response to lidocaine administration.[19] Specifically, there was no significant difference in serum lidocaine concentration, heart rate, blood pressure, end-tidal PCO_2, and oxygen saturation among the three groups. These findings disputed any previous assertion that using a catheter provided an advantage by instilling medications more peripherally (therefore closer to the absorptive surface). They also reported that catheter use led to a significantly longer interruption in ventilation (10.2 seconds) compared to the direct ET instillation group (3.6 seconds).[19]

These techniques were evaluated in a porcine model representing pediatric respiratory arrests.[20] Epinephrine was instilled through an ET tube, a feeding catheter, and an ET tube with a monitoring lumen. There was no significant difference in hemodynamic response or in the rate of successful resuscitation. Interestingly, by using radiolabeled epinephrine, they were also able to show that medication adherence to the ET tube was minimal and that there was no difference in bilateral pulmonary distribution among the three groups.

ASSESSMENT

There are no specific assessments related to the procedure of endotracheal medication administration. Medications instilled through the ET tube enter the respiratory tract. Large volumes of fluid in the lung may interfere with oxygen exchange, cause a pneumonitis, or cause pulmonary edema. The assessment is related to the resuscitation itself (chest compression, positive pressure ventilation, defibrillation, etc.). There is no method to determine plasma medication levels of endotracheally administered medications in a timely manner to impact clinical care.

AFTERCARE

After a successful resuscitation, there is no indication to remove one of the specialty ET tubes if used. These can be left in place and used similar to a standard ET tube. Place a piece of tape over the needle hole in the ET tube if the needle injection technique was used. Otherwise, no aftercare specific to the procedure of endotracheal medication administration is required.

COMPLICATIONS

The main complication of administering medications by the ET route arises from the "depot effect." Epinephrine, atropine, vasopressin, and lidocaine have been observed to be absorbed in a prolonged fashion, much like a continuous intravenous infusion. This phenomenon has been attributed to local vasoconstriction (epinephrine), poor lung perfusion, vascular congestion due to markedly diminished cardiac output, and comorbid conditions (e.g., pulmonary edema, atelectasis, COPD, etc.) present at the time of the arrest. However, this sustained drug effect has also been observed in nonarrest patients.[8] The result, in the case of epinephrine, is prolonged hypertension, malignant arrhythmias, and tachycardia in the postresuscitative period.[36,41] Endotracheal atropine can cause sustained tachycardia.[5,42] Endotracheal vasopressin can cause sustained bradycardia, prompting experiments with prophylactic atropine.[10] These prolonged effects may hinder both cerebral and cardiac recovery once return of spontaneous circulation is established.[42]

Another drawback to ET medication administration is the transient impairment of gas exchange. Many studies describe an early reduction in PaO_2, which is directly correlated with the volume of liquid instilled. There is a greater drop in PaO_2 after instilling water than after saline. In nonarrest dogs using large volumes of diluent (2 mL/kg), there was a decrease in PaO_2 to 61% of baseline with distilled water as opposed to 75% of baseline with saline.[33] In nonarrest humans with instilled volumes of 10 mL through the ET tube, there was a drop in PaO_2 from 157 to 95 mmHg with saline and from 157 to 103 mmHg with water.[34] Hypoxia, to a much greater extent than hypercarbia, has been reported in nonarrest models. Alterations in pulmonary gas exchange in arrest are less well understood. However, adherence to recommended volumes and the use of hyperventilation postinstillation has the potential to offset this complication.

SUMMARY

Despite concerns regarding the efficacy of ET medication administration, this route remains second line for instances when vascular access (IV or IO) is not available for the instillation of resuscitation medications. When IV or IO access is delayed, the ET route should be considered to increase the chances of successful return of spontaneous circulation. Attempts at vascular access should be continued during the administration of ET medications. The use of the ET route should be discontinued once vascular access is achieved. Despite its inherent issues, knowledge of the ET medication administration procedure can be life saving.

10 Rapid Sequence Induction

Piotr C. Aljindi, Ned F. Nasr, and Isam F. Nasr

INTRODUCTION

Rapid sequence induction (RSI) of anesthesia, sometimes referred to as "crash" induction, has become a safe and effective method of establishing emergent airway control in patients with suspected life-threatening emergencies. It ensures optimal patient compliance in a well-controlled environment. RSI involves the near simultaneous administration of a potent sedative–hypnotic agent and a neuromuscular blocking agent.[1–20] Various pretreatment drug regimens

have been advocated to prevent potentially deleterious side effects, such as aspiration of gastric contents, cardiovascular excitation or depression, and intracranial pressure elevation.

The first endotracheal tubes were developed for the resuscitation of the newborns and victims of drowning in the nineteenth century, but were not used in anesthesia until 1878.[13] Muscle relaxants were not prepared until some 60 years later. Succinylcholine was prepared by the Nobel Laureate Daniel Bovet in 1949, after which it gained the widespread usage it still enjoys today. The RSI technique did not come into modern day practice until the end of World War II.

Patients can be hypoxic, confused, uncooperative, unstable, and unknowing of their medications or medical conditions and can require airway control within minutes of arrival at the Emergency Department. **RSI is the preferred method for securing the airway in the Emergency Department, as these patients are at risk for aspiration.** These risks include vomiting from gastrointestinal obstruction, opioids, or hypotension; regurgitation from diabetic gastroparesis, gastroesophageal reflux, increased gastric pressure, or decreased lower esophageal sphincter tone; impaired laryngeal protective reflexes; and difficult airway management.[7] Conditions such as recent meal ingestion, pain, obesity, and pregnancy place patients at higher risk as well.

INDICATIONS

The primary indication for RSI is to quickly protect and secure the patient's airway. The rationale behind RSI is to create an environment in which the trachea can be intubated as quickly and with as little difficulty as possible. The clinical conditions occurring at the time of attempted intubation are therefore of great importance. During RSI, the drugs used to produce hypnosis and muscle relaxation interact together to produce the intubating conditions. A complete list of the indications for RSI appears in **Table 10-1**.

CONTRAINDICATIONS

There are few contraindications to RSI. It should not be performed by an inexperienced intubator. If the physician has doubts about his or her ability to intubate the patient, an awake intubation should be considered. The unavailability of equipment, contraindications to muscle relaxants, and critically ill patients in whom the airway can be secured by other methods (fiberoptic intubation, topical anesthesia, or minimal sedation with a benzodiazepine and/or narcotic) are also contraindications to RSI. Any contraindication to the use of succinylcholine is also a contraindication to RSI. **Table 10-2** lists the many common contraindications to the use of succinylcholine. Patients in cardiopulmonary arrest do not require RSI as they should not have any muscle tone to overcome. A relative contraindication is a patient in whom bag-valve-mask ventilation is difficult or anticipated to be difficult.

TABLE 10-1 Indications for RSI in the Emergency Department

Airway protection and risk for pulmonary aspiration (e.g., full stomach, pregnancy, and obesity)
Application of advanced cardiac life support and administration of drugs
Definitive maintenance of airway patency
Depressed level of consciousness and questionable ability to maintain a patent airway
Emergency surgery and requirement for general anesthesia
Head trauma with a decreased Glasgow Coma Scale score
Head trauma with the need for airway control
Head trauma with the need for ventilation
Potentially difficult intubation after airway evaluation
Respiratory failure, actual or impending
Uncontrolled seizure activity requiring airway control
Uncooperative or combative patient with compromised airway

Source: Adapted from Ref. 2 and 7.

TABLE 10-2 Contraindications to the Use of Succinylcholine

Cardiac arrhythmia
Children and adolescents unless no other option exists
Exaggerated hyperkalemia in susceptible patients
More than 24 h after major burns and trauma
Crush injuries
Denervation beyond 48–72 h after injury[14]
Prolonged immobilization
Paraplegia or hemiplegia
Disuse atrophy
Severe abdominal infection
Muscular atrophy
Metastatic rhabdomyosarcoma[14]
History of malignant hyperthermia in the patient or in their family history
Hypersensitivity to the drug
Increased intracranial pressure (relative)
Increased intragastric pressure (relative)
Increased intraocular pressure (relative)
Masseter muscle spasm or rigidity
Plasma cholinesterase deficiency (relative)
Skeletal muscle myopathies in the patient or in their family history

Source: Adapted from Ref. 1, 2, 8, and 14.

EQUIPMENT

- Supplemental oxygen with appropriate tubing and connectors
- Laryngoscope handle with extra batteries
- Laryngoscope blades, various sizes and types
- Endotracheal tubes, various sizes
- Wire stylet, malleable type
- Nonrebreather oxygen masks, various sizes
- Oropharyngeal airways, various sizes
- Nasopharyngeal airways, various sizes
- Alternative airway devices
- Suction source with appropriate tubing
- Suction catheters for endotracheal tubes
- Yankauer suction catheter
- Bag-valve-mask devices, various sizes
- Face masks, various sizes
- Stethoscope
- Water-soluble lubricant or anesthetic jelly
- Tape
- Benzoin adhesive
- Syringes, 10 and 20 mL
- Medications drawn up and labeled
- Pulse oximeter
- Cardiac monitor
- Automatic sphygmomanometer
- End-tidal carbon dioxide (CO_2) monitor/device
- Crash cart
- Resuscitation medications
- Personnel (respiratory technician, medication nurse, recorder, in-line stabilization assistant)

TABLE 10-3 Pharmacologic Adjuncts to Intubation in the Premedication Phase

Agent	Standard dose	Trauma dose	Blood pressure	Cerebral perfusion pressure
Fentanyl*	2.0–8.0 μg/kg	1.0–3.0 μg/kg	Stable	Stable
Sufentanil†	0.25 μg/kg	0.1–0.2 μg/kg	Stable	Stable
Alfentanil‡	5.0–25.0 μg/kg	5 μg/kg	Stable	Stable
Remifentanil¶	0.25–1.0 μg/kg/min	0.05–0.5 μg/kg/min	Stable	Stable
Lidocaine§	1.0–1.5 mg/kg	1.0–1.5 mg/kg	Stable	Stable or increased

* Minimal hemodynamic or cerebrovascular effects. Useful agents for blunting the noxious stimuli of direct laryngoscopy or intubation. The halftime of equilibration between the effect and plasma is relatively slow (5–6 minutes). May cause central vagal stimulation with resultant bradycardia and occasionally hypotension in patients with high sympathetic tone.

† Similar to fentanyl, but more potent and faster offset.

‡ Similar to fentanyl, but faster onset and duration of action. The halftime of equilibration between the effect site and the plasma is 1.5 minutes, making this opioid a very appropriate drug to provide a transient peak effect after a single bolus dose. May prevent the increase in intraocular pressure caused by succinylcholine.[8]

¶ Similar to alfentanil in terms of fast onset. Extremely rapid clearance (3–4 L/minute) due to esterase metabolism, resulting in a rapid and predictable recovery.

§ Useful adjuvant agent for blunting airway reflexes. Also blunts blood pressure, intracranial pressure, and intraocular pressure responses to intubation, involuntary muscle movements after etomidate, and injection site pain from propofol and etomidate. Topical lidocaine is also effective in blunting reflexes.

Source: Adapted from Chapter 8.

The equipment required for RSI is the same as that for any intubation.[10,13] Complete details regarding the selection of properly sized equipment can be found in Chapters 7 and 11. In addition, **backup equipment should be readily available if the patient cannot be intubated.** This can be a laryngeal mask airway, a cricothyroidotomy tray, a retrograde guidewire kit, or a percutaneous jet ventilation system to name a few.

PATIENT PREPARATION

RSI can be performed with little or no preparation. If possible, a few steps can be performed while the patient is being evaluated. Administer supplemental oxygen to the patient with a nonrebreather mask. Apply a noninvasive blood pressure cuff, continuous pulse oximetry, and cardiac monitoring. Obtain intravenous access. If time permits, pharmacologic agents can be used to increase gastric pH and motility (antacids, H_2 receptor blockers, and metoclopramide). An antisialagogue (atropine or glycopyrrolate) may also be administered to decrease excessive oral and respiratory tract secretions.

Evaluate the airway (Chapter 6). **If, after evaluation of the airway, there is sufficient doubt as to the possibility of intubating the patient successfully, a neuromuscular relaxant should not be administered.** Consideration should be given to securing the airway in another fashion (e.g., awake intubation).

TECHNIQUE

The three main characteristics of RSI are preoxygenation, application of cricoid pressure, and the avoidance of positive pressure ventilation (if possible) prior to securing the airway with a cuffed endotracheal tube. In addition, RSI requires the presence of ancillary equipment and experienced assistance. The details of timing, drug choice, and dosage are not rigidly defined. A RSI protocol is described below from start to finish.

Preoxygenate the patient with 100% O_2 by a nonrebreather mask, or ventilate with a bag-valve-mask device using cricoid pressure. This will build an oxygen reserve and prevent hypoxemia during induction. Traditionally, preoxygenation for 5 minutes is the routine practice. If this is not practical, attempt to preoxygenate the patient for 3 minutes.[6] However, four maximal inspirations are equally effective in the cooperative patient.[6] Oxygen administration via noninvasive positive pressure ventilation can improve oxygenation more rapidly than by a face mask.[21]

While an assistant is preoxygenating the patient, evaluate the airway to anticipate any difficulties during the intubation (Chapter 6). Assemble all required equipment. Connect the bag-valve device to a mask and an oxygen supply. Lubricate and place the malleable stylet into the endotracheal tube. Attach a syringe to the inflation port of the endotracheal tube cuff. Inflate the cuff to look for any air leaks. Deflate the cuff and leave the syringe attached to the inflation

TABLE 10-4 Selected Pharmacologic Properties of the Neuromuscular Relaxants

Agent	Intubation dose (mg/kg)	Average intubating time (min)	Clinical duration (min)	Comments
Succinylcholine	Children: 2 mg/kg Adults: 1 mg/kg[16] IM: 4 mg/kg	1	4–6	Agent used for rapid sequence intubation.[1,2] Associated with side effects such as exaggerated hyperkalemia in susceptible patients (>24 h after major burns and trauma, crush injury, denervation, prolonged immobilization, paraplegia, hemiplegia, muscular dystrophy) and malignant hyperthermia. Elevates intraocular, intracranial, and intragastric pressures. Use the total body weight (not the lean weight) even in the morbidly obese or pregnant patient.
Rocuronium	0.6–1.2 Children 2–12 years old: 0.9–1.2[17]	0.7–1.1	31–67	An alternative to succinylcholine provided that there is no anticipated difficulty in intubation.[4]
Vecuronium	0.08–0.10	2.5–3.0	25–40	Cardiovascular effects unlikely. Alternative to succinylcholine.
Cisatracurium	0.15–0.20	1.5–2.0	55–65	Stereoisomer of atracurium. No cardiovascular effects. Organ-independent elimination.
Atracurium	0.4–0.5	2.0–2.5	35–45	Elimination independent of liver and kidney. Releases histamine.
Pancuronium	0.06–0.10	2.0–3.0	56–100	Tachycardia and sympathetic nervous system activation.

TABLE 10-5 Pharmacology of the Anesthetic Induction Agents

Agent	Dose (mg/kg)	Steady-state volume of distribution (L/kg)	Clearance (mL/min/kg)	Elimination half-life (h)
Thiopental	Adults: 3.0–5.0 Children: 3.0–5.0 Infants: 7.0–8.0[18]	2.5	3.4	11.6
Etomidate	0.2–0.3	2.5–4.5	10.0–20.0	2.0–5.0
Propofol	Adults: 1.5–2.5 Children: 3.0–6.0	2.0–10.0	59.4	4.0–7.0
Midazolam	0.1–0.2	1.0–1.5	7.5	1.0–4.0
Ketamine	1.0–2.0	2.5–3.3	16.0–18.0	1.0–2.0
Methohexital	1.0–3.0	0.4	6.56	22 days
Fentanyl	0.002–0.02	4.0	4.8–10.5	3.5–4.0

Source: Adapted from References 3, 7, 8, and 18.

port. Attach the laryngoscope blade to the handle and make sure that the light is functional. Simultaneously, the nurses should apply a noninvasive blood pressure cuff, continuous pulse oximetry, and cardiac monitoring to the patient. They should also draw up and label the required medications, establish intravenous access, set up the suction, record all events, and continuously observe the noninvasive blood pressure readings, cardiac monitor, and pulse oximeter.

If there is no suspicion of a cervical spine injury, position the patient in the optimum "sniffing" position. If there is suspicion of a cervical spine injury, an assistant should provide manual in-line axial stabilization of the head and neck during the intubation sequence and remove the anterior aspect of the cervical spine collar to allow for maximal mouth opening and access to the neck.

Premedicate the patient (**Table 10-3**). The mnemonic "LOAD" has been used to indicate the pretreatment drugs for RSI.[15] The mnemonic stands for lidocaine, opioid (specifically, fentanyl), atropine, and defasciculation. Lidocaine (1.0 to 1.5 mg/kg) can be given to blunt the intracranial pressure response, transient hypertension, bronchospasm, and tachycardia associated with intubation. Fentanyl (2 to 3 µg/kg) or one of its derivatives can be given to also blunt the intracranial pressure response, transient hypertension, and tachycardia associated with intubation. Atropine (0.01 to 0.02 mg/kg, minimum 0.1 mg, maximum 1.0 mg) should be given to children less than 1 year old to prevent bradycardia in response to direct laryngoscopy. Administer a defasciculating dose of a nondepolarizing neuromuscular blocking agent. This is one-tenth of the intubating dose (**Table 10-4**). Phenylephrine (50 µg) can be given to attenuate the hypotensive response to intubation. Administer an appropriate induction agent as indicated by the clinical setting and patient's hemodynamic status (**Tables 10-5 and 10-6**). Flush the intravenous line with 5 to 10 mL of 0.9% normal saline solution after each drug to ensure delivery.

Administer a neuromuscular blocking agent.[1,2,5] Numerous agents are available (**Table 10-4**). The most commonly used medications are succinylcholine (1.0 to 1.5 mg/kg) or rocuronium (1.0 to 1.2 mg/kg). **Succinylcholine is the preferred agent. Its effects are short lasting (4 to 6 minutes). This is especially useful if the patient cannot be intubated, as they will need to be ventilated with a bag-valve-mask device until the succinylcholine wears off.** Rocuronium allows the same intubating conditions as succinylcholine except that it lasts for 30 to 60 minutes. This is problematic if the patient cannot be intubated.

An assistant should apply cricoid pressure as soon as the patient loses consciousness and maintain it until successful oral endotracheal intubation has been confirmed. Avoid mask ventilation if possible. If hypoxemia or hypercarbia ensues, begin mask ventilation to a maximum pressure of 20 cmH_2O while maintaining cricoid pressure.

Intubate the trachea 60 to 90 seconds after the succinylcholine (or rocuronium) has been administered and the patient's muscles are relaxed, as noted by apnea and jaw relation. **Confirm the correct position of the endotracheal tube by visualizing the tube passing through the vocal cords, observing sustained presence of end-tidal CO_2 on the capnograph, and auscultating breath sounds at the midaxillary lines.**[11,12] Auscultate over the epigastric area to ensure that ventilation is not audible over the stomach. Release cricoid pressure. If indicated, administer a long-acting paralytic agent (**Table 10-4**). After successful intubation, administer additional sedative hypnotics and analgesics as dictated by clinical needs. Obtain a chest radiograph to confirm proper placement of the endotracheal tube.

SPECIAL CONSIDERATIONS IN PEDIATRIC PATIENTS

Rapid sequence induction is often used in the Emergency Department for securing the airway of pediatric patients. The indications and equipment, except for being smaller, are essentially not different than in the adult patient. Infants and young children have

TABLE 10-6 Cardiovascular and Central Nervous System Effects of Anesthetic Induction Agents

developmental differences in head and neck anatomy (Chapter 6). These differences make the Miller blade the preferred laryngoscope blade for intubation in this group. Infants and young children have a higher volume of distribution, which is why they require different doses of induction agents as reflected in **Tables 10-4 & 10-5**.

Preoxygenation is particularly important for infants and children. Compared with adults, these young patients have a higher oxygen consumption rate and a lower functional residual capacity. Consequently, oxygen desaturation occurs much more rapidly. If the child is desaturating or apneic, careful bag-mask ventilation with small tidal volumes (while maintaining cricoid pressure) should be performed to achieve adequate preoxygenation.

The use of succinylcholine remains controversial in pediatrics. Rapid sequence induction and laryngospasm are perhaps the last remaining indications for the use of succinylcholine in pediatrics. In 1994, the US Food and Drug Administration (FDA) recommended that the use of succinylcholine in children be reserved for emergency intubation and instances where the immediate securing of the airway is necessary due to the risks of hyperkalemia. This includes patients with laryngospasm, difficult airways, full stomachs, or for intramuscular use. If a child has no vascular access, succinylcholine (4 mg/kg) can be administered intramuscularly. It will provide a maximum onset of blockade in 3 to 4 minutes and last approximately 20 minutes. If there is a contraindication to using succinylcholine, rocuronium can be used for RSI. Children between 2 and 12 years old require more rocuronium than adults. The recommended doses are 0.9 to 1.2 mg/kg in this age group.

Atropine is commonly used in young children. Atropine (20 μg/kg) administered as a premedication is indicated in all children <1 year old and in all ages if a second dose of succinylcholine is required to intubate the patient.[19] There is a risk of bradycardia with the use of succinylcholine in children. This can be attenuated by premedicating the patient with atropine (20 μg/kg) or glycopyrrolate (10 μg/kg).[20]

ASSESSMENT

Confirm that endotracheal intubation is successful. This includes auscultation, fogging of the endotracheal tube with ventilations, as well as presence of persistent end-tidal CO_2. End-tidal CO_2 can be confirmed using a capnograph or a chemical (colorimetric) indicator device that consists of a pH-sensitive indicator where the dye changes its color in the presence of CO_2. A minimum of six breaths should be administered before a determination is made regarding successful endotracheal intubation. This will eliminate false-positive readings obtained by CO_2 forced into the stomach during mask ventilation, antacids in the stomach, or carbonated drinks in the stomach. False-negative results may be seen with very low tidal volumes and low end-tidal CO_2 concentrations during severe hypotension or cardiac arrest. During cardiopulmonary resuscitation (CPR), a negative result requires an alternative method of confirming the position of the endotracheal tube because compromised circulation causes low end-tidal CO_2.[12] Other methods used to confirm endotracheal intubation include fiberoptic endoscopy with direct visualization of the tracheal rings and carina, pulse oximetry (low saturation is a late sign for esophageal intubation), blood gas analysis, chest radiography, and a variety of detection devices. Please refer to Chapter 12 for more information regarding the confirmation of endotracheal intubation.

AFTERCARE

The aftercare is the same as for any intubated patient. Secure the endotracheal tube with tape or a commercially available device. Administer adequate sedation and neuromuscular relaxation as necessary. Place a nasogastric tube to decompress the stomach.

TABLE 10-7 Complications of RSI

Airway trauma
Awareness
Bradycardia
Cerebral anoxia
Complication specific to the medications administered
Corneal injury
Death
Dental damage
Hypertension
Hypotension
Hypoxia
Increased intracranial pressure
Increased intraocular pressure
Myocardial ischemia
Pulmonary aspiration
Tachycardia

COMPLICATIONS

The complications associated with RSI are numerous (**Table 10-7**), ranging from minor airway trauma to cerebral anoxia and death. These can result from the RSI or the intubation. **The technique of RSI should be performed only by experienced physicians. The availability of alternate invasive airway devices and techniques can often prevent complications if oral endotracheal intubation is unsuccessful.** A more complete discussion is contained in Chapter 11.

SUMMARY

RSI is the preferred method to secure an airway on an emergent basis and where there is a risk of aspiration of gastric contents. In experienced hands, it is a relatively safe procedure with few complications. The choice of pharmacologic agents used will vary by physician experience, physician preference, the clinical condition of the patient, and the pharmacology of the agents.

11 Orotracheal Intubation

Eric F. Reichman and Joseph Cornett

INTRODUCTION

Airway control is the first and most critical action of the Emergency Physician. The "A" in the ABC's demands that no other action may take place until the airway is secure. Endotracheal (ET) intubation inserts an artificial airway connecting the respiratory system to the outside world and provides definitive control of the airway. Once the ET tube is in place, all methods of support can be applied. If the airway is not secure, nothing can help the patient. ET intubation can be accomplished by a variety of methods. The method of choice will be dictated by physician preference and experience, the patient's condition, and the available equipment. The most common method of ET intubation is orotracheal intubation. **There are no good alternatives to intubation when oxygenation and ventilation are threatened. All actions should be focused on two objectives: to get the ET tube placed quickly and in the right location.** The proper preparation, practice, and personnel can assure that the "nightmare airway" is an extremely rare event.[1]

ANATOMY AND PATHOPHYSIOLOGY

For the purposes of intubation, our discussion of the anatomy starts at the lips and travels inward to end at the right mainstem bronchus. As you approach the patient, visualize the normal structures expected and match them with what is seen. Distortion occurs from edema or trauma. Structures may be hidden by vomit or blood. Airway structures are viewed upside down, from the position of standing over the head of the supine patient, and the potential for disorientation multiplies.

Begin at the face and move inward (**Figures 11-1 & 11-2**). The philtrum of the upper lip will be located at the 6 o'clock (bottom) position. Symmetrical swelling, carbon deposits, blistering, or signs of trauma to the lips can indicate that the inner anatomy of the airway may be altered and the intubation more difficult. Moving inward, open the patient's mouth and check the teeth for fractures, size, and the presence of removable dental devices. Large upper incisors and/or limited jaw opening will make orotracheal intubation more difficult. The tongue hangs down from the floor of the lower jaw (mandible) and ends with the tip against the upper (maxillary) incisors (**Figure 11-2**). Visualize the tongue as a hanging oval of tissue with two "tips." The first is the anterior tip of the tongue proper. The second is the epiglottis. The anatomic "floor" of this view is formed by the hard and soft palates, which end at the palatopharyngeal arch (**Figure 11-2**). The uvula is located inferiorly and in the midline. The palatoglossal arch and palatopharyngeal arch form twin vertical pillars that lie posterior to the molars of the upper teeth (**Figure 11-2**). All of these structures are potential sources of obstruction and must be evaluated for swelling, deformity, or trauma. The "back wall" is the posterior wall of the pharynx (**Figure 11-2**).

At the posterior wall of the pharynx, the airway bends 90° to run almost parallel to the bed. Visualized from the perspective of the top of the patient's head, the root of the tongue and the lingual tonsils are located at the 12 o'clock position (**Figures 11-3 & 11-4**). The tongue continues into a blind pocket known as the vallecula. Following the vallecula posteriorly, it is continuous with the epiglottis. The epiglottis hangs with its tip pointing downward. Directly behind and protected by the epiglottis is the entry to the remainder of the airway (**Figure 11-4**). The esophagus lies at the 6 o'clock position. From the viewpoint of the intubator, the hypopharynx appears like the numeral 8. The top half is the airway and the bottom half the esophagus.

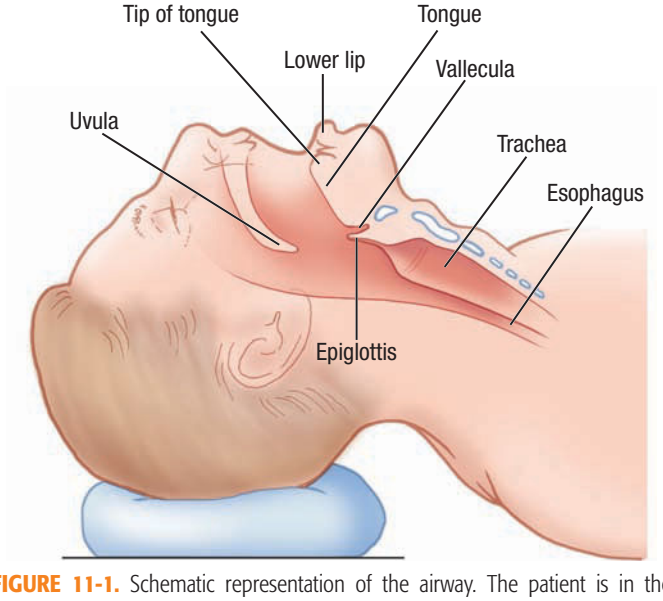

FIGURE 11-1. Schematic representation of the airway. The patient is in the "sniffing" position.

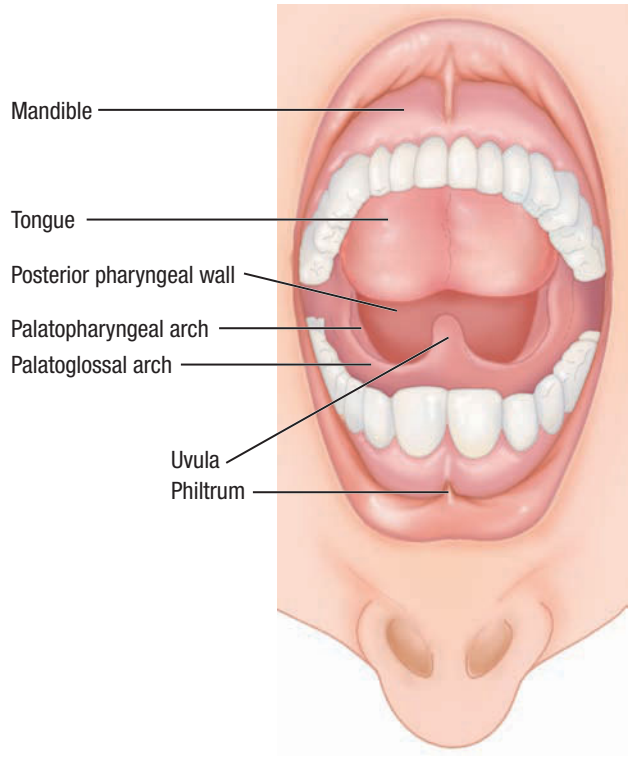

FIGURE 11-2. The oral structures as viewed from above the supine patient's head.

Under the epiglottis is the larynx (**Figure 11-5**). The vocal cords are located in the midline and form an "A" shape, with its apex superior and toward the epiglottis. **Identifying the vocal cords is important, since the visualization of the ET tube passing between the cords is proof of a successful ET intubation.** The arytenoid cartilages are paired structures. One lies at the posterior aspect of each vocal cord. The aryepiglottic folds are paired structures that span from the lateral edge of the epiglottis to the arytenoid cartilages. They contain the muscles that move the arytenoid cartilages, and subsequently open and close the vocal cords. The trachea bifurcates at the carina into the right and left mainstem bronchi. In some patients, the cartilaginous tracheal rings are visible through the vocal cords.

INDICATIONS

Any threat to oxygenation and/or ventilation is a relative indication for orotracheal intubation. If the threat is simple and easily removed, remove it. **If there is uncertainty that the patient's airway patency, respiratory drive, or oxygenation cannot be maintained without intervention, orotracheal intubation is required. Time is of the essence. The decision to intubate early can make the difference between a controlled, successful procedure and a chaotic, "crashing" nightmare.** Orotracheal intubation can be performed to administer resuscitation medications, ensure a patent airway, deliver oxygen, isolate the airway, reduce the risk of aspiration of gastric or oral contents, suction the trachea, ventilate the patient, and apply positive-pressure ventilation. Other indications for orotracheal intubation include altered mental status, head injury requiring hyperventilation, hypoxemia, hypoventilation, apnea, lack of a gag reflex, shock, and unconsciousness.

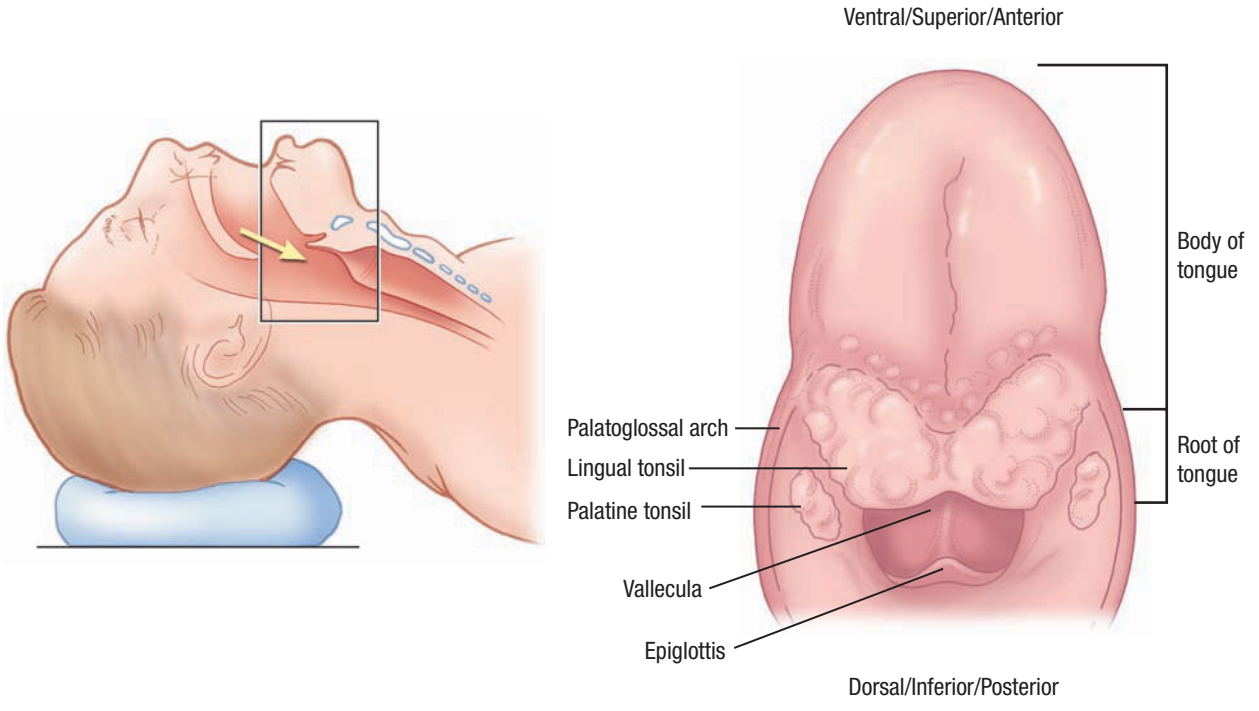

FIGURE 11-3. The tongue and adjacent structures as viewed from above the supine patient's head.

CONTRAINDICATIONS

Orotracheal intubation is relatively contraindicated in patients who do not need it, who are likely to be injured by the procedure, or whose injuries make success unlikely. Spontaneous breathing with adequate ventilation and normal mental status may allow less invasive techniques such as continuous positive airway pressure (CPAP) in patients whose medical conditions are likely to respond quickly to interventions, such as cardiogenic pulmonary edema or pneumonitis.[2] Trauma patients, with likely cervical spine injury or anterior neck wounds, as well as severely immobile arthritis patients may be injured by the manipulation required during orotracheal intubation.[3] Severe orofacial injuries, bleeding, deep airway obstruction, or gross deformity of the head and neck may make successful intubation impossible. A quickly changing obstruction, such as edema or an expanding hematoma, may require a surgical airway if orotracheal intubation is delayed. **Choose a surgical airway if the manipulation or time required for orotracheal intubation puts the patient at risk for spinal injury or hypoxia.**[4] Orotracheal intubation should not be performed by individuals unfamiliar with the equipment and technique.

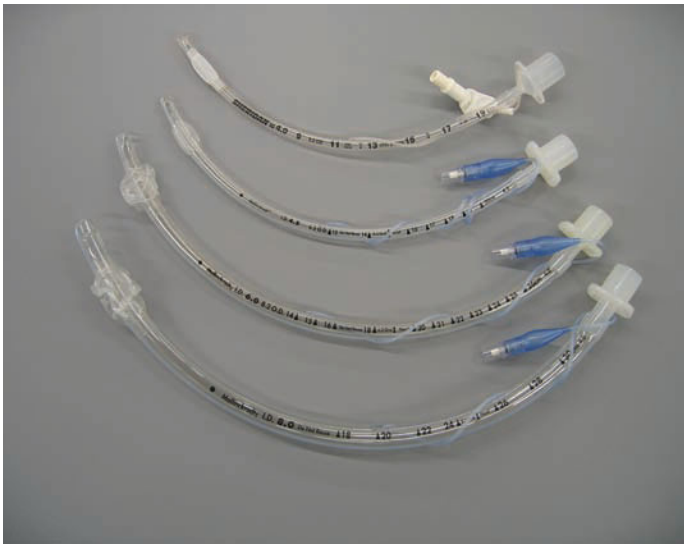

FIGURE 11-6. A variety of ET tubes.

EQUIPMENT

- ET tubes, various sizes (**Table 11-1**)
- 10 mL syringe
- Water-soluble lubricant or anesthetic jelly
- Wire stylet, malleable type
- Laryngoscope handle
- Fresh batteries for the laryngoscope
- Laryngoscope blades, various sizes and shapes
- Supplemental oxygen with appropriate tubing and connectors
- Nonrebreather oxygen masks, various sizes
- Wall suction with appropriate tubing
- Yankauer suction catheter
- Bag-valve device, sizes: infant, child, adult small, adult medium, adult large
- Oral airways, sizes: infant, child, adult 3 to 5
- Nasal airways, various sizes
- Benzoin adhesive
- Tape
- Pulse oximeter
- Cardiac monitor
- Automatic sphygmomanometer
- End-tidal carbon dioxide (CO_2) monitor/device
- Cricothyrotomy backup tray
- Crash cart
- Resuscitation medicines
- Personnel (respiratory technician, medication nurse, in-line stabilization assistant, and recorder)
- Medications (premedications, induction, anesthetics, paralytics), see **Tables 11-1 to 11-2**

Many institutions make their own "intubating/airway kit." It contains all the commonly used equipment in a portable container or cart that can be moved wherever required in the Emergency Department. While differences will exist between institutions, the kit commonly includes adult and pediatric laryngoscope handles, various sizes and types of laryngoscope blades, various sizes of oropharyngeal airways, various sizes of nasopharyngeal airways, tongue blades, malleable stylets, various sizes of ET tubes, syringes, tape, and commercially available devices to secure the ET tube. Some institutions may have a single kit, or separate kits for adult and pediatric patients.

ET TUBES

The ET tube is a clear polyvinyl chloride disposable tube that is open on both ends (**Figure 11-6**). The proximal end contains a standard size (15 mm) connector that will attach to the bag-valve device, a ventilator, and other sources of positive-pressure ventilation. The distal end is beveled. It has a perforation, located approximately 0.5 to 0.75 cm from the tip and opposite the bevel, known as the Murphy eye. Printed on the tube are the size, a radiopaque line to aid in radiographic visualization, and 1 cm incremental marks beginning at the tip. An inflatable cuff is positioned proximal to the Murphy eye. A pilot balloon with an inflation port, to inflate the cuff, hangs from the proximal third of the ET tube. A syringe, filled with air, attaches to the inflation port to inflate and deflate the cuff.

The ET tube cuff is a high-volume, low-pressure balloon. It is designed to accommodate a high volume of air before the intracuff pressure rises. This is an extremely important feature. If the intracuff pressure rises, it is transmitted to the delicate tracheal mucosa where it can cause pressure necrosis and ischemia.

The choice of ET tube size will vary based on the patient's age, anatomic anomalies, body habitus, and airway anatomy (**Table 11-1**). **The ET tube is sized based on the internal diameter (ID) measured in millimeters.** The size is printed onto the surface of the ET tube for reference. The sizes begin with 2.5 mm and increase in 0.5 mm increments. Some generalities hold true in most patients. Adult males usually require a size 7.5 to 9.0 cuffed ET tube. Adult females usually require a size 7.0 to 8.0 cuffed ET tube.

ET tube selection in children can be made by one of several methods. A Broselow tape will identify the proper size tube. Visually select a tube with an ID that matches the size of the width of the nail of the patient's little finger, the width or diameter of the fifth finger, the diameter of the distal phalanx of the third finger, or the external nares luminal diameter. All these visual methods

will approximate the same size ET tube. The following formula may be used to confirm the uncuffed ET tube size: (16 + child's age in years)/4. Tables based on the child's age, length (Broselow tape), or weight may be used to estimate the proper ET tube size. An uncuffed ET tube should be used in children under 28 days of age to prevent the complications of subglottic and tracheal stenosis. After determining the proper size ET tube, also select and prepare a tube that is one size smaller in case the patient's airway is smaller than expected.

Traditional teaching holds that cuffed ET tubes increase the risk of ischemic damage to the tracheal mucosa due to compression between the cuff and the cartilaginous rings, resulting in the old mandate to use uncuffed ET tubes in children younger than 8 years of age. There have been numerous advances in modern ET tubes that are changing this orthodoxy.[41] Current American Heart Association Guidelines now recommend, but do not require, a cuffed ET tube for children older than 28 days of age. In the first 28 days of life, the cricoid narrowing functions as a cuff. For children over 28 days of age, the cuffed ET tube is just as safe as an uncuffed ET tube.[25,26] The high volume, low pressure cuffs found on new ET tubes allow the cuff to produce a seal at much lower pressures. The use of cuffed ET tubes is becoming more common in pediatric ICUs and Emergency Departments. Several studies have shown no increase in postintubation stridor or reintubation when cuffed ET tubes are used in controlled settings with regular cuff pressure monitoring.

In addition to providing some protection from aspiration, other potential benefits resulting from the use of cuffed ET tubes in children include allowing ventilation at higher pressures, maintenance of more consistent ventilatory parameters, and fewer changes of inappropriately sized ET tubes. Cuffed ET tube size can be calculated using the equation (age in years/4) + 3, or by use of an ET tube one-half size smaller than the calculated uncuffed ET tube size.[7,21]

All ET tubes should be examined for defects before use. Attach a 10 mL syringe filled with air to the pilot balloon inflation port. Inject the air to inflate the cuff. The cuff should inflate symmetrically and have no air leak. Deflate the cuff completely. Leave the syringe attached to the pilot balloon in order to inflate the cuff after the ET tube has been inserted into a patient's airway. If an ET tube is defective, discard it and open a new ET tube.

LARYNGOSCOPES

The laryngoscope is a handheld device that is used to elevate the tongue and epiglottis to expose the glottis. **It is a device that is held in the left hand regardless of which hand of the user is dominant.** It consists of a handle (**Figure 11-7**) and a blade (**Figures 11-8 & 11-9**). The handle contains the battery for the light source. The distal end of the handle has a fitting where the handle connects to the blade. A transverse bar indicates where the indentation on the proximal blade attaches to the handle. There are many types of laryngoscope handles. They all have the same basic design, but are available in a variety of diameters and lengths (**Figure 11-7**). Smaller diameter (thinner) laryngoscope handles may be better suited for use with the smaller sized pediatric laryngoscope blades. Shorter, "stubby" laryngoscope handles may offer an advantage when proceeding with intubation of obese or barrel-chested patients, especially in cases where the neck cannot be manipulated. The shorter handle will not catch on the chest wall during attempts to place the laryngoscope blade in the patient's mouth.

The laryngoscope blade may have a removable bulb attached to its distal third. A fiberoptic bundle within the blade transfers power from the handle to the bulb. Other laryngoscope blades

FIGURE 11-7. A variety of laryngoscope handles.

FIGURE 11-8. The Macintosh laryngoscope blades.

FIGURE 11-9. The Miller laryngoscope blades.

only contain fiberoptic bundles which transmit light, with the light source located within the handle. The choice of the type and size of laryngoscope blade will vary with physician experience and preference. **The best blade is one that the intubator feels comfortable and confident using.** The curved Macintosh blade is most commonly used (**Figure 11-8**). It is the easier blade to use for those with little experience with orotracheal intubation. Many feel that it requires less forearm strength to use as compared to the straight blade. The large flange allows for easier control of the tongue and the flat curved shape of the spatula fits the natural curve of the tongue. The straight Miller blade is often reserved for those experienced with the blade and with orotracheal intubation (**Figure 11-9**).

The tip of the curved Macintosh blade fits into the vallecula and indirectly lifts the epiglottis to expose the vocal cords (Figure 11-10). A size 2 blade is used for 3 to 6 year olds. A size 3 blade is used for children starting at about age 6, for women, and for small to average-size males. A size 4 blade is usually reserved for large males.

The tip of the straight Miller blade goes directly under the epiglottis to lift it and the tongue to expose the vocal cords (Figure 11-11). Use the straight blade, if possible and the intubator is familiar with its use, to intubate patients under 2 years of age. A straight blade makes controlling the epiglottis and tongue easier than with a curved blade. It also makes visualization of the vocal cords easier due to its smaller flange profile. A size 0 blade is used for premature babies and neonates up to approximately 1 month of age. A size 1 blade is used for children from approximately 1 month of age to toddlers up to 2 years of age. A size 2 blade is used for children 3 to 6 years of age. Children between 6 and 12 years of age may require either a size 2 or 3 blade depending on their body size. A size 3 blade is used for adolescents, women, and average-size males. A size 4 blade is rarely used, and then primarily for large males.

If one cannot remember the proper blade size, it can be determined based on patient anatomy.[20] Place the base of the blade, excluding the handle insertion block, at the level of the patient's upper incisor teeth. The tip of the blade should be located within 1 cm proximal or distal to the angle of the patient's mandible. Correct blade size allows for approximately 90% of first attempt intubations to be successful versus 57% if the blade is too small.[20]

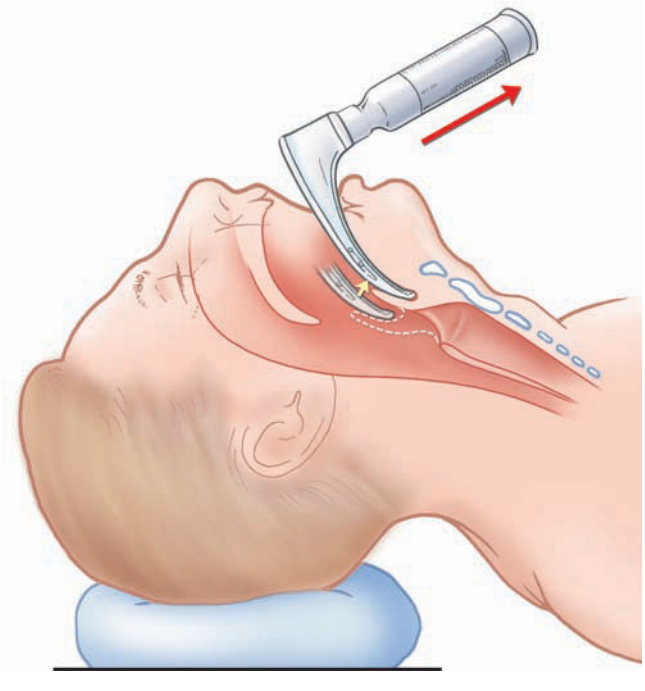

FIGURE 11-10. Use of the Macintosh blade. It is inserted into the vallecula to elevate the mandible, tongue, and epiglottis as a unit.

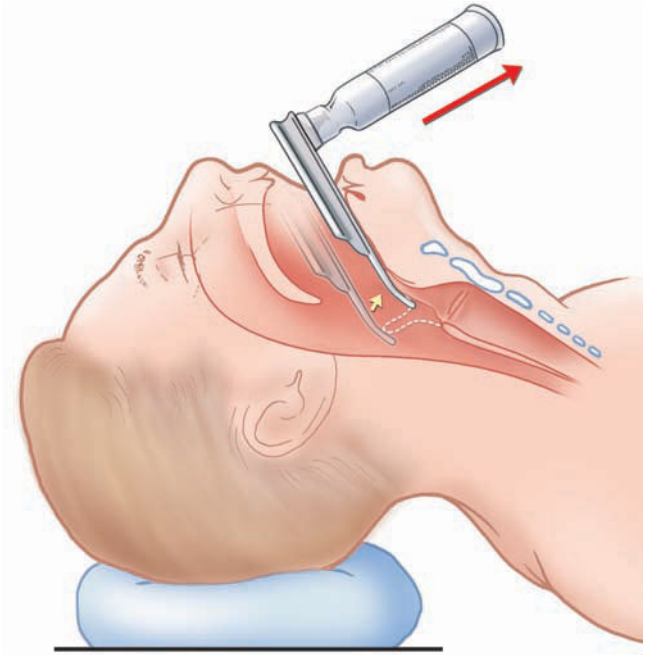

FIGURE 11-11. Use of the Miller blade. It is inserted below the epiglottis to elevate the mandible, tongue, and epiglottis as a unit.

There are a wide variety of laryngoscope blades commercially available. They tend to be variations of the curved Macintosh or Straight Miller blades. The McCoy blade is a curved blade with a hinged tip. The tip can be flexed by depressing a lever on the laryngoscope handle. This flexion augments indirect elevation of the epiglottis by stretching the hypoepiglottic ligament. The Flexiblade (Arco-Medic Ltd., Omer, Israel) laryngoscope also has a levering blade. The extra lift provided by these blades may improve visualization of the vocal cords.[8,9] The Propper Flip-Tip laryngoscope blade (Propper Manufacturing Co., Long Island, NY) has a lever that elevates its tip up to 90° to lift the epiglottis. Other variations of the Macintosh blade include the incorporation of a variety of prism or mirror systems. These modifications allow for indirect visualization of otherwise obscured vocal cords. The Belscope (International Medical Inc., Burnsville, MN), Truvue EVO2 (Truphatek International Ltd, Netanya, Israel), Lee-Fiberview (Anesthesia Medical Specialties, Beaumont, CA), and Viewmax (Rusch, Duluth, GA) blades are examples of these types of modifications.[8,10,11]

There have also been many variations of the straight laryngoscope blade. Today, the Miller is the most popular straight blade. Other variants include the Phillips and Henderson blades. These modify components such as the cross section, the blade channel width, tip style, and light source placement. These modifications represent efforts to avoid such problems as dental trauma, laceration of the ET tube cuff, improve tongue displacement, minimize tip trauma, and obscuration of the light source by secretions.

In addition to traditional metal laryngoscope blades, plastic single-use blades are also available. These single-use plastic blades were developed, in part, to concerns regarding possible transmission of infectious agents by incompletely sterilized metallic blades. A study comparing plastic versus metallic Macintosh laryngoscope blades

in 1177 patients found that metallic blades had higher first attempt intubation rates, fewer cases of difficult intubation, and used alternative airway interventions less often than when intubation was attempted with a plastic blade.[12] Plastic blades cause less dental trauma when used on dental models.[16] The rates of dental trauma in patients when compared to metal blades are not known. The use of single-use disposable plastic blades cannot be recommended at this time unless circumstances do not allow proper cleaning of metallic laryngoscope blades.

STYLETS

The stylet is a semirigid piece of metal that is bendable (**Figure 11-12**). It is often plastic coated. It inserts into the lumen of the ET tube. It should be lubricated with a water-soluble lubricant or an anesthetic jelly prior to insertion into the ET tube. **The tip of the stylet should be 1 cm proximal to the tip of the ET tube to prevent injury to the patient's airway.** The ET tube, with a stylet, can be bent to maintain a specific shape. The stylet is used to facilitate passage of the ET tube through the vocal cords. It is commonly bent into a "hockey stick" or "J" shape for most intubations. A greater curvature is often used for intubations when the larynx is "anterior," in difficult intubations, and in "blind" intubations.

A modification of the traditional stylet is the Parker Flex-It™ Directional Stylet (Parker Medical, Highlands Ranch, CO). This is a plastic articulating stylet that requires no prebending. The stylet has a built-in gentle curve. It has a button on its proximal end that extends from the ET tube. When pushed with the thumb, it allows the curvature of the ET tube to be continuously adjusted during intubation attempts.

FIGURE 11-12. The intubating stylet. It may be bent into any required shape. When inserted into an ET tube, it will form the ET tube into the desire shape. The most common shapes are the "J" and the "hockey stick."

PREPARATION

PHYSICIAN

Once the decision to intubate has been made, the Emergency Physician must use their training and experience to begin leading the team toward a successful intubation. Although the process must move quickly, the Emergency Physician must, by example, ensure a calm and orderly environment. Making the decision to intubate earlier allows the team to follow a shorter and easier time line. The Emergency Physician must visualize this time line and identify actions and potential problems before they occur. **A backup plan should also be available in case orotracheal intubation is impossible.** Any Emergency Department patient about to be intubated is a high priority, so do not be afraid to use resources liberally. Obtain assistants to help as soon as the decision to intubate is made.

PERSONNEL

Shortly before the procedure begins, assemble the entire team near the bed and go over "the game plan" calmly and quickly. All personnel involved with the procedure should be gloved, gowned, and masked. Eye protection should be worn by all personnel to protect against splash injury from blood and secretions. **Explicitly identify assistants and assign their roles early.** Give instructions clearly and calmly before the procedure begins. It is helpful to write down medications and doses in the order that they will be given and to review them quickly with the medication nurse. Emphasize that it will be the nurse's job to draw up, label, and administer the medications, followed by a saline flush. Reinforce that during the procedure this will be a particular nurse's only job. The respiratory assistant has three important tasks: helping to ventilate the patient, applying cricoid pressure, and handing the ET tube to the intubator so that visual contact with the vocal cords is not lost. If cervical spine immobilization is needed, a third assistant should be explicitly instructed as to how and when the team leader would like the patient's neck secured.

EQUIPMENT

The mnemonic "SOAPME" can be used to help review the equipment required for intubation: Suction, Oxygen, Airway, Pharmacology, Monitoring, Equipment.[13] Check that the room is ready and all equipment is within arm's reach. Turn on the suction and the oxygen. Confirm that both systems work. Attach the suction tip and check to see whether there is a small finger hole in the barrel that must be covered for the suction to work. If so, close it with a piece of tape so that the suction is "always on." This is not a concern if a Yankauer suction catheter is being used. Ensure that the suction tubing is long enough to reach the center of the bed. Place the suction catheter under the mattress to the right of the patient's head and within easy reach. Place the spare suction tip nearby. Set the oxygen flow regulator to 15 L/min. Apply a nonbreather mask to the oxygen and the patient. Place the bag-valve device near the head of the bed and within easy reach. Confirm that the noninvasive blood pressure cuff, cardiac monitor, and pulse oximeter are working and attached to the patient. Confirm that the end-tidal CO_2 monitor is nearby and working. If such a monitor is unavailable, a disposable in-line monitoring device should be available. Ensure that the patient has at least one working intravenous line.

Assemble the intubation equipment. Place the proper size laryngoscope blade on the handle. Open the blade and confirm that the light works. Close the blade into the ready position, flat against the handle, to keep the bulb cool and not drain the batteries. Take the ET tube and the backup smaller one and prepare them. Insert the 10 mL

syringe into the inflation port of the pilot balloon for the ET tube cuff. Inject enough air to inflate the balloon. If there is no leak, deflate the balloon until it is completely flat against the ET tube. **Leave the syringe attached.** Liberally lubricate the stylet with a water-soluble lubricant. Insert the stylet into the ET tube until its tip is 1 cm proximal to the distal tip of the ET tube. Place a bend in the stylet as it enters the proximal end of the ET tube to keep the stylet from advancing. Bend the stylet/ET tube assembly into a curve roughly approximating a "hockey stick" or "J" (**Figure 11-12**). Lubricate the tip of the ET tube and the collapsed cuff. This prevents the ET tube from getting caught on the epiglottis and making its advancement through the vocal cords difficult. Place the assembly back into the ET tube package. Place the ET tubes, laryngoscope, backup laryngoscope handle and blades, oral airways, and tape on a tray within easy reach of the bed. Check the room lighting. Raise the bed to minimize excessive bending and better visualize the patient's airway.

PATIENT PREPARATION

If the patient is competent and awake, explain the procedure, clarify advance directives, and obtain consent. If time permits, a history is especially helpful. The mnemonic AMPLE can help to provide quick information: allergies, medications, past medical history, last meal, and events leading to the current problem.

Confirm again that the appropriate monitoring sources are working and attached to the patient. Confirm adequate intravenous access. Place the patient, with a normal neck, in the "sniffing" position, with the head extended at the atlantooccipital joint while the neck is relatively flexed. A folded towel under the occiput helps to gently raise and tilt the head back into the proper position (**Figures 7-1, 11-1, & 11-13**). **Correct positioning is probably the most important preparation of the patient.** Dentures should be left in place temporarily, as they help to stabilize the mouth and prevent occlusion during preoxygenation and bag-valve-mask ventilation.

To intubate the obese patient, place them into the head-elevated position using a ramp or pile of sheets under their head and shoulders (**Figure 7-2**). This position facilitates spontaneous ventilation, mask ventilation, and laryngoscopy.[22–24] It also prolongs the patients oxygen saturation during and after rapid sequence induction.

If the patient is breathing spontaneously, begin preoxygenation for 5 minutes before the procedure (if time permits). Use a well-fitting nonrebreather mask with the oxygen flow regulator set at 15 L/min. This displaces nitrogen from the lungs and gives the patient a physiologic reservoir of oxygen for approximately 5 minutes while apneic. **Remember: 5 minutes of preoxygenation provides 5 minutes of protection.**[5] If bag-valve-mask ventilation is required, have an assistant apply posteriorly directed cricoid pressure to minimize gastric distention and decrease the chance of vomiting and aspiration. Have assistants ready to turn the patient onto his or her left side to minimize the risk of aspiration if vomiting occurs. Monitor the pulse oximeter to assure good oxygenation and ventilation. It should rise to the high 90s and remain there. If not, check the O_2 circuit from the wall to the patient and confirm that spontaneous breathing is still occurring.

TECHNIQUE

The evaluation and preparation for orotracheal intubation are complex and essential. If done well, the intubation will hopefully be quick and anticlimactic. Position the respiratory assistant to the right side near the patient's head. The intubator should stand at the head of the bed. Adjust the bed to place the mattress level with the intubator's umbilicus. Pull the bed away from the wall at least 2 feet and clear a "maneuvering space" of tubes, lines, and equipment to prevent distractions. If in-line cervical immobilization is needed, the assistant should stand at the intubator's left hip, ready to remove the collar and hold the neck in position.

Grasp the laryngoscope with the left hand. **It is a left-handed instrument regardless of the handedness of the intubator.** Pull it open and lock the blade onto the handle. Confirm that the light is functioning. The tip of the laryngoscope blade should be pointed toward the patient's chin. Pass the prepared ET tube and suction catheter to the respiratory assistant, who will place them into your right hand when asked. This allows the intubator to maintain constant visual contact with the patient's airway during the procedure.

Induction of anesthesia is the final preparation for orotracheal intubation. The choice of drug sequence is based on the physician's experience and the patient's condition (**Table 11-2**). A typical sequence begins with a defasciculating dose of a nondepolarizing neuromuscular blocking drug. After 2 to 3 minutes, induce anesthesia with a sedative followed immediately by a paralytic agent (i.e., succinylcholine). Apply cricoid pressure. Once the patient's muscles are relaxed, perform the intubation as described below. Please refer to Chapters 8 and 10 regarding the complete details of the pharmacology of the induction agents and rapid sequence induction. **Some patients, especially the old and sick, may stop breathing earlier than anticipated. Be prepared to intubate before the expected time of drug onset.**

Observe the patient's chest. Watch it rise. When it stops, note the time. Place your right thumb on the patient's jaw. Gently pull down the lower lip and open the mouth. Reinspect the oral cavity. Remove any dentures or foreign bodies. Compare what you see with what you expect to see. Fix any problems as you go further into the airway. If blood or vomit is seen, ask for the suction catheter. **Apply the suction catheter without removing your gaze from the patient's airway.** When done suctioning, hold the suction catheter up for the assistant to take.

INTUBATING WITH THE (CURVED) MACINTOSH BLADE

Firmly grasp the laryngoscope in the left hand (**Figure 11-13A**). Insert the tip of the Macintosh laryngoscope blade into the right side of the patient's mouth. Smoothly advance the blade inward while keeping slight upward pressure against the tongue. Use the blade to trap and push the tongue to the left as the blade is simultaneously moved to the midline, "clearing a path" for your gaze. Keep the left wrist firm. **Use the forearm, wrist, and hand as a single unit and avoid bending or flexing the wrist. It is essential to move the patient's tongue up and to the left.** The tongue will protect the mandibular teeth from being injured by the laryngoscope blade. It allows the laryngoscope blade to be moved away from the maxillary teeth. It also opens a path to visualize the patient's airway.

When the blade has been inserted all the way, lift the patient's airway up and forward exactly along the long axis of the laryngoscope handle, which should be aimed toward a point directly above the patient's chin (**Figures 11-10, 11-11, & 11-13B**). **Do not "cock" or "crank back" on the laryngoscope handle with your wrist, or the back of the laryngoscope blade may break the patient's incisors.** The epiglottis should be seen at the base of the tongue.

A variable amount of force is required to lift the mandible, tongue, and soft tissues to visualize the vocal cords. More force is required to visualize the vocal cords in patients who have a large tongue, are obese, have redundant pharyngeal soft tissue, or have trismus. Grasp the laryngoscope handle as close to its base as possible in these patients. The lower grasp provides more control of the laryngoscope and a mechanical advantage to apply more force without dental trauma.

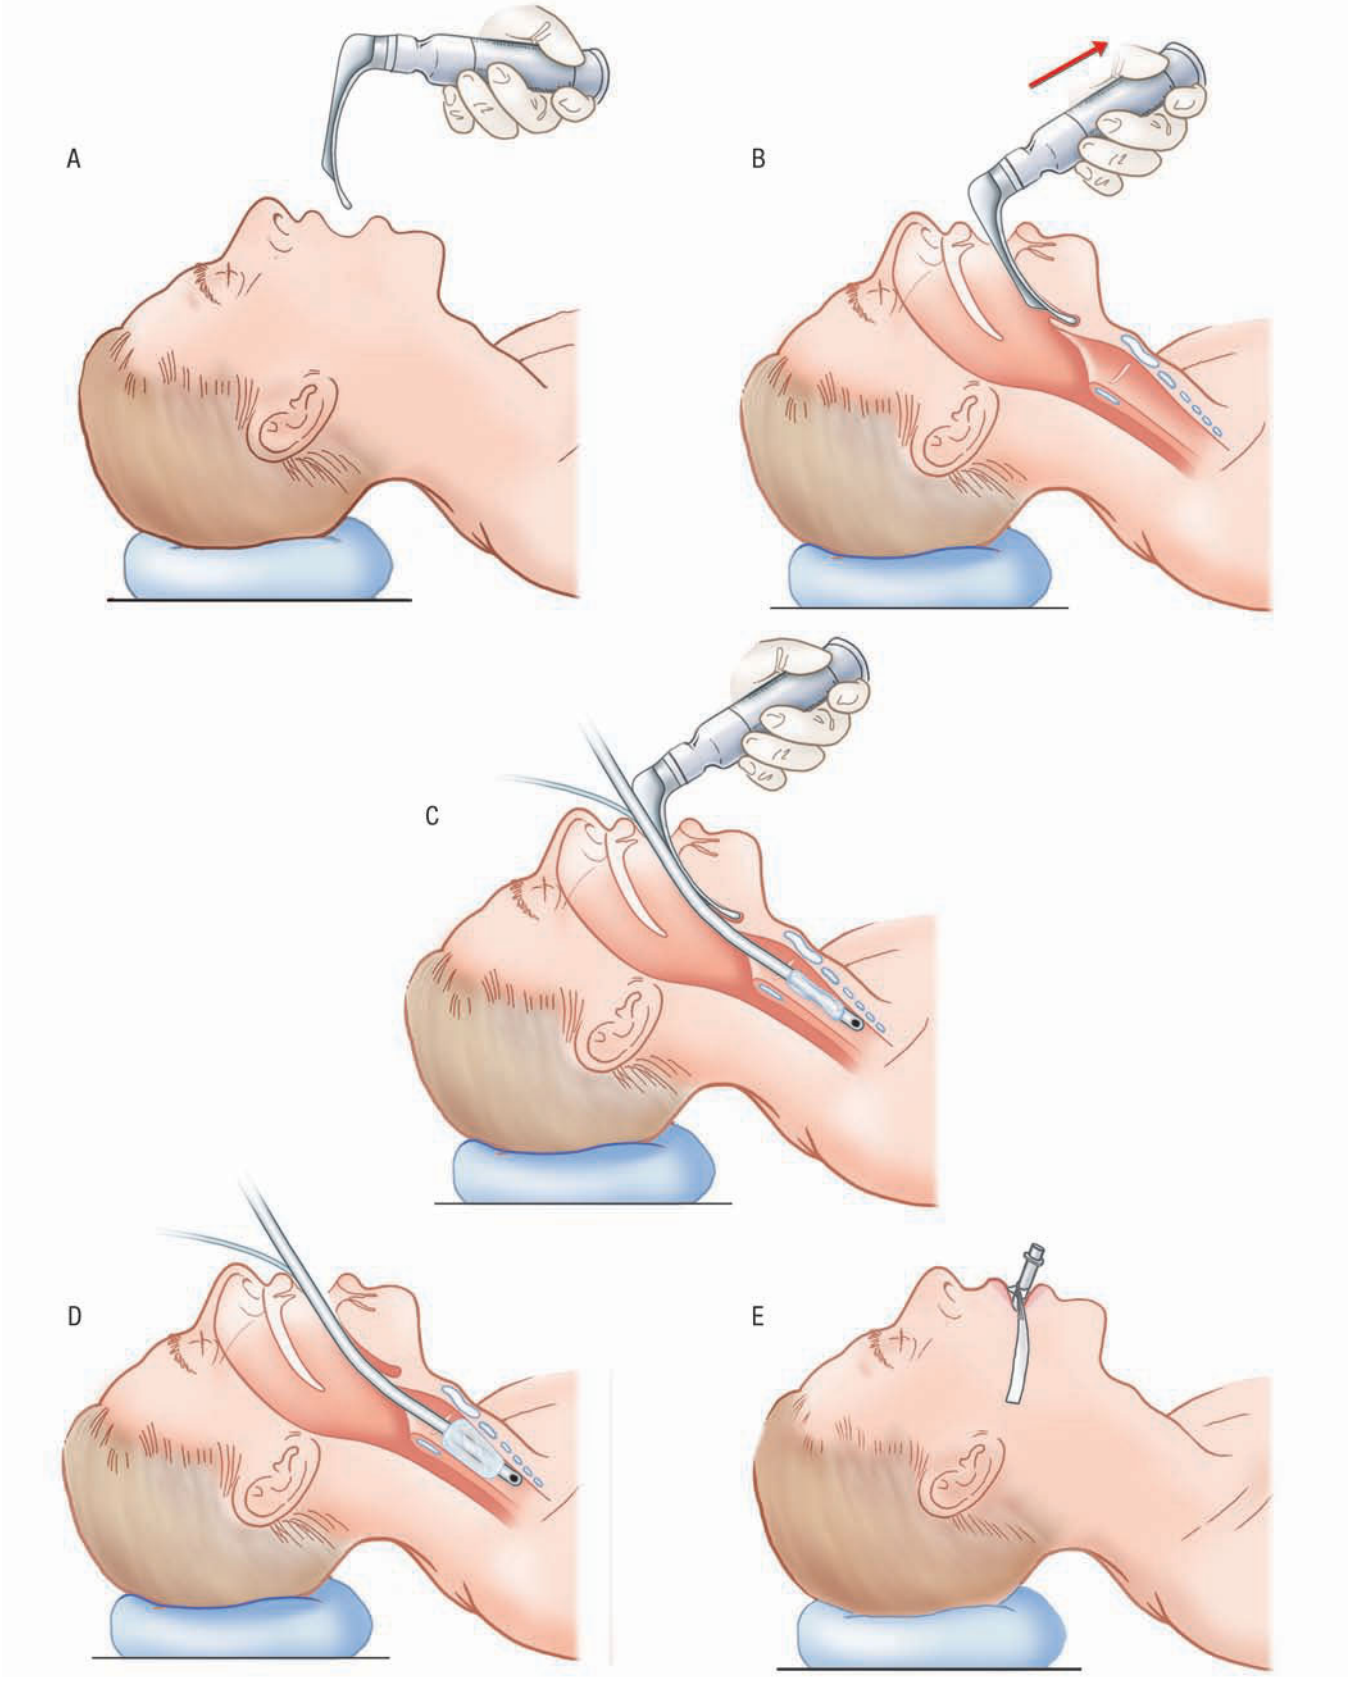

FIGURE 11-13. Orotracheal intubation with the Macintosh blade. The patient is in the "sniffing" position. **A.** Proper positioning of the laryngoscope blade above the patient's mouth. **B.** The blade is inserted into the vallecula. The handle is lifted anteriorly and inferiorly to elevate the mandible, tongue, and epiglottis (*arrow*). The glottis will be visible. **C.** The ET tube is inserted into the trachea until the cuff is below the vocal cords. **D.** The laryngoscope has been removed and the cuff inflated. **E.** The ET tube is secured.

TABLE 11-2 Rapid Sequence Induction Medications for Specific Patient Profiles

Patient type	Premedication*	Induction and paralysis†
"Normal adult"	Vecuronium (0.01 mg/kg)	Etomidate (0.3 mg/kg) or propofol (1–2.5 mg/kg) or thiopental (3 mg/kg) and succinylcholine (2 mg/kg)
"Normal child"	Vecuronium (0.01 mg/kg) and atropine (0.02 mg/kg, min dose 0.1 mg)	Thiopental (5 mg/kg) and succinylcholine (2 mg/kg)
Asthma, adult	Lidocaine (1.5 mg/kg) and atropine (0.5 mg)	Ketamine (1–2 mg/kg) and succinylcholine (2 mg/kg)
Asthma, child	Lidocaine (1.5 mg/kg) and atropine (0.02 mg, min 0.1 mg)	Ketamine (1–2 mg/kg) and succinylcholine (2 mg/kg)
Head injury, adult	Vecuronium (0.01 mg/kg) and lidocaine (1.5 mg/kg) and fentanyl (3–5 μg/kg)	Etomidate (0.3 mg/kg) and succinylcholine (2 mg/kg)
Head injury, child	Vecuronium (0.01 mg/kg) and atropine (0.02 mg/kg, min 0.1 mg) and lidocaine (1.5 mg/kg) and fentanyl (3–5 μg/kg)	Thiopental (5 mg/kg) and succinylcholine (2 mg/kg)
Head injury, adult, hypotensive	Vecuronium (0.01 mg/kg) and fentanyl (3 μg/kg) and lidocaine (1.5 mg/kg)	Etomidate (0.2 mg/kg) and succinylcholine (1.5 mg/kg)
Head injury, child, hypotensive	Vecuronium (0.01 mg/kg) and atropine (0.02 mg/kg, min 0.1 mg) and lidocaine (1.5 mg/kg) and fentanyl (2–3 μg/kg)	Midazolam (0.15 mg/kg) or etomidate (0.3 mg/kg) and succinylcholine (2 mg/kg)
Hyperkalemia or renal failure, adult	None	Etomidate (0.3 mg/kg) or propofol (1.0–2.5 mg/kg) or thiopental (3 mg/kg) and rocuronium (0.6 mg/kg) or vecuronium (0.01 mg/kg)
Hyperkalemia or renal failure, child	None	Thiopental (5 mg/kg) and rocuronium (0.6 mg/kg) or vecuronium (0.01 mg/kg)
Status epilepticus, adult	None	Thiopental (3 mg/kg) and succinylcholine (2 mg/kg)
Status epilepticus, child	None	Thiopental (5 mg/kg) and succinylcholine (2 mg/kg)
Pregnancy	Atropine (0.5 mg)	Ketamine (1–2 mg/kg) and rocuronium (0.6 mg/kg) or vecuronium (0.01 mg/kg)

* Given 3 minutes before intubating ($T = 3$).

† Given simultaneously at the beginning of intubation ($T = 0$) and wait for 45 to 60 seconds for onset of paralysis.

Advance the tip of the laryngoscope blade into the vallecula—the space between the base of the tongue and the body of the epiglottis (**Figures 11-10 & 11-13B**). Lift the laryngoscope handle to raise the tongue, jaw, and epiglottis as a unit (**Figure 11-10**). Observe carefully as the epiglottis pivots upward and uncovers the glottis (**Figure 11-5**). The vocal cords should be visualized. Cricoid pressure (Sellick's maneuver) may make intubation more difficult. If the cricoid pressure is adversely impacting the view, it should be relaxed or even removed.[14] The application of cricoid pressure by an assistant pressing the cricoid cartilage back, upward, rightward, and posteriorly (in this sequence) can help bring the vocal cords into view when the intubator cannot apply more lifting force due to lack of strength or reluctance to lift the airway, as in a suspected neck injury. **This is known as the BURP maneuver.**[27]

Another anterior neck manipulation maneuver known as **optimal external laryngeal manipulation (OELM) or bimanual laryngoscopy** may be applied.[28] They differ from the BURP maneuver in that the intubator uses their right hand to manipulate the larynx into the optimal position while simultaneously viewing the patient's airway and controlling the laryngoscope with their left hand. An assistant then assumes control of the larynx, maintaining the same position as the intubator proceeds to insert the ET tube. Alternatively, to limit laryngeal movement during the hand-off, the intubator can use their right hand to manipulate an assistant's hand on the patient's larynx. When properly positioned, instruct the assistant to keep their hand still while the intubator removes their hand off the assistant's hand. A third variation uses the assistant to manipulate the patient's larynx while the intubator verbally directs them.

When the vocal cords are visualized, instruct the assistant to pass the ET tube into your right hand. This allows you to keep a "visual lock" on the vocal cords. Insert the ET tube into the right side of the patient's mouth. Advance the ET tube so that the tip reaches the vocal cords without letting the body of the tube block the view. Continue to advance the ET tube through the vocal cords until the cuff passes through them and into the trachea (**Figure 11-13C**). Advance the tube an additional 2 to 3 cm. **The tip and cuff of the ET tube must be visualized passing through the vocal cords to assure placement in the trachea.**

The fit of the ET tube through the vocal cords always seems to be tight, even in larger patients. A well-lubricated tip with the cuff completely collapsed is essential. Rolling the tube gently between the thumb and the index finger at the moment of insertion can also help pilot the tip between the vocal cords. If the ET tube is too large or the vocal cord opening narrow, ask the assistant to pass the smaller ET tube, which has already been prepared.

The average depth of insertion (in cm) of the ET tube starting from the patient's lips is listed in **Table 11-1**. It can also be calculated using one of the following formulas: ET tube ID (in mm) × 3, (age in years/2) + 12 for patients over 2 years of age to a maximum of 18 years of age, or age + 10 for children less than 8 years of age.

Once the ET tube has been inserted, the intubator's right hand must hold the tube in place continuously until it is properly secured. The assistant should inflate the ET tube cuff with the attached 10 mL syringe of air (**Figure 11-13D**) and then remove the syringe and stylet. **The intubator must hold the ET tube firmly to make sure that it does not become dislodged when the stylet is removed.** The assistant should attach the end-tidal CO_2 monitor and the bag-valve device to the ET tube. If symmetrical lung sounds are heard on auscultation and if pulse oximetry and CO_2 monitoring appear appropriate, secure the ET tube in position in the right corner of the patient's mouth (**Figure 11-13E**).

INTUBATING WITH THE (STRAIGHT) MILLER BLADE

Intubating with the straight blade is similar to the curved blade with a few differences. Insert the laryngoscope blade completely. If the epiglottis is seen, insert the tip directly under and slightly beyond it. Lift the epiglottis and airway as above by raising your hand along the long axis of the laryngoscope handle toward a point above the patient's chin (**Figure 11-11**). **If neither the epiglottis nor the vocal cords are seen, the tip of the laryngoscope blade is in the esophagus.** Locate the airway by lifting as above while slowly withdrawing the laryngoscope blade. As the tip slides back, it will "catch" the epiglottis and the airway should "fall down" into view. The BURP or OELM maneuver may now be applied if necessary. Some physicians use a variation of this to localize the epiglottis by inserting the blade

deeply and lifting, then withdrawing while feeling for the "give" as the epiglottis tip falls off of the retreating blade, and then readvancing a small distance to "scoop up" the epiglottis, exposing the airway. The remainder of the technique is the same as described above.

ASSESSMENT

In the Emergency Department, simple common-sense methods will quickly and accurately assess ET tube placement. The confirmation of ET intubation is briefly described in this section. Please refer to Chapter 12 for a more detailed discussion. **The assessment must be made quickly!** An ET tube in the wrong place, the esophagus, is as quickly dangerous as a properly placed one is lifesaving. **Was the ET tube visualized passing through the "A frame" of the vocal cords? This is the most important assessment.** If it was directly visualized being placed and continuously held in place, it is properly positioned. Is the pulse oximeter reading in the high 90s and steady or rising? Is the CO_2 monitoring appropriate? Be familiar with the monitor in your institution. Electronic monitors will show a respiratory waveform and a numerical value. In-line colorimetric monitors connected between the ET tube and the respiratory circuit will change color with inspiration and expiration to indicate the flow of CO_2 passed the device.

Evaluate the patient. Symmetrical upper chest rise without increasing abdominal size suggests proper placement. Persistent "fogging" or condensation inside the ET tube with each breath for at least six ventilations will also confirm proper placement. Auscultate lateral to the nipples for strong and symmetrical breath sounds during positive-pressure breaths. Avoid auscultating in the midline, where "normal" breath sounds can be heard from a misplaced ET tube in the esophagus. Auscultate at the lateral apices and bases of the lungs. Auscultate over the epigastrium. Correct placement will give strong, symmetrical breath sounds except in the epigastrium. If epigastric sounds are strongest or "gurgling" or vocalization is heard, assume incorrect ET tube placement. Breath sounds that are asymmetrical and stronger on the right indicate a right mainstem intubation. Deflate the cuff and gently withdraw the ET tube in 1 cm increments while auscultating. Continue to withdraw the ET tube until equal breath sounds are heard. Secure the tube and reinflate the cuff.

Obtain a chest radiograph after clinically confirming the placement of the ET tube. The tip of the radiopaque stripe of the ET tube should be over the third or fourth thoracic vertebra and 3 to 4 cm above the carina of the trachea. Always inspect the radiograph for any signs of a pneumomediastinum, pneumothorax, or hemothorax.

Clinical assessment of the ET tubes position should take less than 15 seconds. If you are unsure of the ET tube position, leave the first tube in place while applying cricoid pressure. If the patient's pulse oximetry reading is in the mid- to high 90s, reinsert the laryngoscope and look to see if the ET tube is passing between the vocal cords. Alternatively, the ET tube can be removed and intubation reattempted. If the pulse oximetry is low, remove the ET tube and ventilate the patient with a bag-valve-mask device for 30 to 60 seconds to allow the pulse oximetry to rise into the high 90s before making a second attempt at intubation. **Do not ventilate the patient by a bag-valve-mask without the application of cricoid pressure. The stomach can inflate with air and increase the risk of aspiration.**

Some physicians prefer to leave the misplaced ET tube in place. Leaving the first tube might seem to complicate subsequent intubation attempts but can serve to vent gastric vomit out of the oropharynx as well as to locate the esophageal entrance during the next attempt at direct visualization of the airway.

As long as ventilation is possible with the bag-valve-mask device and pulse oximetry can be maintained above 92% ($PO_2 = 60$ mmHg), two or three attempts can be made at orotracheal intubation. If 30 seconds elapse or pulse oximetry falls to 92%, stop the intubation attempt and ventilate the patient for 30 to 60 seconds, as above. In training programs, the third attempt should be made by the most skilled person available. Three failed attempts define a "failed airway" and call for rescue intubation by an alternative method. **Any patient in whom bag-valve-mask ventilation becomes impossible must be given a surgical airway.**

AFTERCARE

The ET tube must be secured to prevent it from migrating distally or proximally. The traditional method of wrapping tape around the ET tube then around the patient's head is rarely used today. If used properly, tape functions just as well or better than commercially available ET tube holders.[19] A variety of disposable, relatively inexpensive, and single patient use ET tube holders are commercially available. They are easy to apply, adjust, and reposition if necessary. The basic unit is a nonlatex plastic ET tube holder that positions over the patient's mouth, a cushioned neckband, and Velcro closures for a snug fit. There are many variations of this basic unit.

A nasogastric tube or orogastric tube is often placed after orotracheal intubation to remove air, fluid, and gastric juices from the stomach. This tube must also be secured. It is either taped to the patient's face or to the ET tube to prevent it from migrating distally or proximally. One specific ET tube holder is a novel device that deserves mention. The Intubix™ (Intubix LLC, Houston, TX) is an ET tube holder with a built-in bite guard and orogastric tube side port (**Figure 11-14**). It allows the blind passage of the orogastric tube through the side port as well as securing it in position.

Postintubation management should include pain control, sedation, and paralysis if indicated. The patient should be sedated, and possibly paralyzed depending on the situation, so they do not fight the ET tube and extubate themselves. **The patient should never be paralyzed and not sedated so they are aware and but unable to respond. This is considered cruel.** Administer an opioid analgesic as required for pain control. The patient may require repeated bolus dosing of these medications or a continuous infusion for analgesia, sedation, and/or paralysis depending on their condition.

COMPLICATIONS

HYPOXEMIA AND MISPLACED ET TUBES

Hypoxia is the most destructive complication. It often results from prolonged intubation attempts, with or without proper preoxygenation, and unrecognized misplaced ET tubes. Without adequate oxygenation, irreversible brain injury begins to occur within 2 to 3 minutes. Hypoxia can result in cardiac arrhythmias.

An unrecognized esophageal intubation will result in significant morbidity and mortality. After intubation, the proper ET tube placement should be confirmed by auscultation, chest rise, fogging in the ET tube, end-tidal CO_2 monitoring, and chest radiography. **Any manipulation or movement of the ET tube or the patient's upper body (head, neck, and torso) should be followed by an assessment of the ET tube position. It can easily become dislodged and migrate into the hypopharynx and esophagus.** Other methods to confirm ET tube placement include inserting a fiberoptic bronchoscope through the ET tube and visualizing the tracheal rings and carina (Chapter 21) or inserting a lighted stylet and following the illumination into the trachea (Chapter 17).

CARDIOVASCULAR COMPLICATIONS

Bradycardia can be produced by pharyngeal manipulation. It may be especially pronounced in children because of their higher vagal

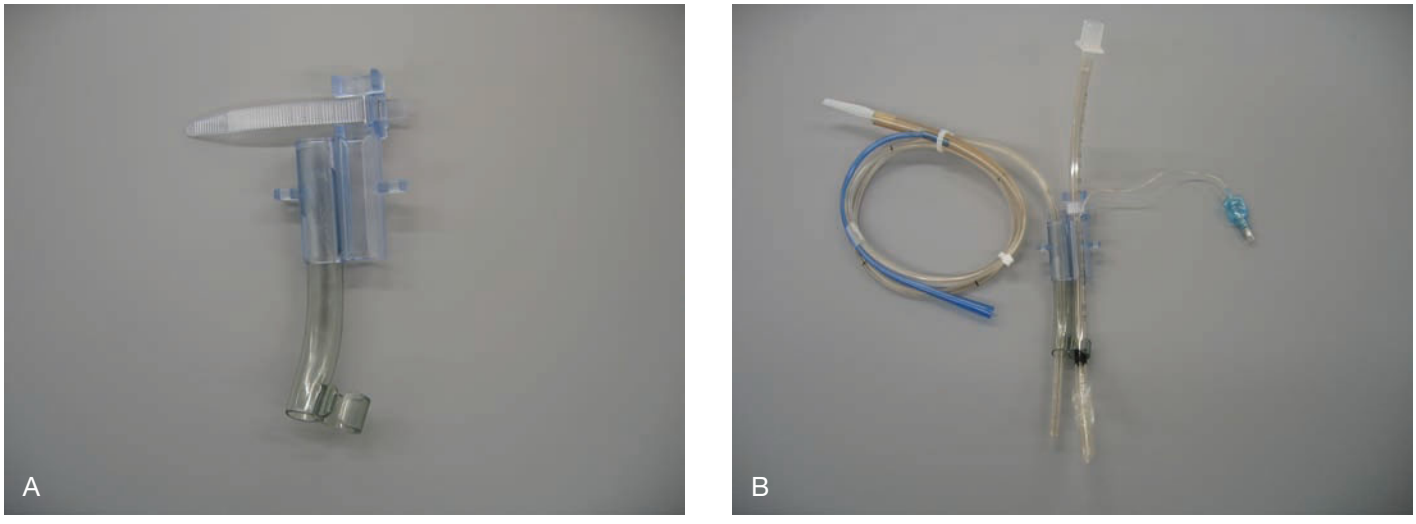

FIGURE 11-14. The Intubix ET tube holder. **A.** The unit. **B.** The unit with an ET tube and an orogastric tube attached.

tone. Pretreatment with atropine (0.02 mg/kg with a minimum dose of 0.15 mg) in children under 6 years of age can avoid this. It will also serve to decrease airway secretions.

Increased intracranial pressure can occur as a result of the direct laryngoscopy. The exact cause of this transient rise is unknown. Lidocaine has been postulated as being of benefit in blunting this but is so far unproven. A dose of 1.5 to 2.0 mg/kg IV may be used as a premedication if time allows and the patient's condition warrants its use.

MECHANICAL COMPLICATIONS

Direct mechanical complications from the laryngoscope include lacerations of the lips, trauma to the pharyngeal wall, broken teeth, or dentures that may be aspirated and require later removal. Vomiting can cause subsequent chemical and bacterial pneumonitis. A pneumothorax is a rarely seen complication of laryngoscopy. It is more often associated with positive-pressure ventilation. Laryngoscopy may cause apnea, bronchospasm, and/or laryngospasm due to prolonged stimulation of the pharynx.

Laryngospasm may result from insertion of the laryngoscope blade or attempts to advance the ET tube through the vocal cords. This occurs more often in patients who are awake, semiconscious, not paralyzed, and not anesthetized. It may be prevented by the application of nebulized lidocaine, topical anesthetic spray, transtracheal injection of lidocaine, or laryngeal nerve blocks. If laryngospasm occurs during intubation, remove the laryngoscope and begin positive-pressure ventilation. **Positive-pressure ventilation will often overcome the laryngospasm. If not, consider paralyzing the patient immediately with succinylcholine or performing a surgical airway.**

The ET tube and stylet can be a source of mechanical complications.[15,17,18] A sore throat is a common and self-resolving nuisance. Uvular necrosis occurs when it is compressed between the ET tube and palate. This rare complication is self-limited and often heals within 2 weeks. Treatment includes antihistamines, steroids, and possibly antibiotics. The stylet protruding from the distal end of the ET tube can cause soft tissue contusions and lacerations, perforation of the vocal cords, hemorrhage into the airway, and perforation of the trachea. Proper stylet placement with its tip within the ET tube will prevent these complications. ET tube cuff overinflation can result in mucosal sluffing, pressure necrosis, and hemorrhage. Tracheal rupture is a rare but life-threatening complication.[17,18] It may be due to cuff overinflation, a protruding stylet, intubation using more rigid and less pliable stylets, pushing through a weakness or defect, or from multiple intubation attempts. The complications associated with cuff overinflation can be prevented by using manometry, which is seldom used.

AIR LEAKS

A "leak" of air out from the patient's mouth or nose during ventilation signifies a mechanical problem with the ET tube. If the cuff is damaged, the ET tube must be removed and replaced. Check the position of the ET tube by direct laryngoscopy. If the cuff is located between or above the vocal cords, it will not secure the airway properly. Deflate the cuff, advance it through the vocal cords, and reinflate the cuff. If the cuff slowly deflates, there may be a leak in the pilot balloon. Reinflate the cuff and apply a hemostat to the tubing attached to the pilot balloon or attach a closed stopcock to the inflation port.

ASPIRATION

The risk of aspiration increases in patients with difficult airways or full stomachs. This includes obese and pregnant patients. The use of an awake ET intubation or rapid sequence induction with cricoid pressure may minimize the risk of aspiration. **A properly placed ET tube with the cuff inflated will decrease, but not totally eliminate, the risk of aspiration.**

THE UTILITY OF THE SELLICK MANEUVER

The use of cricoid pressure was introduced in 1774 in its use to prevent gastric distention during artificial ventilation of drowning victims.[29] Sellick reintroduced the application of cricoid pressure in 1961.[30] Cricoid pressure theoretically causes an occlusion of the upper esophagus by trapping it between the cricoid cartilage and the vertebral bodies. It has since been used on a daily basis for rapid sequence induction by Anesthesiologists and Emergency Physicians. This maneuver was thought to prevent regurgitation and gastric insufflation during positive-pressure ventilation. The application of cricoid pressure was later termed the "Sellick maneuver."

Sellick's original publications were small observational studies self-reporting on his technique. These studies were not blinded, controlled, or randomized. Several subsequent studies determined the amount of force required to occlude the esophagus on cadavers

and patients. It is not practical or possible to measure the cricoid force applied during clinical care in the Emergency Department.

Multiple studies have found adverse effects associated with the Sellick maneuver.[28,31–35] It can worsen the laryngoscopic view of the airway. Other complications include bruising, airway obstruction, cricoid cartilage fracture, goiter hemorrhage, subconjunctival hemorrhage, and esophageal rupture. Cricoid pressure decreases lower esophageal sphincter tone and may explain in part the cases of pulmonary aspiration prior to intubation.

Although the Sellick maneuver is considered a "standard of care," very little evidence supports its use to prevent aspiration.[33–35] This does not mean that the Sellick maneuver should not be performed! It may be of benefit to prevent aspiration, especially in the Emergency Department where patients often have "full stomachs." If intubation or ventilation is difficult using the Sellick maneuver, slowly release cricoid pressure in an attempt to improve ventilation or airway visualization.

ENDOTRACHEAL CUFF PRESSURE

Inflation of the ET tube cuff is required to adequately ventilate a patient without an air leak, provide positive-pressure ventilation, and prevent aspiration. There can be a fine line between proper cuff inflation and overinflation. One of the goals of any procedure is to prevent complications from the procedure itself. Overinflation of the ET tube cuff can result in mucosal necrosis, mucosal sloughing, hemorrhage, tracheal rupture, or subsequent tracheal stenosis. Physicians have traditionally palpated the pilot balloon to estimate cuff pressure and prevent any complications from overinflation. This method is not accurate.[36,37]

Measurement of the cuff pressure is a simple, quick, and inexpensive procedure. It should be considered whenever a patient is intubated.[38] Cuff pressure should be measured if a patient is transported by air as the cuff pressure changes at elevated altitudes.[39,40] A pressure of up to 20 cmH_2O provides an adequate seal, without compromising mucosal blood flow and lowers the risk of subsequent subglottic stenosis. Tracheal mucosal blood flow shows a decline at 30 cmH_2O, and is completely blocked at 45 cmH_2O. An ET tube cuff pressure manometer is needed to measure these pressures accurately.

There are numerous methods to quickly assess cuff pressure. Palpation is not accurate and should not be used. The simplest method is to use a manometer. These devices (Cufflator, Posey Corp., Pasadena, CA or Rusch Endotest, Teleflex Medical, Research Triangle Park, NC) allow the simultaneous inflation of the cuff while monitoring the cuff pressure on a dial. These devices function similarly to those used to inflate a car tire. While simple to use, they can be cumbersome due to their shape and weight. An in-line device that attaches to the cuff inflation port is available (PressureEasy Cuff Pressure Controller, Smiths-Medical, Dublin, OH). The device has an indicator window that signals when the cuff pressure is maintained between 20 and 30 cmH_2O. A third novel device is the Pressure Alert Endotracheal Tube (www.jamesdysonaward.org/projects/project.aspx?ID=598). This device is not yet commercially available. It incorporates a "pop-up" button into the pilot balloon that alerts the user when the cuff pressure is too high.

SUMMARY

Orotracheal intubation is both common and lifesaving. It is the primary and preferred method of airway management. Every Emergency Physician must master this skill. With proper preparation, definitive control of the airway can be obtained. This assures that patients can be oxygenated and ventilated when they cannot do this on their own. Good team leadership skills are nearly as important as physical dexterity and assure an orderly and quick procedure. Rapid patient assessment is important to prevent complications. If orotracheal intubation is unsuccessful, another form of intubation or a surgical airway should be performed.

12 Confirmation of Endotracheal Intubation

Tarlan Hedayati and Leonardo Rodriguez

INTRODUCTION

This chapter will review the various methods utilized to confirm appropriate endotracheal (ET) intubation. **Direct visualization of the ET tube passing through the vocal cords is the preferred method for the initial assessment of a properly placed airway.** Unfortunately, this is not always feasible. Rates for incorrect ET tube placement have been noted to be up to 25%.[1,2] **The verification of correct ET tube placement is as or more important than the intubation procedure. Lack of proper confirmation of ET tube placement has the potential for serious patient harm and catastrophic outcomes if unrecognized and uncorrected.**

For approximately 20 years, there has been ongoing research and development to improve upon the basic techniques of physical examination confirmation of ET intubation. Physical examination with auscultation has been found to be inadequately sensitive (94%) and specific (83%) as an independent method for confirmation of correct ET tube placement.[3] This chapter discusses the use of physical exam findings, esophageal detection devices (syringe and bulb), carbon dioxide (CO_2) detection devices (a qualitative detector and a continuous quantitative monitor), and imaging techniques (radiography and ultrasound). Each method is described for a patient with normal anatomy and the absence of any pathology (e.g., neck or chest trauma). While all these methods can be used in all patients, certain patient conditions or pathology may affect the accuracy of some methods. **No single method is universally or completely reliable, obviating the need for a multiple method approach.** This multiple method approach to confirmation of ET intubation is now the accepted practice according to The American College of Emergency Physicians (ACEP) Board of Directors policy statement as of April 2009.[4]

PHYSICAL EXAMINATION

Since the advent of ET intubation, the use of physical examination methods has been the mainstay for the initial evaluation of proper ET tube placement. Direct visualization of the insertion of the ET tube through the vocal cords and into the trachea is the first method to confirm proper ET tube placement. Postintubation direct visualization of the ET tube using laryngoscopy or bronchoscopy, noting tracheal rings past the end of the ET tube, is the next best method of assessing correct ET tube placement.

Secondary methods for confirmation of ET intubation are an absolute requirement. Auscultate the chest and abdomen to assess for delivery of air to the lungs via either a bag-valve device or a mechanical ventilator (**Figure 12-1**). First, auscultate over the epigastrium to assess for the absence of sounds in the stomach. The presence of an enlarging abdomen or audible air inflation into the stomach with each positive-pressure ventilation may be the initial sign of an ET tube in the esophagus or an esophageal intubation. The next auscultation points are located at the chest wall lateral to the nipples. Auscultate bilaterally from top to bottom for the presence and equality of breath sounds. **Avoid auscultating over the**

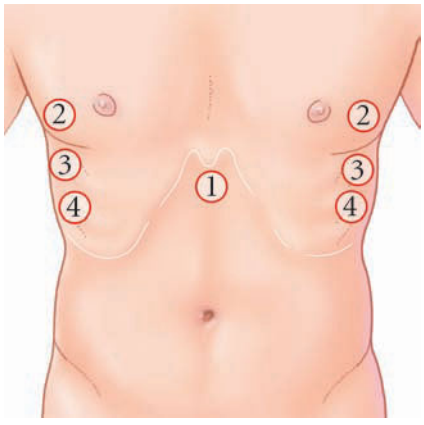

FIGURE 12-1. The order of auscultation after intubation to confirm ET tube placement begins at the epigastrium[1] listening for the absence of air sounds, then down both sides of the chest wall, just lateral to the nipple line.[2–4]

FIGURE 12-2. Examples of the bulb and the syringe esophageal detector device (Photo courtesy of Wolf Tory Medical, Salt Lake City, UT).

central portion of the chest. This may lead to the misinterpretation of the transmission of esophageal or gastric inflation.[5] These sounds may mimic airway breath sounds and lead to failure in detecting an esophageal intubation.

The final note pertaining to auscultation involves equality of breath sounds. The anatomy of the left and right mainstem bronchi allow for a preferential right mainstem bronchial intubation when the ET tube is placed too deep. As a general rule, insertion in centimeters to a depth three times the diameter size of the ET tube (e.g., 21 cm for a 7.0 mm size ET tube) at the level of the incisor teeth is preferred. This will generally place the ET tube approximately 3 to 4 cm above the carina in an adult.[6] If breath sounds are stronger over the right lung fields, deflate the ET tube cuff and gradually withdraw the ET tube in 1 cm increments until the bilateral breath sounds are equal. This will prevent complications from inadequate ventilation and oxygenation as well as resultant pulmonary edema in the nonventilated lung.[7] Please refer to Chapter 11 for a more complete discussion of ET tube size, insertion depth, and placement for adults and children.

The next assessment involves taking a step back and visualizing the chest wall and ET tube characteristics with each breath. Unequal or a lack of chest rise and fall with each instilled breath may indicate a misplaced ET tube either in a mainstem bronchus or in the esophagus, respectively. Condensation and/or fogging in the ET tube with each breath has been used frequently in the past to confirm proper ET tube placement. This has been proven to be an unreliable source of confirmation.[8] It should only be used in conjunction with auscultation and visualization of bilateral chest wall movement. The presence of vomit in the ET tube, in the absence of an aspiration event, may be a sign of an esophageal intubation.

The final postintubation physical assessment is an evaluation of oxygenation via skin signs and, more reliably, pulse oximetry. Cyanosis and a downtrending oxygen saturation seen on a pulse oximeter are delayed findings. The patient may experience significant hypoxemia before cyanosis appears or before there is a significant drop in the pulse oximetry. **Do not rely upon cyanosis and pulse oximetry as a first-line assessment to confirm proper ET tube placement.**

ESOPHAGEAL DETECTOR DEVICES

Esophageal manometer devices utilize the structural differences between the trachea and esophagus in determining correct ET tube placement. The semicircular tracheal cartilaginous rings provide a constant open passage for the flow of air. The tubular esophagus with its lack of a luminal support structure collapses and prevents movement of air when suction is applied.[9] The two types of ET tube confirmation devices that rely on this anatomical variance are the syringe and the manometer or bulb methods (**Figures 12-2 & 12-3**).

The syringe method relies on a gradual and constant retraction of the plunger, while its tip is attached to the proximal end of the ET tube utilizing a manufactured connector (**Figure 12-3**).[10] The plunger will draw back easily and without resistance if the ET tube is correctly placed in the trachea (**Figure 12-3A**). The volume of aspirated air should be greater than 30 mL over a period less than 4 seconds.[11] Resistance when drawing back the plunger is seen when the distal end of the ET tube is incorrectly placed in the esophagus (**Figure 12-3B**). An airtight seal must be created between the syringe and the ET tube to prevent any air leak that would lead to a false-positive test and result in the assumption that the ET tube is in the trachea.

Similarly, the manometer or bulb method relies on the collapse of the esophageal wall. Compress the bulb to remove any air contained within. Firmly and securely apply the bulb to the proximal end of the ET tube while still compressing the bulb. Release compression on the bulb. If the bulb inflates fully and easily, the ET tube is presumably in the trachea. If the bulb does not inflate fully and easily, the ET tube is presumably in the esophagus.

There are numerous circumstances with which an esophageal detector device has repeatedly failed to identify an improperly placed ET tube.[9–14] Most notably is after bag-valve-mask ventilations in the absence of cricoid pressure. The stomach and esophagus can inflate with air and allow for easy flow of air into the device simulating airflow from the airway. The device may fail to detect a misplaced ET tube when the distal end of the ET tube is just above the vocal cords. In this instance, there is no resistance to airflow and the bulb or syringe device easily fills with air.

This method has been shown to falsely identify an esophageal intubation when the ET tube is placed into a mainstem bronchus or the tip of the ET tube is pressed against the tracheal wall. The subsequent resistance to back flow of air into the syringe or bulb mimics that of the collapsed wall of the esophagus. If this should occur, withdraw the ET tube 1 cm and attempt using the esophageal detector device again. Repositioning should continue to result in resistance to aspiration or bulb inflation if the ET tube is in the esophagus. The presence of heavy or thick pulmonary secretions or fluid in the lungs can plug the airways and reduce the flow of air to prevent air aspiration by the syringe or bulb inflation.[12] Care must be taken so

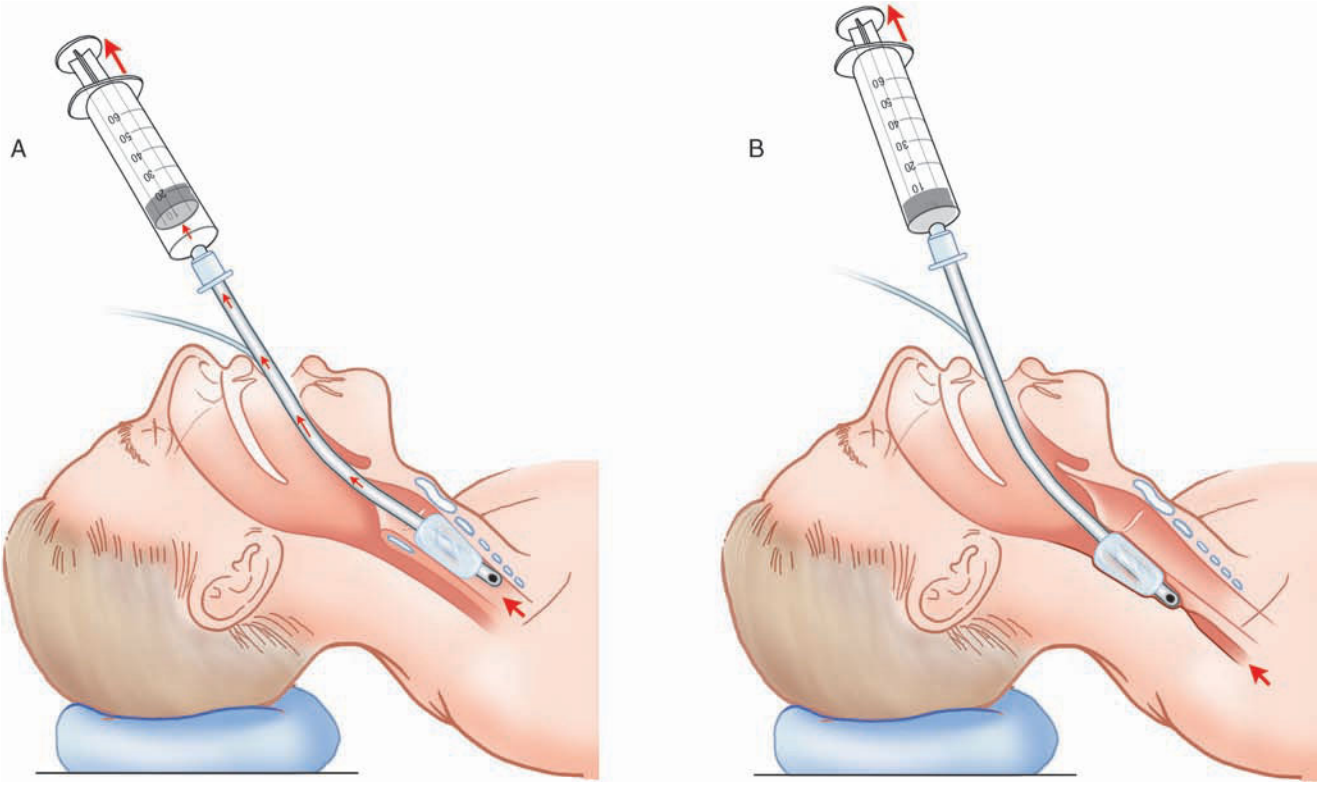

FIGURE 12-3. Using the syringe esophageal detector device. **A.** Correct placement of the ET tube in the trachea allows for aspiration of air. **B.** Placement of the ET tube in the esophagus will result in resistance to aspiration due to collapse of the esophageal wall.

as not to rapidly aspirate and potentially draw the tracheal mucosa into and obstructing the ET tube yielding a false-negative result.[11] In the obese patient, the posterior noncartilaginous segment of the tracheal has been shown to collapse into the trachea and prevent the flow of air.[13–16]

When taking into account the limitations of esophageal detection devices and their use as an adjunct to other methods, they can provide a rapid and inexpensive method for confirming ET tube placement.[17–19] This is especially evident in the patient with circulatory collapse, hypotension, cardiac arrest, or a pulmonary embolism where other devices are limited.[18]

CARBON DIOXIDE DETECTORS AND CAPNOGRAPHY

Since 1985, the utility of end-tidal CO_2 detection as a means for confirming proper ET intubation has been studied and recently confirmed to be the "most accurate" modality according to ACEP.[20] The premise of end-tidal CO_2 detection devices requires the presence of exhaled CO_2 passing through and exiting the ET tube. Adequate circulation is required for CO_2 to be produced and transported from the lung parenchyma. The accuracy of this modality relies on its use in the noncirculatory collapsed/cardiac arrest patient. The April 2009 ACEP Board of Directors statement goes further to state that end-tidal CO_2 detection, using either qualitative or quantitative methods, approaches 100% sensitivity and specificity in the patient with an inflated cuffed ET tube and spontaneous circulation. Nearly every case of a false-negative detection of a correct ET tube placement (i.e., correct ET tube placement in the absence of end-tidal CO_2 detection) has been discovered in the cardiac arrest patient.[15,16,21–25]

End-tidal CO_2 detection devices can be utilized either qualitatively as a one-time spot check using a colorimetric detector or can be monitored continuously via capnography. Both are utilized in a similar fashion. They are in-line devices that have two connectors, one of which attaches to the proximal end of the ET tube and the other attaches to the oxygen delivery device (bag-valve device or mechanical ventilator tubing).

The colorimetric end-tidal CO_2 detector utilizes a piece of pH-sensitive material that lies beneath a clear plastic window. The presence of CO_2 flowing through the device, typically using six manual breaths as the maximum number needed and the minimum amount to clear any gastric CO_2, causes a color change from purple to yellow that then changes back to purple in the absence of CO_2 (**Figure 12-4**). The minimum concentration of end-tidal CO_2 required for a color change is 0.5%. This is one reason that the recent literature has focused on whether newborns and children produce sufficient quantities of end-tidal CO_2 for accurate detection.

Capnography, or continuous quantitative graphical demonstration of end-tidal CO_2 detection, involves placement of an infrared

FIGURE 12-4. Colorimetric end-tidal CO_2 detectors before (left) and after (right) exposure to exhaled CO_2. Note the change in the color of the pH paper from purple to yellow when exposed to CO_2.

detector in-line between the end of the ET tube and the oxygen delivery device (bag-valve device or ventilator tubing). The infrared detector is then connected with a cable to the electronic monitor that interprets the reading and generates a waveform representation of the end-tidal CO_2 levels. One of the advantages of this method over the qualitative approach is the ongoing monitoring of CO_2 production. This allows a continuous assessment of the airway as well as the overall quality of resuscitative efforts with some determination of outcome.[3]

The main disadvantage CO_2 detectors for confirmation of ET intubation are false-negative results in poor perfusion states, cardiopulmonary arrests, and the presence of secretions on the device. In the noncardiac arrest patient with adequate cardiac output and pulmonary flow, sensitivities approach 100% (76% in cardiac arrest) for ruling out esophageal intubation have been found in patients of all ages.[26–28]

If the distal end of the ET tube is located just above the vocal cords in the hypopharynx, a false-positive result may lead the physician to believe the airway is secure. The device may detect adequate levels of CO_2 without a properly secured and definitive airway in the trachea. False-positive results from an improperly placed ET tube erroneously believed to be in the trachea may occur when the device is used a short time after the patient has consumed a carbonated beverage. The device cannot recognize that the CO_2 is actually coming from the stomach.

The universal presence of capnography is not yet a reality. Its utility in most circumstances with few exceptions is undeniable. The colorimetric end-tidal CO_2 detector is equally reliable to capnography. It is a disposable, rapid, less expensive, and more widely available means to assess proper ET tube placement in the noncardiac arrest patient.[20]

RADIOGRAPHY

Although there may be a lack of availability of capnography in most Emergency Departments, this is far less an issue with either radiography or ultrasonography.[29] These methods, unlike those mentioned previously, are unique in that they rely on anatomic relationships for confirmation of ET tube placement. Radiography and ultrasonography may be particularly useful in the cardiac arrest patient.

The main utility for radiography in the confirmation of ET intubation lies in its ability to detect whether the ET tube is placed too deeply into the trachea. Locating the end of the ET tube approximately 3 to 4 cm above the carina may prevent some of the complications associated with a right mainstem intubation. The postintubation chest radiograph can assist in identifying any complications that may have resulted during the intubation. This includes aspiration, tracheal injury, a pneumomediastinum, or a pneumothorax. **The postintubation chest radiograph does little to distinguish between esophageal versus tracheal intubation. The delay in obtaining a radiograph to confirm ET tube placement puts the patient at significant risk.**

ULTRASONOGRAPHY

The use of ultrasound (US) in the Emergency Department has gained significant popularity in the diagnosis of various diseases and pathology. There are multiple methods for utilizing US guidance to assess for proper ET tube placement. Two common methods of confirming proper ET tube placement are described below. The benefits of these two methods are that ventilation is not required for ET tube placement confirmation and, in the case of an accidental esophageal intubation, there is no risk of inflating the stomach, or its resultant emesis and aspiration of gastric contents.

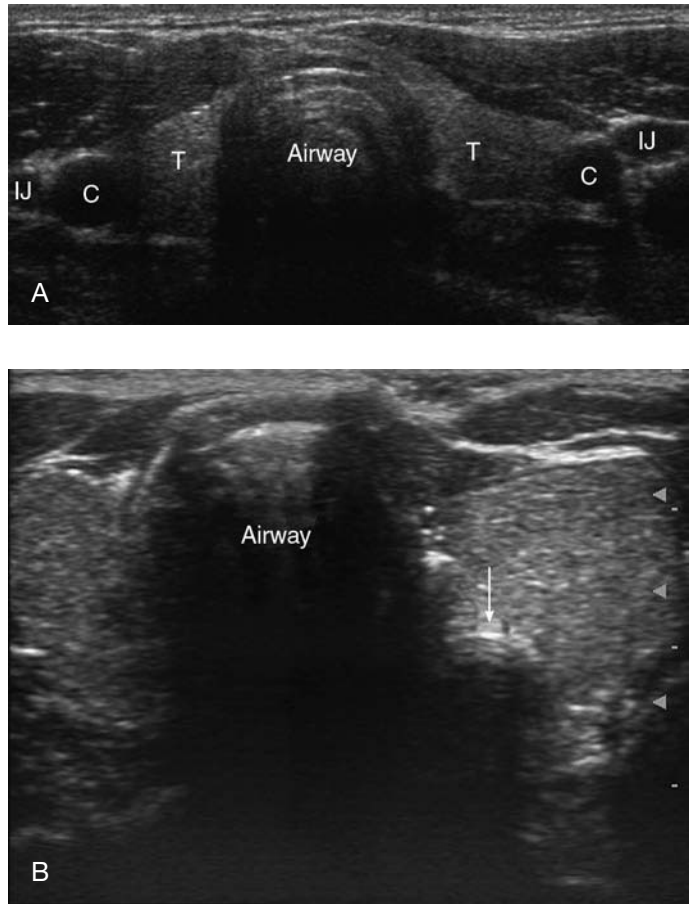

FIGURE 12-5. Ultrasound images at the level of the sternal notch to confirm proper ET tube placement. **A.** Endotracheal intubation. The signature double echo of the plastic ET tube can be seen in the airway or trachea. (C, carotid artery; IJ, internal jugular vein; T, thyroid gland). **B.** Esophageal intubation. The ET tube (*arrow*) is in the esophagus. It is positioned deep and lateral to the airway (Ultrasound images courtesy of Sam Hsu, MD).

The first method uses a high frequency linear US transducer. Place the US probe horizontally at the level of the suprasternal notch. A properly placed ET tube in the trachea will show the shadowing of the ET tube posteriorly without direct visualization of the esophagus (**Figure 12-5A**). In the event of an esophageal intubation, the trachea appears similarly to the previously described image but the esophagus will be visualized just to the left of the trachea with posterior shadowing due to the presence of the ET tube (**Figure 12-5B**). A small, prospective, randomized, controlled study found 100% sensitivity and 100% specificity in the accuracy of US as a modality to confirm ET tube placement.[30]

The second technique uses similar methodology over the cricothyroid membrane. Place the US transducer longitudinally over the cricothyroid membrane to identify and the hyperechoic anterior and posterior laryngeal walls are identified. The appearance of a "snowstorm" pattern between the two lines indicates correct ET tube placement.[31]

Foreign bodies are often hyperechoic and appear bright white on US. One study looked at using US to confirm ET tube placement both with and without a stylet within the ET tube.[34] The basic idea being the addition of the stylet would increase the sensitivity and specificity of identifying correct ET tube placement. It would add additional hyperechoic shadows to those of the ET tube. The use of a stylet did not improve the US localization of the ET tube within the trachea.

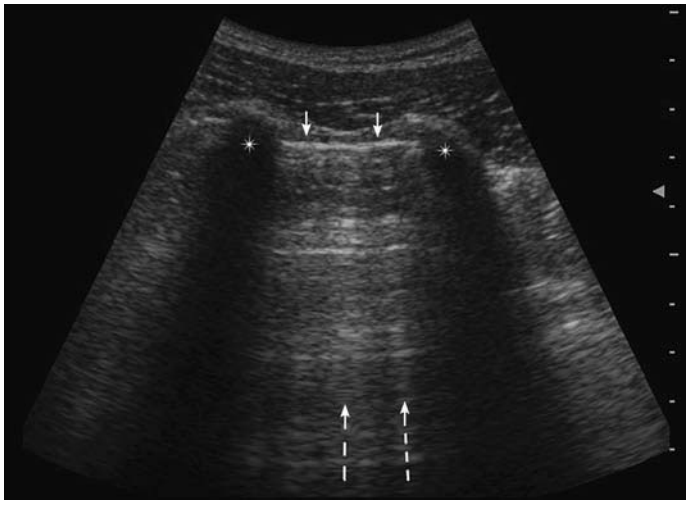

FIGURE 12-6. Ultrasound through the chest wall demonstrating the bright interface (*solid arrows*) of the visceral and parietal pleura generating the "sliding lung sign" during ventilation. The dashed arrows demonstrate echogenic bands moving side-to-side with ventilations. The asterisks (*) identify the ribs (Ultrasound image courtesy of Sam Hsu, MD).

Ultrasonography of the chest wall has been studied as a method of confirming ET tube placement.[32] This method does require ventilation of the patient in that it utilizes the visceral–parietal pleural interface of the lungs to confirm inflation of the lung. Apply the US probe to the anterior-superior chest wall. Orient the US probe vertically over the second and third ribs in the midclavicular line. The visceral and parietal pleural interface can be seen and appreciated as the so-called "sliding lung sign" (**Figure 12-6**). The hyperechoic interface will be seen moving back and forth with each respiration.[32]

TRACHEAL TUBE INTRODUCERS

The tracheal tube introducer (TTI) or gum elastic bougie has long been used by Anesthesiologists to intubate in difficult conditions. The TTI is a flexible rod-like device whose distal end is slightly angled. It is inserted through the patient's vocal cords with the angled tip facing anteriorly during direct laryngoscopy. It is then advanced into the trachea. Advancement of the TTI causes the tip to slide along the anterior tracheal cartilage rings. A "click" is palpable as the tip crosses each tracheal ring. Eventually, the TTI will stop or "hang-up" as it passes into smaller bronchi. The ET tube is then advanced over the TTI and into the lung.

Intubate the patient using direct laryngoscopy. To verify proper positioning of the ET tube, insert the lubricated TTI into the ET tube with the angled tip facing anteriorly. Advance the TTI through the ET tube. The tip should catch on each tracheal ring and "click" to verify proper ET tube position. The lack of any "clicks" or "hang-up" suggests an esophageal intubation. Like all other methods of confirming ET intubation, this method is not 100% perfect.[33]

SUMMARY

Insertion of an ET tube always requires verification that it is properly placed. No one tool or technique is sufficient for any or all situations or circumstances. The best method to confirm proper ET tube placement involves utilizing multiple methods, keeping limitations in mind, and ongoing repeat assessments. Any change in a patient's clinical condition requires reverification that the ET tube is still properly positioned. The ongoing research and development of improved methods obviates the critical importance of rapid and accurate confirmation of ET intubation.

13 Video-Assisted Orotracheal Intubation Devices

Pholaphat Charles Inboriboon

INTRODUCTION

Direct laryngoscopy was introduced in 1895 by Afred Kirstein. Since that time, physicians have developed instruments to improve visualization of the larynx while limiting tissue trauma. The Macintosh and Miller laryngoscope blades were developed in the 1940s and have been the primary tool for endotracheal (ET) intubation.[1] Although they have been effectively used for most ET intubations, there are limitations to their ability to allow direct visualization of the glottis and surrounding structures. Numerous adjuncts have since been developed to assist in ET intubation.[1]

The recent development of video laryngoscopy marks a new era in airway management. Traditional direct laryngoscopy requires alignment of the oral, pharyngeal, and laryngeal axes to visualize the glottis (**Figure 6-5**). Despite mechanical manipulation, it is not always possible to align these three axes. **The major advantage of video laryngoscopy is that it does not require the Emergency Physician to align the three airway axes, reducing the need for manipulation and potential traumatic forces on the airway.[2] Through the use of a video camera, video laryngoscopes provide a superior view of the glottis when compared to traditional direct laryngoscopy. The eye of the video laryngoscope camera is within centimeters of the glottis and provides a wider angle of vision than the 15° of traditional direct laryngoscopy. The video monitor magnifies the view of the airway making structures easier to visualize.** This chapter reviews a representative number and types of devices currently available and used in Emergency Departments.

PENTAX AIRWAY SCOPE

The Pentax Airway Scope (Pentax Medical CO., Montvale, NJ), also known as the Pentax AWS or the AWS, is a rigid video laryngoscope (**Figure 13-1**). It incorporates the blade, camera, and an ET tube targeting mechanism into one device. It is designed for use in the prehospital setting, Emergency Department, and operating room.[3,4]

INDICATIONS AND CONTRAINDICATIONS

The AWS can be used for elective and emergent intubations. Patients with their head and neck immobilized can benefit from intubation with this device. It provides better visualization of the glottis, decreased cervical movement, and a higher success rate in comparison to traditional direct laryngoscopy.[5,6] Intubation with the AWS produces less airway stimulation than either the Glidescope or traditional laryngoscopes, thus minimizing the hemodynamic changes associated with intubation.[6,7] There are no contraindications to the use of the AWS.

EQUIPMENT

The AWS incorporates an imaging system and a targeting system into one portable tool. It is ergonomically designed to minimize tissue trauma. Its use does not require the alignment of the three airway axes. The imaging system provides an illuminated 90° field of view.[3] The AWS produces better glottic visualization than

FIGURE 13-1. The Pentax AWS (Photo courtesy of Pentax Medical Co., Montvale, NJ).

traditional direct laryngoscopy.[32] The external shell is composed of a water-resistant plastic making it suitable for use in the prehospital setting and the Emergency Department.

The body is an integrated 12 cm long cable attached to a charge-coupled device camera and a 2.4 in full-color LCD monitor (**Figure 13-1**). The monitor is hinged and allows a 0° to 120° angle for optimal viewing. The monitor screen incorporates a target symbol used to facilitate intubation. External monitoring and recording can be utilized with the external output. The device is battery operated utilizing two AA alkaline batteries for 1 hour of continuous operation.

The PBLADE is a plastic, single-use, disposable, and transparent laryngoscope blade that attaches to the body of the AWS (**Figure 13-1**). It is designed to follow the natural curvature of the upper airway and minimize the need for manipulation of the three airway axes. The PBLADE is composed of Lexan plastic that resists fogging, but not to the extent of the Glidescope antifogging mechanism.[8] The fiberoptic cable and camera rest inside the cavity of the PBLADE. An ET tube is loaded into a track located on the right side of the PBLADE. It accommodates a size 6.0 to 8.5 ET tube. Through the use of this guided track, intubation is performed without the use of a stylet. Suctioning can be performed under direct visualization with a 4.0 mm (12 Fr) or smaller suction catheter inserted through the PBLADE's suction port.

PREPARATION

Prepare and check the AWS before each use. Turn on the device. The video image and target symbol should appear on the monitor. The power lamp below the monitor should illuminate. Immediately replace the batteries if the monitor displays a flickering battery image. Check the light source. Place a hand below the tip of scope to ensure that it is illuminating. **Do not look directly at the light source.**

Attach the PBLADE to the AWS. Loosen the lock ring on the scope by rotating it in a leftward direction. **Align the triangular marks on the PBLADE and on the AWS body to ensure proper positioning prior to connection.** Insert the flexible fiberoptic tube through the scope insertion port on the PBLADE. Realign the triangular marks. Keep the connector ring pressed in the direction of the scope body and push in the connector of the PBLADE. Release the connector ring. Confirm that the PBLADE is firmly attached and that the tip of the AWS comes into close contact with the scope window. Secure the connection by turning the lock ring in the rightward direction.

Load the ET tube. Liberally lubricate the ET tube with a water-soluble lubricant. Insert the ET tube by sliding it along the ET tube-guide groove. Fix the ET tube onto the hooks located on the proximal end of the PBLADE. Adjust the ET tube so that the tip is aligned with the inferior edge of the PBLADE tip (**Figure 13-1**). Apply medical grade antifogging to the outside of the PBLADE's scope window.

TECHNIQUE

Gently insert the PBLADE into the patient's mouth similar to a traditional laryngoscope blade. Insert it along the right side of the mouth. Gently and slowly advance the PBLADE. Always visually observe the blade as it is inserted to prevent damage to the patient's lips, teeth, and other soft tissues during insertion. **Do not put pressure on the teeth and make sure that the tongue is not pushed inward while inserting the PBLADE.** Once inserted, reposition the device to the midline.

Observe the monitor to visualize the airway and epiglottis. Secretions can be suctioned by introducing a 12 French suction catheter through the suction catheter insertion port. Perform suctioning while observing the location of the suction catheter tip on the monitor. Visualize the epiglottis. Slide the epiglottis lifting blade underneath the epiglottis. Gently elevate the device to elevate the epiglottis. Gently manipulate the device until the glottis is aligned with the target symbol on the monitor screen. Gently advance the ET tube through the glottis until the ET tube marker line reaches the glottis. Inflate the ET tube cuff. Detach the ET tube from the hooks. Gently remove the PBLADE from the patient's mouth while securely holding the ET tube in place. Confirm proper ET tube position.

ALTERNATIVE TECHNIQUES

In rare circumstances, the Emergency Physician cannot be positioned above the patient's head. An inferior or lateral approach can be utilized. Insert the PBLADE as described above. Adjust the position of the screen using the hinge to obtain an optimal viewing angle. Once the epiglottis is visualized, the remainder of the technique is exactly as described previously. It may feel awkward to manipulate the device and the ET tube from a position inferior or adjacent to the patient's head.

Insertion of the fully assembled AWS may not be possible in obese patients and others with large chests.[9] Separate the PBLADE loaded with the ET tube from the AWS. Insert the PBLADE into the oropharynx under direct visualization. Gently and carefully reattach the AWS to the PBLADE. Be careful not to traumatize the patient's lips, teeth, or airway soft tissues. Once the device is reassembled, proceed with intubation as described above.

This technique can be used for patients in which deep sedation and induction are contraindicated. An off-label technique for awake intubation has been described.[10] Assemble the device. Attach a Bodai connector to the proximal end of the ET tube. Insert a 14 French suction catheter into the lumen of the ET tube via the Bodai connector. Attach the breathing circuit to the other branch of

FIGURE 13-2. The McGrath Laryngoscope. **A.** The device. **B.** The blade has been inserted and the ET tube is advanced through the vocal cords (Photos courtesy of LMA North America, San Diego, CA).

the Y-connector to administer oxygen at a rate of 10 L/min. Insert a tracheal spray tube, smaller than 12 French, through the original suction channel. Attach a syringe loaded with topical anesthetic solution to the proximal end of the tracheal spray tube. Suctioning can be performed through the ET tube as the PBLADE is advanced. The topical anesthetic agent can be delivered via the spray tube. Once the glottis is visualized, the local anesthetic solution can be delivered to and through the vocal cords prior to advancing the ET tube through the glottic opening.

COMPLICATIONS

Placement of the AWS may not be possible in patients with limited mouth opening.[4] The diameter of the PBLADE is approximately 2.5 cm. An alternative airway device should be readily available if paralysis does not improve mouth opening. Visualization of the vocal cords can be limited by secretions.[11] A suction catheter should always be readily available. Insert the PBLADE slowly to prevent it from being inserted into pooled secretions. Visualization may not be possible despite aggressive suctioning in the case of particulate matter or severe bleeding. If this occurs, be prepared to use an alternative airway device. Incorrect or forceful insertion can result in dental trauma and soft tissue injuries. The other complications associated with this device are similar to those of direct laryngoscopy.

Since the ET tube is loaded onto the PBLADE, its maneuverability is limited. Employ a bougie in cases where visualization of the glottis is possible but intubation is not successful. Align the PBLADE and ET tube as much as possible with the glottis. Pass a bougie through the ET tube. Advance and direct the bougie through the vocal cords. Slowly and gently advance the ET tube over the bougie under video guidance.[11]

Despite a quicker time to visualization and insertion of the ET tube, the time from initiation of intubation to ventilation is not significantly different from traditional direct laryngoscopy.[8] It is speculated that this is due to the increased time it takes to remove the ET tube from the AWS postintubation. The time to ventilation can be reduced by beginning manual ventilation before removal of the PBLADE from the oropharynx. This technique should be considered in patients that are hypoxic postintubation.[4]

McGRATH LARYNGOSCOPE

The McGrath Laryngoscope (LMA North America, San Diego, CA) is a video laryngoscope that is designed to provide a clear video view of the glottis with minimal changes in the traditional direct laryngoscopy technique. It is the most portable video laryngoscope and modeled after the traditional Macintosh laryngoscope blade (**Figure 13-2A**). It is a refinement of the "smart scope" laryngoscope developed by Matt McGrath. As a British university student, he won the 1999 Royal Society of Arts student design competition for outstanding design achievement for his portable laryngoscope with a small video monitor attached to the handle.[8]

INDICATIONS AND CONTRAINDICATIONS

The McGrath laryngoscope is indicated for elective and emergent intubations. It is useful in difficult intubations in which the three airway axes may be difficult to align.[2,12–14] This includes patients with cervical spine immobilization, limited mouth openings, tongue edema, and high Cormack and Lehane grade airways. It is indicated for use in pediatric patients weighing 15 kg or more.[15] The McGrath laryngoscope is not indicated for use in awake intubations.[16]

EQUIPMENT

The McGrath laryngoscope consists of three main components: the handle module, the camera stick, and the blade (**Figure 13-2A**). The handle module houses the power source and the video monitor. The nonslip rubberized handle contains a single AA battery and the power switch. At the crown of the handle module rests the 1.7 in color LCD monitor. The monitor can rotate around the handle 360° and can be tilted to adjust the viewing angle. The camera stick houses the camera and light source. Its length is adjustable to produce a blade length ranging from a Macintosh size 3 to 5 blade. The disposable single-use plastic blade fits over the distal camera stick to protect the camera and to assist in lifting of the epiglottis.

PREPARATION

Preparing the McGrath laryngoscope for use is quite simple. Unscrew the cap on the top of the handle and insert the AA battery. The top of the handle is opened by turning it counterclockwise and closed by turning it clockwise. Apply the camera stick onto the handle. Pull out the release safety catch at the base of the handle and rotate it so that it is aligned parallel to the long axis of the camera stick. Slide the camera stick into the base of the handle. Return the safety catch to its original position. Firmly attach the disposable sterile laryngoscope blade to the camera stick. Slide it over the camera stick until it firmly latches. Adjust the blade length by sliding the camera stick through the clamp handle. A click will be heard for

each adjustment in the blade size. Turn the power on by pressing the power switch on the top of the handle. The LED light on the LCD monitor will be continuously lit if there is adequate battery power. If it blinks, the battery power is low and the battery should be changed prior to using the device.

TECHNIQUE

The intubation technique using the McGrath laryngoscope is similar to that used in traditional direct laryngoscopy.[16] Insert the tip of the blade in the midline and superior to the tongue. Slowly advance the blade and rotate its tip toward the larynx in the sagittal plane until the epiglottis is visualized via direct visualization or via indirect visualization using the camera monitor. Further advance the blade until its tip rests in the vallecula. Gently lift the blade until the glottis is visualized. Gently elevate the device to elevate the epiglottis. The monitor should show the vocal cords as well as the surrounding structures (**Figure 13-2B**). If only a portion of the vocal cords is visible, slightly withdraw the blade until the desired view is obtained (**Figure 13-2B**). Gently manipulate the device until the glottis is centered on the monitor screen. Insert and advance the proper size ET tube through the vocal cords with the assistance of either a malleable stylet or a bougie. The ET tube with a stylet should ideally be hockey stick shaped 5 cm from the tip of the ET tube to optimize maneuverability.[12] Gently advance the ET tube through the glottis until the ET tube marker line reaches the glottis. Inflate the ET tube cuff. Withdraw the stylet or bougie. Gently remove the blade from the patient's mouth while securely holding the ET tube in place. Confirm proper ET tube position.

ALTERNATIVE TECHNIQUE

An alternative technique can be performed in those patients with limited mouth opening or chest anatomy that prevents placement of the device into the oropharynx using the traditional laryngoscopic technique.[13] Disarticulate the camera stick from the handle to facilitate placement of the blade into the oropharynx. Insert the camera stick and blade similar to introducing a tongue depressor into the oral cavity. Attach the handle to the camera stick. Intubate the patient as previously described.

COMPLICATIONS

If the epiglottis obstructs visualization of the glottic opening, apply greater upward force to lift the epiglottis. If this is not successful, the plastic blade may be used in the same manner as a miller blade. Redirect the blade to lift the epiglottis, visualize the glottis, and intubate as previously described. Incorrect or forceful insertion can result in dental trauma and soft tissue injuries. The other complications associated with this device are similar to those of direct laryngoscopy.

If the monitor image is unclear, check for fogging. Apply an antifog solution as needed.[8] A blurred image can result from the blade not being latched onto the camera stick. The video lens should be flush with the viewing window of the blade. If neither of these maneuvers is successful, remove the blade from the device and clean the camera lens with a gentle soft wipe.

A grade I view may be obtained of the glottis yet the ET tube cannot be advanced into the trachea. This may be due to the acute bend and long flange of the blade.[30] The device provides a view of the glottis without the alignment of the three airway axes. This requires the ET tube to have a more acute bend than normally used for direct laryngoscopy. Place an acute bend in the styletted ET tube approximately 7 to 10 cm from the tip. Another option is to advance the ET tube into the glottis while simultaneously withdrawing the stylet, thus not inserting the styletted ET tube into the glottis.

FIGURE 13-3. The Berci–Kaplan DCI Video Laryngoscope (Photo courtesy of Karl Storz Endoscopy-America, El Segundo, CA).

BERCI–KAPLAN DCI VIDEO LARYNGOSCOPE

The Berci–Kaplan DCI video laryngoscope is a video Macintosh intubating laryngoscope developed by Drs. Kaplan, Ward, and Berci (Karl Storz Endoscopy-America, El Segundo, CA).[17] It incorporates micro video imaging technology into a traditional laryngoscope blade. This reduces the learning curve in operating this device for those experienced with traditional direct laryngoscopy. It is ideal for use when training the novice in the traditional direct laryngoscopic technique.[17,18] A fiberoptic bundle extends from the proximal end of the laryngoscope blade allowing for a larger angle of viewing and a magnified view of the airway. This video laryngoscope has been marketed for use as part of an "all-in-one" video intubation system (**Figure 13-3**).

INDICATIONS AND CONTRAINDICATIONS

The video laryngoscope is indicated for normal and difficult intubations, in both pediatric and adult patients. The large video screen makes this device particularly useful for difficult intubations requiring external manipulation of the airway by an assistant. There are no contraindications to the use of the video laryngoscope.

EQUIPMENT

The video laryngoscope device consists of various laryngoscope blades, the DCI camera head, and the control unit. The video laryngoscope blade houses the camera optics. It is available in Macintosh (sizes 3 and 4), Miller (sizes 0, 1, and 3), and the Doerges universal blade styles. The lens provides a viewing angle of 60° to 80°, depending on the type of laryngoscope blade. The laryngoscope blade is

integrated into the ergonomic handle (**Figure 13-3**). The handle attaches to the camera head, the interface between the control unit and the video laryngoscope. Other interchangeable airway devices can be attached to the control unit including the Bonfil's scope, Brambrinck scope, and fiberoptic scope. The control unit incorporates the light source, an image processing module, imaging memory, power supply, a keyboard, and a color LCD monitor.

PREPARATION

Attach the selected laryngoscope blade to the camera head. Turn on the control unit. The laryngoscope blades can be changed with the control unit powered on. Apply medical grade antifogging solution onto the camera lens.

TECHNIQUE

An advantage of this video laryngoscope is that the intubation technique does not differ from that of traditional direct laryngoscopy. The added benefit of indirect visualization is that less force is needed to visualize the glottis. An assistant can view the monitor to facilitate external manipulation of the larynx to bring the glottis into view. The ET tube can be passed through the glottic opening under either direct or video-assisted visualization. Gently advance the ET tube through the glottis until the ET tube marker line reaches the glottis. Inflate the ET tube cuff. Withdraw the stylet or bougie. Gently remove the blade from the patient's mouth while securely holding the ET tube in place. Confirm proper ET tube position.

ALTERNATIVE TECHNIQUE

A limitation of this video laryngoscope is its relatively large handle with cables protruding from its proximal end. This can impede intubation in patients with large chests, short necks, or cervical spine immobilization.[19] Insert and advance the laryngoscope blade into the patient's mouth from the side. Gently rotate and return the laryngoscope handle into the midline once the blade is deep enough and the handle can clear the chest. Proceed with intubation as previously described.

COMPLICATIONS

A known issue with this video laryngoscope is lens fogging. This is particularly problematic in patients that are not fully paralyzed. This can be prevented by applying a medical grade antifogging solution, a thin layer of water-soluble lubricant, or the patient's saliva on the lens.[19] Blood and other secretions can obscure the view. This can be reduced by not inserting the laryngoscope blade into pooled secretions and by the use of suctioning.[19] Incorrect or forceful insertion can result in dental trauma and soft tissue injuries. The other complications associated with this device are similar to those of direct laryngoscopy.

Common barriers to purchasing this device are its cost and its large size. The large size of the control unit limits its portability unless it is placed on a rolling cart. Despite this, the control unit can be used in conjunction with several other of the companies airway devices. This makes it a worthwhile investment in Emergency Departments that utilize other compatible airway devices.[19]

C-MAC VIDEO LARYNGOSCOPE

The C-Mac (Karl Storz Endoscopy-America, El Segundo, CA) is a video laryngoscope system released in 2009 (**Figure 13-4A**). It replaces the original video laryngoscope by Karl Storz. It has numerous advantages including being more compact and portable, the blade width is decreased, and the video technology has been

FIGURE 13-4. The C-Mac Video Laryngoscope. **A.** The C-Mac system. **B.** The C-Mac. **C.** The C-MAC PM (Photos courtesy of Karl Storz Endoscopy-America, El Segundo, CA).

improved. The original video laryngoscope incorporated a fiberoptic camera and video system into a traditional laryngoscope blade. The C-Mac abandons this technology for a CMOS micro video camera. This allows the video system to be incorporated within the laryngoscope blade. The CMOS micro video camera provides an enhanced area of view and does not have the issue of fogging.

INDICATIONS AND CONTRAINDICATIONS

The C-Mac video laryngoscope is indicated for normal and difficult intubations, in both pediatric and adult patients. There are no contraindications to the use of the video laryngoscope.

EQUIPMENT

The completely handheld portable C-Mac consists of three main components: the blade, the electronic module, and the monitor (**Figure 13-4B**). The blade reproduces the curvature of the traditional Macintosh blade and is composed of stainless steel. The proximal end has been flattened to reduce the amount of mouth opening required for intubation and to reduce the risk of oral trauma. The lens is located approximately one-third of the distance from the tip of the blade and provides a 60° field of vision. The CMOS chip housed in the blade provides lens antifogging and an optimal image quality. The blade is available in several sizes.

The electronic module is the interface between the laryngoscope blade and the monitor unit. The module permits easy operator-controlled video documentation. Images can be recorded as still shots or video sequences using the incorporated key pads.

The 7 in, high-resolution monitor is housed in an impact-resistant and splash-protected plastic body. The top of the monitor has an integrated secure digital (SD) memory card and an USB port for video recording and transfer. The monitor automatically white balances when it is turned on. The monitor image can be further modified using the touch key controls to the right of the monitor screen. The monitor device also houses a lithium ion battery with a 2 hour operating time when fully charged.

Several new attachments make the C-Mac quite versatile (**Figure 13-4A**). The C-Mac PM incorporates a 2.4 in LCD monitor that inserts into the laryngoscope handle (**Figure 13-4C**). This eliminates the electronic module, cord, and base unit. The LCD monitor unit can be used with all the C-Mac laryngoscope blades. The C-Cam is a camera head that attaches to the monitor unit. Through this, numerous other airway devices can be attached including all Storz airway devices, the Bonfil's scope, and other fiberoptic scopes (**Figure 13-4A**).

PREPARATION

Preparing the C-Mac for use is quite simple.[20] Insert the electronic module into the video laryngoscope blade receptacle. The blade can later be changed while the monitor is on. Insert the yellow connection cord of the electronic module into the yellow socket on the back of the monitor. If the battery symbol turns red, connect the power cord into the blue socket on the back of the monitor and plug in the power supply. The battery sign will indicate that the unit is charging. Insert an SD card into the monitor for recording and image capture. An alternative is to connect an external video recording source into the USB port.

Turn on the C-Mac using the power switch located at the left lower corner of the display monitor. Check the camera for proper functioning by focusing the lens under the laryngoscope blade on your hand. The camera's light source should be visible on the hand. The light intensity, color saturation, and contrast can all be adjusted using the key pads located on the monitor. Wipe the lens with a soft cloth or lens tissue if the video image is blurry. If this does not improve the image, clean the contacts of the electronic module. Recording can be performed by pressing the record button located on the laryngoscope blade handle.

TECHNIQUE

The intubation using the C-Mac is exactly the same as using traditional direct laryngoscopy.[20] Insert the laryngoscope blade into the oral cavity under direct visualization. Advance it past the oropharynx and into the vallecula. Lift the laryngoscope handle upward to improve visibility. Visualization can be performed by either direct visualization or via the monitor. Gently advance the ET tube through the glottis until the ET tube marker line reaches the glottis. Inflate the ET tube cuff. Withdraw the stylet or bougie. Gently remove the blade from the patient's mouth while securely holding the ET tube in place. Confirm proper ET tube position.

COMPLICATIONS

Incorrect or forceful insertion can result in dental trauma and soft tissue injuries. The other complications associated with this device are similar to those of direct laryngoscopy.

GLIDESCOPE

The Glidescope (Verathon Inc., Bothell, WA) combines a video camera with a patented antifog system into a portable laryngoscope blade and monitor system. The blade design modifies the traditional Macintosh blade curvature to provide a more anterior view of the larynx. The Glidescope was developed by a Canadian surgeon.[8] Modifications in the basic design have resulted in several models (**Figure 13-5**). The Cobalt Glidescope utilizes a single-use disposable blade for a rapid turnaround without sterilization between uses.[21] The Ranger Glidescope models provide a compact, high impact device originally intended for military and prehospital use.[22]

INDICATIONS AND CONTRAINDICATIONS

The Glidescope is indicated for routine and difficult intubations. It is particularly useful for patients requiring cervical spine immobilization. It has been demonstrated to have a significant advantage over the Macintosh blade in the patient with tongue edema.[23] It can be used in pediatric patients that weigh as little as 1.8 kg. There are no reported contraindications for using this device.

EQUIPMENT

The primary components of the Glidescope are the blade and the video monitor. In the traditional Glidescope and the traditional Ranger Glidescope, all of the blade models incorporate an auto focusing CMOS camera, a LED light source, and a patented antifogging mechanism housed inside of a medical grade plastic shell. The Glidescope blade begins with the traditional Macintosh blade and adds a 60° curvature at the midpoint. This allows for a more anterior view of the airway with less lifting force required.[8] The camera lens lies at the distal aspect of the blade's curve to protect it from secretions while providing a close-up view of the glottis. The Glidescope produces better glottic visualization than traditional direct laryngoscopy.[31,33–35]

The traditional Glidescope blade is a reusable integrated blade and handle. It is available in four sizes. The traditional Ranger blade consists of a reusable integrated blade, a handle, and a video cable that cradles into the body of the Glidescope monitor. It is currently available in two sizes. The Ranger single-use blades are available in six sizes.

FIGURE 13-5. The Glidescope Video Laryngoscope. **A.** The Glidescope GVL system. **B.** The Glidescope AVL system. **C.** The Glidescope Ranger system (Photos courtesy of Verathon Inc., Bothell, WA).

The Glidescope cobalt and Ranger single-use blade consists of a video baton and a STAT blade. The video baton houses the CMOS camera, LED light, and antifogging mechanism. The baton is inserted into a onetime use STAT blade constructed of medical grade plastic. The STAT blade is shaped like the traditional Glidescope blade and provides the protective cover for the baton, reducing the risk of transmitting an infection.[23] This dramatically reduces Glidescope turnaround by eliminating the 30 minutes required to clean traditional blades prior to re-use.[21,23] The baton is available in two sizes and four blade sizes.

The blades are connected to the video monitor through a video cable. The traditional Glidescope and the Cobalt Glidescope have a 7 in, nonglare, color LCD monitor. Housed within the monitor are the battery and the power source. The monitor includes the power switch and control pads that allow adjustment of the video image. The Ranger versions have a rugged shell for field use and a 3.5 in color, nonglare LCD. The body of the monitor incorporates a cradle for the blade. The Ranger Glidescope utilizes a rechargeable lithium ion battery. When fully charged, it can be used for 90 continuous minutes or approximately 20 intubations.[22] Many of the Glidescope models come with the GlideRite rigid stylet, though it is not required for intubation. It is a rigid stylet designed to complement the angle of the Glidescope blades. Intubation with the GlideRite rigid stylet offers no advantages over the standard malleable stylet.[36]

PREPARATION

Preparing the Glidescope for use is quite simple. Attach the Glidescope blade to the monitor using the video cable. Turn on the device and it is ready for use. For the Cobalt and single-use Ranger models, insert the baton into the STAT blade. A click will be heard to confirm that the blade has been securely attached. It is not required to use the GlideRite rigid stylet. It is recommended to curve the malleable stylet 90° to model the shape of the Glidescope blade to facilitate manipulation of the ET tube.[8,21,22,24–26]

TECHNIQUE

The intubation technique using the Glidescope is similar to that of traditional direct laryngoscopy.[21,22] Insert the blade into the midline of the oral cavity. Advance the blade under direct visualization until its tip reaches the pharynx. Continue to advance the blade while observing the monitor to identify the epiglottis. Advance the blade into the vallecula. Lift the blade, if necessary, to elevate the epiglottis. Under direct visualization, insert the ET tube until its tip nears the tip of the laryngoscope blade. Guide the ET tube toward the glottic opening. Pull the GlideRite stylet back approximately 2 cm and advance the ET tube through the vocal cords. This will facilitate passage of the ET tube through the vocal cords while reducing the potential for injury. Gently advance the ET tube through the vocal cords until the ET tube marker line reaches the glottis. Inflate the ET tube cuff. Withdraw the stylet. Gently remove the blade from the patient's mouth while securely holding the ET tube in place. Confirm proper ET tube position.

COMPLICATIONS

Use of a Glidescope for intubation can increase the time to advance the ET tube through the vocal cords when compared to intubation using direct laryngoscopy.[6] This difference in time decreases with increased use and familiarity with the device.[27] It is strongly recommended that novice operators use the Glidescopes on mannequin models and for "routine" intubations prior to using it as a rescue device for difficult intubations.

Intubation with the Glidescope can be difficult in patients with small mouths or large tongues due to the limited area for both the blade and ET tube. In these cases, it may be difficult to pass the ET tube into the larynx. Do not blindly insert the ET tube as it may cause injury to the oropharyngeal tissues.[28] If space is a problem, insert the Glidescope under direct visualization and then move it to the left. The ET tube can then be inserted under direct visualization. The view on the monitor of the larynx may appear deviated.[28] Manipulate the Glidescope to obtain an optimal view on the monitor. An additional technique is to shape the ET tube into a hockey stick or j-curve to facilitate advancement and manipulation from the lateral aspect of the mouth.[6] Incorrect or forceful insertion can result in dental trauma and soft tissue injuries. The other complications associated with this device are similar to those of direct laryngoscopy.

CLARUS VIDEO SYSTEM

The Clarus video system (Clarus Medical LLC, Minneapolis, MN) is a device that can be modified with various accessories for use as a video laryngoscope, an ET tube exchange catheter, a flexible scope, and a malleable stylet.[29] It incorporates the video, lighting, power, and monitor system into one handheld product (**Figure 13-6**). The malleable video stylet shaft and the disposable video laryngoscope blade are designed for intubation.[29] The optional flexible scope is detachable for use as an ET tube exchange catheter.

FIGURE 13-6. The Clarus Video System (Photo courtesy of Clarus Medical LLC, Minneapolis, MN).

INDICATIONS AND CONTRAINDICATIONS

The Clarus Video System is intended for use in performing and confirming placement of an ET tube. It is indicated for use alone or as a video stylet in conjunction with a standard laryngoscope. It can be used for routine and difficult intubations. There are no contraindications to using this device.

EQUIPMENT

The handle of the video system houses the rechargeable power unit. The color LCD display monitor attaches to the handle. The monitor viewing angle can be adjusted with an easy to reach thumb control. The light intensity can be adjusted using controls on the handle. The handle also contains the external video connector and the battery charger port. The distal lens, light LED, and camera are housed in the distal tip of the video stylet shaft.

A disposable tube stop fits on the malleable video stylet to hold the ET tube at the desired height on the stylet. An oxygen port can be connected to the tube stop to supply supplemental oxygen through the ET tube. A detachable and flexible video scope is available for use during ET tube exchange.

PREPARATION

Preparing the Clarus video scope for use requires the device to be assembled. Place the disposable tube stop over the stylet shaft.

Attach the oxygen port to the matching circular receptacle on the tube stop. Attach oxygen tubing to this port if desired. The oxygen flow rate and pressure must be monitored to prevent barotrauma.[29]

Apply an ET tube with a minimum diameter of 5.5 mm and a maximum length of 34.3 cm over the distal tip of the stylet and fitted to the tube stop. Consider applying a water-soluble lubricant onto the stylet to facilitate this process.[29] Consider applying a medical grade antifogging agent to the lens on the stylet tip. Adjust the tube stop so that the stylet tip rests just proximal to the distal end of the ET tube in order to provide optimal visualization and reduce the potential for tissue trauma. Tighten the clamp screw on the tube stop to fix the position of the ET tube onto the stylet shaft. The image on the monitor screen should automatically focus when the device is turned on. The illumination can be adjusted using the dial on the monitor.

TECHNIQUE

Once the device has been properly assembled, it can be used for intubation with a traditional laryngoscope. Insert the laryngoscope and attempt to visualize the vocal cords and other surrounding structures. If visualized, insert the ET tube on the Clarus stylet similar to performing traditional direct laryngoscopy. Visualization of the airway structures may not be possible in patients with difficult airways or those requiring cervical spine immobilization. Use the monitor on the Clarus Scope to direct, manipulate, and advance the styletted ET tube through the glottis. Gently advance the ET tube through the glottis until the ET tube marker line reaches the glottis. Inflate the ET tube cuff. Withdraw the Clarus stylet. Gently remove the laryngoscope blade from the patient's mouth while securely holding the ET tube in place. Confirm proper ET tube position.

COMPLICATIONS

Incorrect or forceful insertion can result in dental trauma and soft tissue injuries. The other complications associated with this device are similar to those of direct laryngoscopy.

KING VISION VIDEO LARYNGOSCOPE

The King Vision Video Laryngoscope (King Systems Inc., Noblesville, IN) is a battery operated, rigid, and portable digital video laryngoscope (**Figure 13-7**). It is simple to use and understand. The King Vision is significantly less expensive than most other video laryngoscopes. The device uses newer organic light emitting diode (OLED) technology.

FIGURE 13-7. The King Vision Video Laryngoscope (Photo courtesy of King Systems Inc., Noblesville, IN).

INDICATIONS AND CONTRAINDICATIONS

The King Vision is indicated for routine and difficult intubations. It can be used in both adolescent and adult populations. The laryngoscope blade is equivalent to a Macintosh #3 size blade. There are no contraindications to using this device as long as a Macintosh #3 blade is appropriate for intubation.

EQUIPMENT

The King Vision has a two-piece design consisting of the color OLED monitor base unit that attaches to a disposable laryngoscope blade (**Figure 13-7**). The two pieces snap together. The monitor unit houses three AAA batteries as the power source, the on/off switch, and a mini USB port for video output to a display monitor or recording device. The batteries provide at least 90 minutes of "on time". The OLED monitor offers increased contrast at a lower cost than LCDs and LEDs. In addition, the monitor is brighter, faster, lighter, thinner, and uses less power than LCDs.

The blades are plastic, single use, and disposable. They are available in two styles, with and without an ET tube channel. The channelled blade accommodates a 6.0 through 8.0 ET tube. The blade is currently only available in a Macintosh #3 size. It differs from the standard Macintosh #3 blade in that it is slightly shorter and wider than the Macintosh #3 blade. The blade is smaller than most video laryngoscopes. It requires a minimum mouth opening of 13 mm for the standard blade and 18 mm for the channelled blade. A CMOS camera and a LED light source are mounted on the disposable blade. The lens has an antifog coating.

PREPARATION

Preparation of the King Vision is quick and simple. Ensure that the power is off. Applying a blade with the unit powered on will result in image distortion. Choose a laryngoscope blade either with or without a channel. Slide the blade onto the monitor piece and snap it in place. The front and back of both the blades and the monitor unit are color coded to facilitate proper orientation. The blade with a channel can be used with or without an ET tube inserted into the channel. If desired, load an appropriate size ET tube (size 6.0 through 8.0) without a stylet into the well-lubricated channelled blade. Use only water-soluble lubricants. Avoid placing lubricant over the lens. Align the distal tip of the ET tube with the end of the channel. Turn on the device. Replace the batteries if the battery indicator light is flashing red. Observe the monitor to ensure that an image is present and clear. The image will be distorted if the unit was powered on when the blade was attached. Simply turn the unit off and then back on to obtain a clear image. The tip of the ET tube, if using the channelled blade, should not be visible on the monitor. If it is visible, pull the ET tube back until the tip is aligned with the tip of the blade and no longer visible in the monitor.

TECHNIQUE

The technique for intubation is similar to traditional direct laryngoscopy if using the standard blade or the channelled blade without loading an ET tube. Insert the blade in the midline and advance it into the oropharynx. Continue to advance the blade toward the vallecula while observing the monitor. The blade can be placed into the vallecula like a Macintosh blade or can be used to elevate the epiglottis like a Miller blade. Use the monitor to direct, manipulate, and advance the styletted ET tube through the glottis. Gently advance the

ET tube through the glottis until the ET tube marker line reaches the glottis. Inflate the ET tube cuff. Withdraw the device. Gently remove the laryngoscope blade from the patient's mouth while securely holding the ET tube in place. Confirm proper ET tube position.

A slight technique modification is required if mounting an ET tube into the channelled blade. Insert the blade as described previously. Center the glottic opening on the screen. Slide and advance the ET tube along the channel and through the vocal cords. Minor manipulation of the blade may be required to align and advance the tip of the ET tube through the vocal cords.

COMPLICATIONS

As with all video intubation devices, imaging can be compromised by excessive secretions or blood in the oropharynx. Incorrect or forceful insertion can result in dental trauma and soft tissue injuries. The other complications associated with this device are similar to those of direct laryngoscopy.

SUMMARY

There is a growing array of video intubation devices available with varied designs. This includes those that embed the camera into the laryngoscope blade, those that embed the video camera into a scope or a stylet for use inside an ET tube, and those that utilize an ET delivery device. For the Emergency Physician, they represent a simple method for routine intubation as well as promising rescue devices for the difficult airway. These devices have varied learning curves. Regardless of which device one uses, it is important to use these devices in both simulation and routine intubation prior to use as a rescue device. These devices are useful for training healthcare personnel in the technique of orotracheal intubation in the prehospital and hospital setting. The use of a video laryngoscope to intubate is much easier than using traditional direct laryngoscopy, especially for novices.

14 Fiberoptic-Assisted Orotracheal Intubation Devices

Michael Lutes and Olga Pawelek

INTRODUCTION

Recent years have seen a rapid expansion in optical devices used to aid in endotracheal intubation. All of these devices use fiberoptics that begin near the distal end and transmit an image to be viewed at the proximal end. Many of these devices are variations on the "optical stylet" concept. They consist of an eyepiece or other viewing mechanism attached to a stylet of varying degrees of flexibility. A standard endotracheal tube can be jacketed onto each device. The stylet can then be used as an adjunct to standard endotracheal intubation or as a stand-alone device.

Traditional direct laryngoscopy requires alignment of the oral, pharyngeal, and laryngeal axes to visualize the glottis. Despite mechanical manipulation, it is not always possible to align these three axes. The major advantage of fiberoptic laryngoscopy devices is that they do not require the Emergency Physician to align the three airway axes, thus reducing the need for manipulation and potential traumatic forces on the airway. Fiberoptic devices provide a superior view of the glottis when compared to traditional direct laryngoscopy. The lens of these devices is within centimeters of the glottis and provides a wider angle of vision than the 15° of traditional direct laryngoscopy. The viewing port magnifies the view of the airway making structures easier to visualize.

A generalized approach to using optical stylet-type devices will first be discussed, followed by the unique features of each selected instrument. This chapter reviews a representative number and types of devices currently available and used in Emergency Departments. The last two devices covered in the chapter, the Airtraq and Bullard laryngoscope, function quite differently than an optical stylet.

INDICATIONS AND CONTRAINDICATIONS

Fiberoptic intubation devices can be used for adult and pediatric difficult (actual or anticipated), elective, emergent, and routine intubations. These devices can be used as "rescue devices" in cases of failed direct laryngoscopy. Patients with their head and neck immobilized, limited mouth opening, morbid obesity, or those requiring awake intubation or intubation while in a sitting position can benefit from intubation with these devices. It provides better visualization of the glottis, decreased cervical movement, and higher success rates in comparison to traditional direct laryngoscopy. These devices can be used to aid in the localization and removal of airway foreign bodies. There are no contraindications to the use of these devices.

USING FIBEROPTIC INTUBATION DEVICES

There are some general guidelines to using fiberoptic intubation devices that will improve the Emergency Physician's success in their implementation. First, it is useful to understand the limitation of these devices. Fogging is a common problem. Fogging can be minimized by applying a medical grade antifog solution to the lighted end of the instrument or warming the distal tip by placing it in a warm blanket or warmed saline solution. Any fluid (e.g., blood, secretions, or vomitus) in the oropharynx will limit the usefulness of these devices. First, suction any fluid and debris from the oropharynx prior to device insertion. Second, care should be taken to avoid touching any mucosal surface with the distal tip of the device. Encountering the mucosa can cause "pink out" and promote fogging of the device; both of which will impair visualization. Fiberoptic intubation devices cannot be used to separate tissues, rather they should follow an open channel created either by a standard laryngoscope or by manual distraction of the patient's jaw.[1] Lastly, small movements are magnified by these devices. Proceed slowly and identify known landmarks as the device is navigated from the mouth to the glottic opening. Getting lost in a field of pink mucosa is best overcome by slowly backing the device out until known landmarks are visualized and identified, and then slowly re-advancing the device along a path of familiar anatomy.

LEVITAN SCOPE

The Levitan Scope (Clarus Medical, Minneapolis, MN) was created by Dr. Richard Levitan (**Figure 14-1**). He is an Emergency Physician, a noted airway educator, and an innovator. The Levitan Scope differs from other devices in this chapter in that it is shorter and requires the endotracheal tube to be cut to a length of approximately 28 cm. While cutting the tube is an inconvenient step, doing so makes the working length of the scope shorter and makes wielding the device easier. The scope is equipped with a side port that allows for oxygen insufflation. The distal end of the device is flexible, allowing it to be bent to the specific needs of the scenario. It is powered by a detachable battery-operated light source or with a standard green-line fiberoptic laryngoscope handle. It is relatively

FIGURE 14-1. The Levitan Scope (Photo courtesy of Clarus Medical, Minneapolis, MN).

affordable compared to some other devices. Much of the intubation strategy described for the Levitan Scope is generalizable to other optical stylets. The techniques and strategies are summarized from a publication by the inventor.[2]

PREPARATION

Prepare the scope for use. Liberally lubricate the scope with a water-soluble lubricant. Do not get lubricant on the lens. Apply an endotracheal tube (6.0 mm or larger) over the shaft. The tip of the scope should be approximately 1 cm from the end of the endotracheal tube. Connect the side port to oxygen tubing. Turn on the oxygen source to provide a flow rate of 5 to 10 L/min. This flow rate allows for oxygen insufflation and aids in keeping the lens clear. The manufacturer recommends bending the distal tip to about 35° in the straight-to-cuff fashion. Attach the light source, either a miniature LED light source or a green-line fiberoptic laryngoscope handle.

TECHNIQUE

The Levitan Scope was designed with the intent of incorporating the option of fiberoptic assistance into every intubation attempt. In the majority of cases, where landmark visualization is feasible with standard laryngoscopy, the scope will simply act as a stylet. Once endotracheal intubation is achieved, additional confirmation can be made by visualizing the tracheal rings via the eyepiece.

When endotracheal intubation is not possible by direct laryngoscopy, the Levitan Scope jacketed with an endotracheal tube can be used for fiberoptic intubation. Obtain the best visualization of the airway anatomy possible using the traditional laryngoscope. Ideally, at least the epiglottis should be visible. Introduce the scope into the mouth under direct vision. Advance it until the tip of the scope is positioned approximately 1 cm superior to the epiglottis. To maintain this position, it may be helpful to rest the device against the patient's dentition at the right corner of the mouth. Avoid touching the distal tip of the scope against the mucosa to prevent "pink out" and fogging.

Switch from direct visualization to fiberoptic viewing via the device's eyepiece. Identify the airway structures. Slowly advance and direct the tip of the scope under the epiglottis. Continue to advance the tip of the device into the glottic opening. If the device is resting at the right corner of the patient's mouth, pivoting the device toward the Emergency Physician will direct the tip of the scope anteriorly toward the glottic opening. Confirm proper placement by visualizing the trachea rings through the eyepiece.

Once the tip of the scope with the jacketed endotracheal tube has been advanced through the vocal cords and into the trachea, remove the laryngoscope. Advance the endotracheal tube by rotating it off the stylet in a counterclockwise fashion. Rotating the endotracheal tube while advancing it helps to prevent the beveled edge from catching on the tracheal rings. Securely hold the endotracheal tube. Remove the Levitan Scope and secure the endotracheal tube.

The Levitan Scope can also be used without a laryngoscope, though it may require more practice to become adapt at this technique. Prepare the scope as described above, with the exception that the distal 3 to 4 cm should be bent to approximately 70°. Grasp the patient's jaw and tongue in the left hand and lift to create an open channel for the scope. Insert and advance the scope in the midline while avoiding contact with the mucosal surfaces. Look through the eyepiece and advance the device through the glottic opening.

VIDEO RIFL

The Video Rigid Intubating Fiberoptic Laryngoscope or Video RIFL (AI Medical Devices Inc, Williamston, MI) is unique among the optical stylets in that it has a flexible tip that can be manipulated with a trigger at the handle-end of the device (**Figure 14-2**). There were originally two models available, the Airway RIFL and the Video RIFL. The Video RIFL replaced the eyepiece of the Airway RIFL with a small LCD screen. The newer Nasal RIFL stylet attaches to the device and allows nasal intubation. The high resolution LCD

FIGURE 14-2. The Airway RIFL (Photo courtesy of AI Medical Devices Inc., Williamston, MI).

screen rotates 180° to provide visualization from any angle. The Video RIFL has a unique tip that articulates up to 135° to navigate obstructions. The device can be used as a stand-alone device or as an adjunct to standard laryngoscopy. It can be used to facilitate intubation through many supraglottic airway devices such as the Air-Q or I-gel. The primary disadvantages of this device are the cost, the relative length of the device, and that it is top-heavy. The length may prove cumbersome for users of shorter stature.

The two-sided RIFL blade can be used in conjunction with the Video RIFL. It is a disposable, single use, plastic blade. Its use is optional. The RIFL blade is inserted into the midline of the patient's mouth and lifted to elevate the tongue, open the airway, and provide a path to the glottis.

PREPARATION

Inspect the Video RIFL for any damage. Turn it on. Liberally lubricate the stylet portion of the device with a water-soluble lubricant. Place a 6.5 mm or larger endotracheal tube onto the stylet. The current model does not accommodate endotracheal tubes less than 6.5 mm. A smaller pediatric version is being developed. Set the tube stop so that the tip of the stylet is just inside the distal end of the endotracheal tube.

TECHNIQUE

The Video RIFL can be used as an adjunct to standard direct laryngoscopy. If the glottic opening can be easily visualized using a standard laryngoscope, the device can simply be used as a stylet to introduce the endotracheal tube into the trachea. If the laryngeal structures are not well visualized with direct laryngoscopy, insert and advance the device as described for the Levitan Scope. Attempt to visualize the epiglottis through the eyepiece or on the LCD screen of the Video RIFL. Advance the device under the epiglottis and through the vocal cords. The trigger-like handle of the Video RIFL can be squeezed to direct the tip of the instrument. Release the handle once the tip of the device passes through the vocal cords in order to facilitate advancement of the endotracheal tube off the device. Advance the endotracheal tube into the trachea. Withdraw the device and secure the endotracheal tube. Confirm proper endotracheal tube placement.

The Video RIFL can be used as a stand-alone device without the aid of a laryngoscope. Grasp the patient's mandible and tongue in the left hand and manually distract it. Insert the Video RIFL into the patient's mouth with the long axis of the device parallel to the palate. Look into the eyepiece or at the LCD screen and attempt to visualize the airway structures. Flex the tip of the device to visualize the vocal cords. Advance the Video RIFL through the vocal cords. Complete the remainder of the procedure as described above.

AIR-VU PLUS FIBER OPTIC SCOPE

The Air-Vu Plus Fiber Optic Scope (Mercury Medical, Clearwater, FL) is an optical stylet designed specifically for aiding in fiberoptic endotracheal tube placement through the Air-Q supraglottic airway (Mercury Medical, Clearwater, FL). It is a rigid device with a curved tip designed to fit the shape of the Air-Q (**Figure 14-3**). The Air-Vu Plus can be used with either a compact LED light source or a standard green-line fiberoptic laryngoscope handle. The device can be used as an optical stylet or as a stand-alone device in the same fashion as the Levitan Scope. The primary advantage of the Air-Vu plus versus other devices is its compatibility with the Air-Q. The primary disadvantage is the rigidity of the device and the fixed curve of the shaft, both of which can make advancement of the device and the endotracheal difficult.

FIGURE 14-3. The Air-Vu Plus Fiber Optic Scope (Photo courtesy of Mercury Medical, Clearwater, FL).

SHIKANI OPTICAL STYLET

The Shikani Optical Stylet or SOS (Clarus Medical, Minneapolis, MN) is unique among the optical stylets in that it comes in both pediatric and adult sizes (**Figure 14-4**). The SOS can be used with a variety of light sources. This includes its own specific handle, a green-line laryngoscope handle, or a fiberoptic cable attached to a remote light source. The SOS is malleable, allowing it be shaped to a 70° to 80° angle at the tip for use as a stand-alone device or a 30° angle when used as an adjunct to standard direct laryngoscopy. The SOS can be attached to oxygen tubing to allow insufflation of oxygen at 5 to 10 L/min. Intubation is achieved in a manner similar to other optical stylets. Advantages of the Shikani Optical Stylet include the availability of adult and pediatric sizes, its malleability, and the option of providing insufflation of oxygen. There are also

FIGURE 14-4. The Shikani Optical Stylet (Photo courtesy of Clarus Medical, Minneapolis, MN.

FIGURE 14-5. The Bonfils Retromolar Intubation Endoscope (Photo courtesy of Karl Storz Endoscopy-America, El Segundo, CA).

several case reports of its successful use in children.[3] The disadvantages are primarily related to its length, which can make coordination of intubation difficult for some users.

BONFILS RETROMOLAR INTUBATION ENDOSCOPE

The Bonfils Retromolar Intubation Endoscope (Karl Storz Endoscopy-America, El Segundo, CA) is simple in appearance (**Figure 14-5**). It can accommodate a 6.5 mm or larger endotracheal tube and has an adjustable tube stop. It can be equipped with either an eyepiece or an adapter to couple with a monitor. It also allows for oxygen insufflation via a side port. The curvature at the tip of the scope is fixed.

Intubation with the Bonfils Retromolar Intubation Endoscope can be achieved in the same fashion as described for other optical stylets in this chapter, either with or without the aid of a standard laryngoscope. In a study in the anesthesiology literature, 103 of 107 patients with unanticipated difficult airways were successfully intubated with this device, with 80% intubated without the aid of a laryngoscope.[4] The other 20% were intubated with a Macintosh blade and the Bonfils scope. A more recent study reports the device's success in the awake intubation of five patients with challenging airways.[5] Despite having higher success rates than traditional direct laryngoscopy, it can be difficult to maneuver this device into proper position under the epiglottis.[6]

AIRTRAQ OPTICAL LARYNGOSCOPE

The Airtraq (Prodol Meditec S.A., Vizcaya, Spain) differs from other devices in this chapter in that it is not an optical stylet, but rather an optical laryngoscope (**Figure 14-6**). It also differs from video laryngoscopes, such as the Glidescope, in that it is portable, completely handheld, battery operated, and does not require an external monitor for viewing. The Airtraq is disposable and designed for single patient use. The guide channel on the side of the Airtraq is anatomically shaped to deliver the endotracheal tube into the glottic opening. The Airtraq is available in four sizes, each with a required minimal mouth opening (**Table 14-1**). An optional reusable wireless

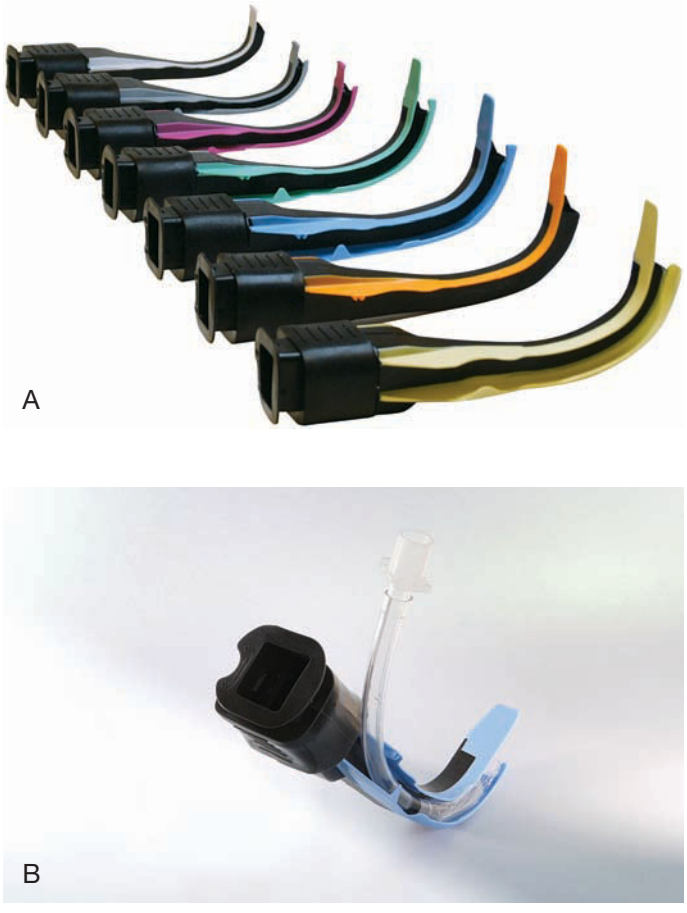

FIGURE 14-6. The Airtraq. **A.** The devices. **B.** An endotracheal tube loaded onto the device (Photos courtesy of Prodol Meditec S.A., Vizcaya, Spain).

video camera can be attached to the viewing window. It will transmit the viewing image to a wireless display monitor and recorder.

The Airtraq has proven to be effective and easy for even novice practitioners to learn to use.[7,8] The prehospital community favors the Airtraq for its compact size, portability, disposability, and being useful in less-than-standard patient positions.[9] The use of an Airtraq results in less cervical spine motion, less hemodynamic stimulation, and a decreased time required to intubate when compared to direct laryngoscopy.[10–12]

PREPARATION

Select the appropriate size Airtraq (**Table 14-1**). Confirm that the patient's mouth can be opened enough to accommodate the Airtraq. Turn on the Airtraq with the switch on the left side of the handle. Turning the Airtraq on early (i.e., at least 30-45 seconds before it is used) in the setup phase allows it to warm up, which also helps to prevent fogging. If the Airtraq is stored in a cold environment (e.g., storage room or ambulance in winter), allow it to warm up for at least 60 to 90 seconds before it is used. Select the appropriate

TABLE 14-1 Airtraq Sizes

Size	Endotracheal tube size	Minimal mouth opening (mm)
#0: Infant	2.5–3.5	12.5
#1: Pediatric	3.5–5.5	12.5
#2: Small	6.0–7.5	16
#3: Regular	7.0–8.5	18

size endotracheal tube. Test the endotracheal tube to ensure that the cuff inflates properly. Liberally lubricate the endotracheal tube and insert it into the channel of the Airtraq (**Figure 14-6B**). The patient can either be left in the neutral position or placed in the sniffing position. Lubricate the Airtraq to prevent it from catching and pushing the tongue posteriorly.

TECHNIQUE

Grasp the prepared device with the left hand. Insert the tip into the midline of the patient's mouth, with the long axis of the Airtraq parallel to the patient. Advance the Airtraq into the hypopharynx by lifting and rotating the viewing end upward. The curved shape of the Airtraq will follow the patient's normal anatomic curvature of the pallet and hypopharynx. When the device is just about upright and perpendicular to the patient, look into the eyepiece and attempt to visualize the epiglottis. Once the epiglottis is visualized, the Airtraq can either be advanced into the vallecula similar to a Macintosh blade or used to directly lift the epiglottis similar to a Miller blade. In either case, the Airtraq must be lifted up to elevate the epiglottis and center the glottic opening on the viewing screen.

Visualize the vocal cords. Advance the endotracheal tube with the right hand while securely holding the Airtraq with the left hand. Visualize the endotracheal tube passing through the vocal cords. If the vocal cords and airway structures are seen but the endotracheal tube will not advance, the vocal cords are probably not in the center of the viewing screen. Slowly withdraw the Airtraq, lift it slightly until the vocal cords are positioned in the middle of the viewing screen, and then advance the endotracheal tube.[13] Once the proper insertion depth is reached, securely hold the endotracheal tube. Gently distract the Airtraq toward the patient's left side while holding the endotracheal tube in its current location to release the endotracheal tube from the side channel. Withdraw the Airtraq from the mouth and inflate the cuff of the endotracheal tube. Confirm proper endotracheal tube position and secure it with tape or a commercial device.

The two most common mistakes are inserting the Airtraq too deep and not lifting it to elevate the epiglottis. Either of these will result in a view of the arytenoid cartilages and the vocal cords, with the viewing screen having the arytenoids centered in the view rather than the vocal cords. This will result in the advancing endotracheal tube hitting the arytenoid cartilages, thus not advancing through the vocal cords. Simply withdraw the Airtraq slightly and lift it upward to center the vocal cords in the viewing screen.

BULLARD LARYNGOSCOPE

The Bullard laryngoscope (Gyrus ACMI, Southborough, MA) is a rigid laryngoscope that combines a curved blade with fiberoptic visualization into a simple and easy-to-use handheld unit (**Figures 14-7 & 14-8**). The proximal handle contains an 11 French (3.7 mm) working port, a site to attach the light source such as a traditional laryngoscope handle or a fiberoptic, and a visualization port (**Figure 14-7**). The port allows oxygen insufflation, suctioning, administration of pharmaceuticals, or the passage of a guidewire to promote tracheal intubation.[14,15] The curved blade is similar in shape to a Macintosh blade. A fiberoptic bundle allows visualization of the vocal cords and tracheal intubation without a direct line of sight.

The Bullard laryngoscope is available in three sizes (**Figure 14-8**). The device is handheld, readily portable, self-contained, and is operated as quickly as a traditional laryngoscope with a Macintosh blade. The ability to visualize the vocal cords without aligning the oral, pharyngeal, and laryngeal axes allows successful intubation with a minimum of cervical spine movement.[14–19]

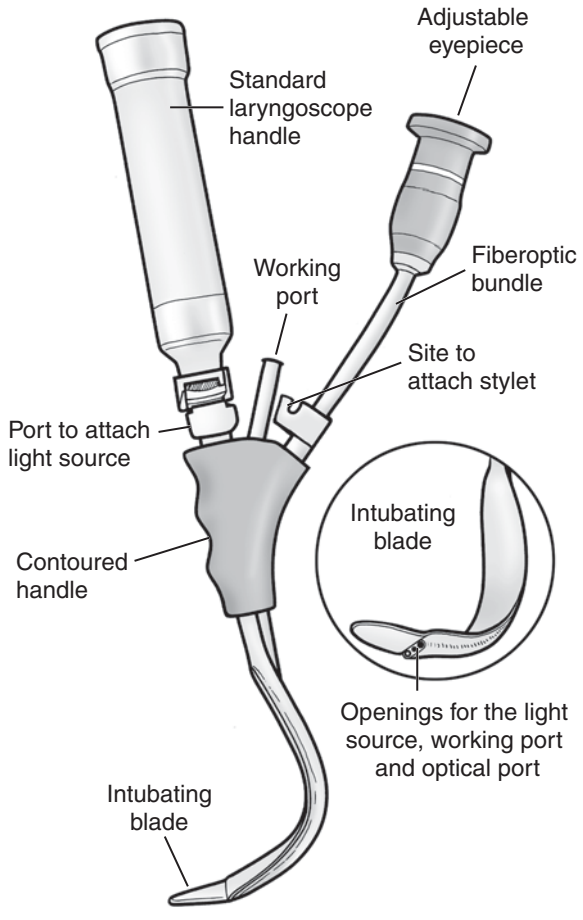

FIGURE 14-7. Anatomy of the Bullard laryngoscope.

PREPARATION

Assemble the Bullard laryngoscope when the possible need for airway intervention is recognized. The working port can be fitted with a three-way stopcock to provide intermittent suction and oxygen insufflation. Attach a traditional laryngoscope handle as the light source. If available, a fiberoptic light source, with the required adapter, may be used to provide illumination. Lubricate the lower half of the intubating stylet with a water-soluble lubricant. Attach

FIGURE 14-8. Three versions of the Bullard laryngoscope. From left to right: the pediatric model, the pediatric long model, and the standard model.

the stylet to the fiberoptic bundle, between the eyepiece and the handle, on the right side of the laryngoscope. Select and load the appropriate size endotracheal tube onto the intubating stylet. The tip of the stylet should extend 0.5 cm past the distal end of the endotracheal tube. Place the tip of the stylet beneath the flange of the blade. It is recommended, but not required, that a disposable plastic blade extender be placed on the tip of the metal blade for adult intubations.

TECHNIQUE

Stand at the head of the bed. Open the patient's mouth to a minimum opening of 0.6 cm between the upper and lower incisors. Grasp the handle of the Bullard laryngoscope parallel to the patient and toward the patient's feet (**Figure 14-9A**). Insert the blade into the midline of the mouth. Lift the laryngoscope handle upward (**Figure 14-9B**). Slightly elevate the Bullard laryngoscope to lift up

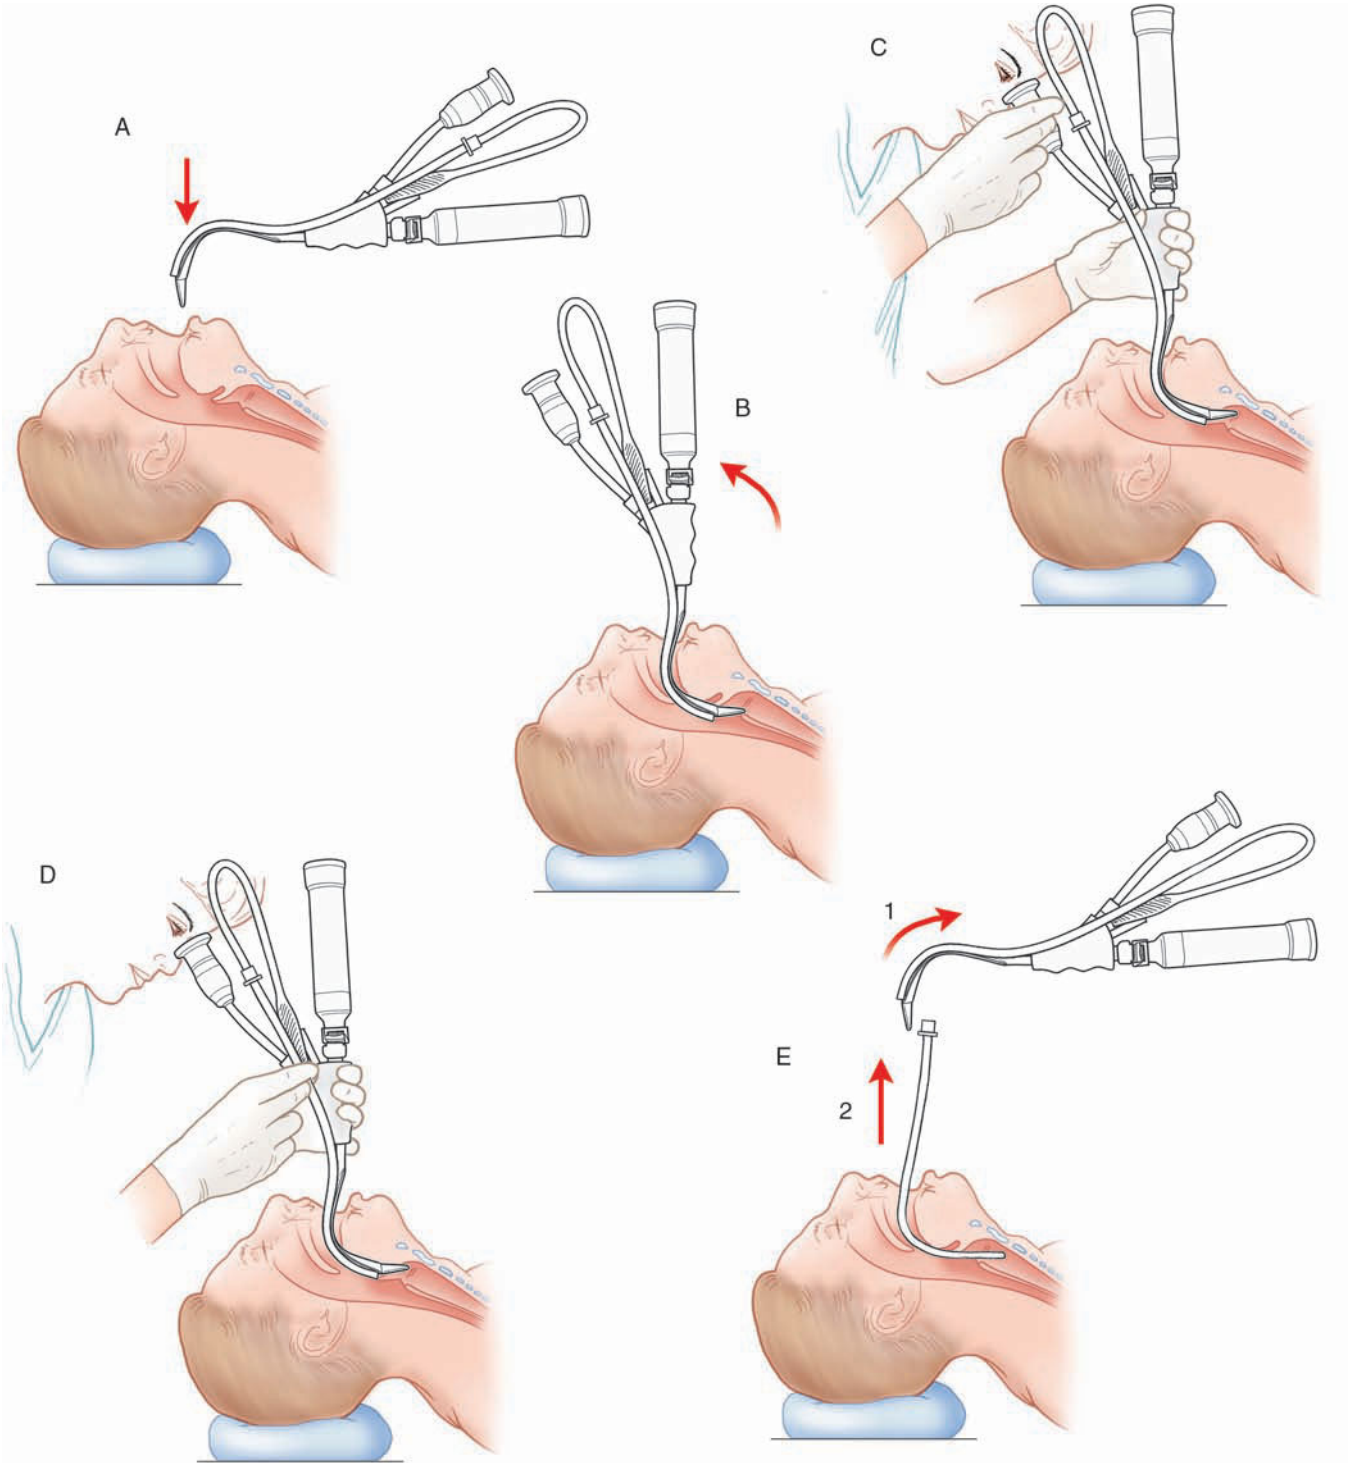

FIGURE 14-9. Intubating with the Bullard laryngoscope. **A.** Inserting the laryngoscope. **B.** Rotation of the handle 90° properly positions the laryngoscope. **C.** Slight elevation of the laryngoscope moves the tongue and epiglottis out of the visual axis. **D.** Advancement of the endotracheal tube under direct visualization. **E.** Removal of the Bullard laryngoscope. It is first rotated 90° toward the patient's feet (*curved arrow*), then lifted out of the mouth (*straight arrow*).

the tongue (**Figure 14-9C**). The blade will follow the contour of the tongue and pharynx with minimal effort.

The blade of the Bullard laryngoscope should elevate the epiglottis (**Figures 14-9C and D**). Visualize the airway through the fiberoptic port (**Figure 14-9D**). The view can be focused by turning the eyepiece. If the blade is not beneath the epiglottis, it can be repositioned by withdrawing the blade toward the posterior pharynx in an attempt to catch the epiglottis. If blood, debris or secretions limit the view, suction through the working port. When the vocal cords are visualized, advance the endotracheal tube under direct visualization (**Figure 14-9D**). Secure the endotracheal tube at the patient's teeth with your nondominant hand. Remove the Bullard laryngoscope with your dominant hand by reversing the technique of insertion (**Figure 14-9E**).

The Bullard laryngoscope allows for other strategies to aid in endotracheal intubation. The stylet has a central opening (4.5 mm in the adult, 3.6 mm in the pediatric long), which can be used to pass an intubating guidewire through the vocal cords.[15] An intubating guidewire may also be passed through the working port and through the vocal cords. In either case, after inserting the guidewire, remove the Bullard laryngoscope and pass the endotracheal tube over the guidewire and into the trachea. It is also possible to pass an endotracheal tube with a standard malleable stylet. The styletted endotracheal tube can be bent into a shape approximating that of the Bullard laryngoscope.

Problems specific to the Bullard laryngoscope include the inability to visualize the vocal cords. First, confirm that the laryngoscope is midline. If the blade is above the epiglottis and the view obscured, reposition it by moving the blade into the posterior pharynx and attempt to capture the epiglottis. To avoid this difficulty, use a disposable plastic blade extender. If the view is obscured by debris, suction through the working port. Once positioned, the stylet with the loaded endotracheal tube should be visualized through the scope. If not, it may have slipped underneath the blade. Reposition the stylet and endotracheal tube without removing the laryngoscope.[15] The stylet, if extended too far beyond the endotracheal tube, may cause abrasions, bleeding, and lacerations to the walls of the oral cavity, oropharynx, and laryngopharynx. These can be prevented with proper assembly of the Bullard laryngoscope.

COMPLICATIONS

The majority of complications associated with fiberoptic devices mirror those of endotracheal intubation. These include failure to intubate, esophageal intubation, right mainstem bronchus intubation, and all of the hemodynamic consequences of intubation. Refer to Chapter 11 for a complete discussion of the complications associated with endotracheal intubation The most common difficulty encountered in endotracheal tube passage is impaction of the endotracheal tube on the right arytenoid cartilage. This obstacle can be overcome by directing the device slightly toward the patient's left side. Alternatively, rotate the endotracheal tube until the bevel is facing the viewing channel.

SUMMARY

A variety of fiberoptic devices are available to help indirectly visualize the glottic opening and aid in intubating the trachea. The scopes have a variety of features including malleable stylets, articulating tips, and differing lengths. The devices can be shaped for differing applications such as being used with and without a laryngoscope or to be inserted through a supraglottic airway. The devices feature different visualization capabilities such as a fixed eyepiece or an optional video screen. Fiberoptic devices offer alternative techniques for managing the airway. Every Emergency Department should have at least one of these devices available to aid in intubation when direct laryngoscopy is difficult or fails.

15 Endotracheal Tube Intubating Introducers and Bougies

Olga Pawelek and Eric F. Reichman

INTRODUCTION

Airway management in the Emergency Department often occurs in an unpredictable and uncontrolled environment, sometimes with the patient arriving unannounced.[1] The American Society of Anesthesiology defines a difficult intubation as an inability to properly insert an endotracheal tube with traditional direct laryngoscopy within three attempts or if it takes longer than 10 minutes.[2] Difficult intubations usually reflect poor glottic visualization during direct laryngoscopy. A four-grade classification system by Cormack and Lehane describe the views of the laryngeal inlet during laryngoscopy.[3] The exact incidence of difficult to intubate patients in the Emergency Department is difficult to extrapolate but estimates range between 6% and 11%.[4,5]

Difficulties arise when the vocal cords cannot be fully visualized due to airway distortion (e.g., edema, expanding hematomas, radiation, surgery, or trauma), airway masses, anatomical variations, cervical collars, deformities of the head and neck, orofacial injuries, or oropharyngeal blood and secretions. One study reported that the vocal cords could not be visualized in 22% of patients wearing a cervical collar.[6] **This failure to visualize the glottis can make intubation difficult or impossible. The intubating introducer, tracheal tube introducer, or bougie can be a good rescue device in these situations.** The main advantage of many of these devices is their angled or coudé tip that can be aimed anteriorly, advanced under the epiglottis, and into the trachea. Intubation with one of these devices was first described by Macintosh in 1949.[7] The device he used was a 60 cm long, 15 French, elastic catheter with a J or coudé tip that was bent 40° at the distal end.

This chapter reviews the general principles for using tracheal tube introducers, intubating introducers, and bougies; as well as reviewing some of the more commonly available devices. The terms tracheal tube introducers, intubating introducers, and bougies are often used interchangeably. This chapter uses the term bougie unless some other term is specific to a manufacturer's device.

INDICATIONS

The bougie is intended to facilitate endotracheal intubation in patients where visualization of the glottis is difficult or inadequate despite external laryngeal manipulation and optimal patient positioning. The most frequent indication for the use of a bougie is the inability to intubate endotracheally using traditional direct laryngoscopy. It can also be used for "routine intubations." The narrower and more flexible bougie, compared to an endotracheal tube, can easily be inserted into the trachea when the glottis is visualized during direct laryngoscopy and the endotracheal tube inserted then advanced over the bougie. A bougie can be inserted directly into the trachea or through a supraglottic airway device to facilitate endotracheal intubation. A bougie may be inserted when the glottic opening is visible, but the endotracheal tube will not

pass through the vocal cords. The bougie serves as a placeholder in these cases and avoids the need to remove the laryngoscope and re-perform direct laryngoscopy when the bougie is available. The use of a bougie to intubate the trauma patient may result in less cervical spine motion than traditional direct laryngoscopy.[8] Long bougies, at least 70 cm, can also be used as an endotracheal tube exchanger.

CONTRAINDICATIONS

There are no absolute contraindications to the use of bougies. Use caution when inserting these in the patient with airway trauma as they can result in additional injury and hemorrhage to the airway structures, perforation (e.g., piriform fossa, trachea, bronchus, or esophagus), or barotrauma.[9–11]

EQUIPMENT

- Endotracheal tubes, various sizes
- 10 mL syringe
- Water-soluble lubricant or anesthetic jelly
- Wire stylet, malleable type
- Laryngoscope handle
- Fresh batteries for the laryngoscope
- Laryngoscope blades, various sizes and shapes
- Supplemental oxygen with appropriate tubing and connectors
- Nonrebreather oxygen masks, various sizes
- Wall suction with appropriate tubing
- Yankauer suction catheter
- Bag-valve device, various sizes
- Oral airways, various sizes
- Nasal airways, various sizes
- Benzoin adhesive
- Tape
- Pulse oximeter
- Cardiac monitor
- Automatic sphygmomanometer
- End-tidal carbon dioxide (CO_2) monitor/device
- Cricothyroidotomy backup tray
- Crash cart
- Resuscitation medicines
- Personnel (respiratory technician, medication nurse, in-line stabilization assistant, recorder)
- Medications (premedications, induction, anesthetics, and paralytics), see **Table 11-2**
- Endotracheal tube introducer or bougie

The bougie is used to facilitate difficult intubation. It is a thin, long cylindrical rod composed of rubber or plastic. Despite sometimes being called "gum elastic bougies," they are not composed of gum or elastic. They are inexpensive, most costing less than US $20.00 each. The bougie is available in numerous adult and pediatric sizes, various degrees of flexibility, and equipped with a variety of ports and/or devices. Bougies are flexible enough to allow an endotracheal tube to freely pass over it or to be inserted through a supraglottic airway device, yet stiff enough to be easily maneuvered and advanced into the airway.

The bougie should not be confused with the more rigid malleable stylet that is inserted into an endotracheal tube and used to alter its shape prior to intubation. Unlike the stylet, a bougie is usually inserted independently of the endotracheal tube and is used as a guide. The bougie is considerably softer, more malleable, and blunter than a stylet. The insertion of a bougie is considered to be a relatively atraumatic procedure.[12]

FIGURE 15-1. The Portex Tracheal Tube Introducer (Photo courtesy of Smiths Medical, Dublin, OH).

ESCHMANN TRACHEAL TUBE INTRODUCER

The Eschmann tracheal tube introducer was formerly known as the gum elastic bougie. Re-usable (or multiple-use) and single-use disposable versions are available. The Eschmann multiple-use introducer was introduced into clinical practice in 1973. The Portex single-use introducer (Smiths-Medical, Dublin, OH) became available in 1997 and replaced the Eschmann Introducer. It is a 60 cm long, 15 French, flexible device with a J-angle at its distal tip (**Figure 15-1**). During use, the multiple-use introducer forms a curve toward its distal end. The single-use introducer is more rigid and is thus more likely to cause trauma.[13] It does not maintain a curved shape when bent and it has a significantly lower tracheal placement rate in simulated grade 3 laryngoscopic views.[14] The multiple-use device retained the curved shape for longer compared with the single-use device.

FROVA INTUBATING INTRODUCER

The Frova Intubating Introducer (Cook Medical Inc., Bloomington, IN) was introduced into clinical practice in 1998. The Frova is a single-use device that is able to maintain the desired curvature—a feature shared with the Eschmann multiple-use introducer.[15] It is a flexible, hollow, radiopaque polyethylene plastic catheter with centimeter markings, and a blunt curved

FIGURE 15-2. The Frova Intubating Introducer with Rapi-Fit adapter. From left to right: the proximal end with the Rapi-Fit adapter, the body with centimeter markings, and the distal end (Photo courtesy of Cook Medical Inc., Bloomington, IN).

tip (**Figure 15-2**). It is available in two sizes, the 14 French version for 6.0 mm and larger endotracheal tubes and the 8 French version for 3.0 mm and larger endotracheal tubes. It is packaged with a removable metal cannula that stiffens the device except for the distal tip. The advantages of the metal cannula are that it can be bent to change the shape of the Frova and make it easier to advance. The disadvantages of the metal cannula are that it makes the Frova more rigid, harder to maneuver, and potentially increases airway soft tissue trauma. Products with the suffix "-FII" also include a stiffening cannula and two Rapi-Fit® adapters for connection to a ventilatory device. Products with the suffix "-FI" include two Rapi-Fit® adapters for connection to a ventilatory device, but no stiffening cannula. The adapter can be used to ventilate the patient and confirm proper tracheal placement before advancing the endotracheal tube. It takes only 15 seconds to attach an aspirating esophageal detector device to the adapter and confirm its position.[16]

SUNMED BOUGIE

The SunMed Bougie (SunMed, Largo, FL) is made of a blend of low and high density polyethylene for optimal stiffness and has depth calibration markings. It is 70 cm long and available as a 10 French pediatric size or a 15 French adult size (**Figure 15-3**). Three versions of these devices are available: the original, the malleable, and a ported version. The original adult version is available with a straight or curved tip and fits 4.0 to 11.0 mm endotracheal tubes. The original pediatric version is only available with a curved tip. The malleable version has a color-coded stopper and fits 6.0 to 11.0 mm endotracheal tubes. A new ported version allows insufflation of oxygen and gas sampling. It is available only in the 15 French size. It uses a blend of low and medium density polyethylene for optimum firmness, and it is depth calibrated in centimeters. A study comparing the SunMed, Portex, Greenfield, and Eschmann bougies demonstrated that Emergency Physicians had better success rates using the SunMed and Greenfield devices, but they had a low preference for the Greenfield bougie.[17]

GREENFIELD FLEX-GUIDE ET TUBE INTRODUCER

The Flex-Guide ET Tube Introducer (Greenfield Medical Sourcing Inc., Austin, TX) is a 60 cm long polyethylene tube that is available in a 15 French (5.0 mm) diameter for adults and a 10 French (3.3 mm) diameter for children (**Figure 15-4**). The ends of the Flex-Guide are smooth and rounded with a bend 2 cm from the distal end, resulting in a 30° coudé tip. The tubing is flexible and can be straightened or bent as required. The adult Flex-Guide has a black band marking 37 cm from its proximal end (**Figure 15-4**) to help determine correct placement depth. The pediatric Flex-Guide has markings every 10 cm (**Figure 15-4**). The Flex-Guide is similar to the Eschmann or Portex bougie, only more economical. This device has been used in the Emergency Department to intubate difficult airways.[18]

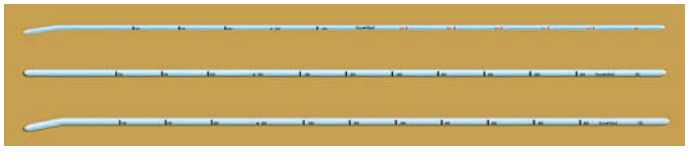

FIGURE 15-3. The SunMed Bougie. From top to bottom: 10 French Coudé tip pediatric version, 15 French straight tip adult version, and the 15 French Coudé tip adult version (Photo courtesy of SunMed, Largo, FL).

FIGURE 15-4. The Greenfield Flex-Guide Endotracheal Tube Introducer adult version (above) and pediatric version (below) (Photo courtesy of Greenfield Medical Sourcing Inc., Austin, TX).

AINTREE INTUBATION CATHETER

The Aintree Intubation Catheter (Cook Medical Inc., Bloomington, IN) was designed to be used with a fiberoptic bronchoscope (**Figure 15-5**). It is packaged with a Rapi-Fit Adapter, which allows ventilation through the device and air exchange through the multiple distal side ports. The Aintree is only available in one size and for use with endotracheal tubes greater than 7.0 mm in diameter. It may also be used as a bougie without the fiberoptic bronchoscope. It is generally not used as a bougie due to it being hollow, flexible, straight, and lacking the flexed tip of a typical bougie.

ENDOTRACHEAL TUBE EXCHANGERS

The use of an endotracheal tube exchanger to facilitate orotracheal intubation similar to a bougie is not recommended. These devices are straight, very flexible, thin-walled, and hollow tubes. Their flexibility makes it difficult to advance into the trachea and more often enters the esophagus. When inserted and warmed by the patient's body temperature, these thin-walled hollow tubes become even more flexible.

FIGURE 15-5. The Aintree Intubation Catheter. From left to right: the proximal end with the Rapi-Fit adapter, the body with centimeter markings, and the distal end (Photo courtesy of Cook Medical Inc., Bloomington, IN).

PATIENT PREPARATION

The patient preparation is exactly the same as that for orotracheal intubation (Chapter 11). Refer to Chapter 11 for a complete discussion regarding the patient preparation. The patient should be appropriately monitored with electrocardiography (ECG), end-tidal CO_2 monitoring, noninvasive blood pressure cuff, and pulse oximetry. As for any situation where airway manipulation is to occur and the patient's protective airway reflexes are blunted or ablated, a fully functioning suction apparatus with a variety of catheters must be immediately available. Place the patient supine with their head in a neutral position.

Place the patient, with a normal neck, in the "sniffing" position, with their head extended at the atlantooccipital joint while the neck is relatively flexed. A folded towel under the occiput helps to gently raise and tilt the head back into the proper position. **Correct positioning is probably the most important preparation of the patient.** Dentures should be left in place temporarily, as they help to stabilize the mouth and prevent occlusion during preoxygenation and bag-valve-mask ventilation.

TECHNIQUES

OROTRACHEAL INTUBATION

The bougie can be used in anticipation of a difficult airway or when a difficult airway is encountered and direct laryngoscopy is not successful. Instruct an assistant to ventilate the patient with a bag-valve-mask device. Liberally lubricate the bougie with a water-soluble lubricant. Insert the laryngoscope loaded with either a Macintosh or Miller blade. Elevate the laryngoscope and attempt to visualize the epiglottis and vocal cords. If the vocal cords are visualized, partially or completely, insert the bougie through the vocal cords and into the trachea.

If the vocal cords are not visualized, attempt to pass the bougie under the epiglottis with the curved distal tip facing anteriorly (**Figures 15-6A & 16-6B**). Slowly and carefully advance the bougie distally toward the trachea. The bougie will slightly jump or bounce as its tip is advanced over each tracheal ring (**Figure 15-6C**). This is sometimes referred to as the "palpation of a click" as the tip passes over each tracheal ring. Advance the bougie approximately 10 to 15 cm into the trachea (**Figure 15-6D**). Securely hold the bougie in place. **Do not remove the laryngoscope after the bougie is placed within the trachea. The laryngoscope will continue to elevate the tongue and allow easier passage of the endotracheal tube.**

There are several signs that signify proper bougie placement within the trachea. If the bougie is unable to be advanced more than 40 cm from the patient's lips in an adolescent or adult, or more than 24 cm in the child, it is likely caught at the carina or bronchus as the airway narrows. This is sometimes referred to as the "hold-up" sign. The "hold-up" sign in addition to the palpation of "clicks" as it is inserted confirms proper tracheal positioning of the bougie.[19] If the bougie freely advances more than 40 cm from the adolescent or adult patient's lips, or 24 cm in the child, it is most likely in the esophagus or stomach. One study noted the bougie getting caught and the palpation of "clicks" to be a less reliable indicator of tracheal placement than some other studies.[20] An assistant performing the Sellick maneuver should feel the tip of the bougie passing under their fingertips as it is advanced down the trachea. The bougie will rotate as the tip passes the carina and enters the mainstem bronchus. It will rotate clockwise if it enters the right mainstem bronchus and counterclockwise if it enters the left mainstem bronchus.

Instruct an assistant to load the endotracheal tube over the bougie and slide it to the level of the patient's lips. **The assistant should hold and advance the endotracheal tube until its tip is at the patient's lips while the Emergency Physician controls the bougie, controls the laryngoscope, and provides instruction to the assistant. The Emergency Physician must now grasp and control the endotracheal tube with their right hand while the assistant holds the bougie securely in place.** Advance the endotracheal tube over the bougie and into the trachea (**Figure 15-6E**). Under direct visualization, rotate the endotracheal tube 90° counterclockwise so that the bevel is facing posteriorly as the endotracheal tube passes through the vocal cords. This maneuver allows the endotracheal tube bevel to not get caught on the arytenoid cartilage and to gently spread the arytenoids with a minimum of force, thus avoiding any injury to the vocal cords.[21] **If resistance is felt, do not try to advance the endotracheal tube.** Instruct the assistant to slightly withdraw the endotracheal tube, rotate it in a slightly more counterclockwise direction, and re-advance it again.

Hold the endotracheal tube firmly in place. Remove the laryngoscope. Remove the bougie. Secure the endotracheal tube, confirm its proper position, and begin ventilation of the patient.

ALTERNATIVE OROTRACHEAL INTUBATION TECHNIQUE

An assistant is not always available to load the endotracheal tube and advance it over the bougie. An alternative is for the Emergency Physician to preload the endotracheal tube on the bougie (**Figure 15-7**) and insert them as a unit without the use of an assistant. Load the endotracheal tube over the bougie so that the bougie projects approximately 10 cm from the distal end of the endotracheal tube (**Figure 15-7A**). Form a loop with the endotracheal tube and proximal bougie and grasp it with the right hand (**Figure 15-7A**). A second technique is to load the endotracheal tube on the bougie so that the bougie projects approximately 6 to 10 cm from the distal end of the endotracheal tube and grasp it with the right hand (**Figure 15-7B**).

Insert the laryngoscope into the patient's mouth and attempt to visualize the glottis. Grasp the bougie loaded with the endotracheal tube in the right hand. Insert the distal end of the bougie through the vocal cords and into the trachea. Remove the laryngoscope. Advance the endotracheal tube over the bougie and into the trachea. Securely hold the endotracheal tube. Remove the bougie. Secure the endotracheal tube, confirm its proper position, and begin ventilation of the patient.

BOUGIE-GUIDED SUPRAGLOTTIC AIRWAY INSERTION

Bougies can be used to guide supraglottic airway devices.[22–24] A bougie was utilized as a guide through the Pro-Seal LMA.[22] The esophageal channel of the LMA was used to load the bougie and place it in the esophagus. This resulted in a better success rate than using the LMA introducer tool. The bougie-guided insertion caused less trauma than the LMA insertion tool after failed digital insertion of the ProSeal LMA. A similar technique has been used in the pediatric population.[23] Other studies have used bougies as guides through a supralaryngeal device for rescue intubation.[24]

BOUGIE-ASSISTED RETROGRADE INTUBATION

Retrograde intubation with a bougie may be considered as an emergent airway management option.[25] A patient was successfully intubated using a modified retrograde technique through a tracheal defect with a bougie. The bougie is often more conveniently

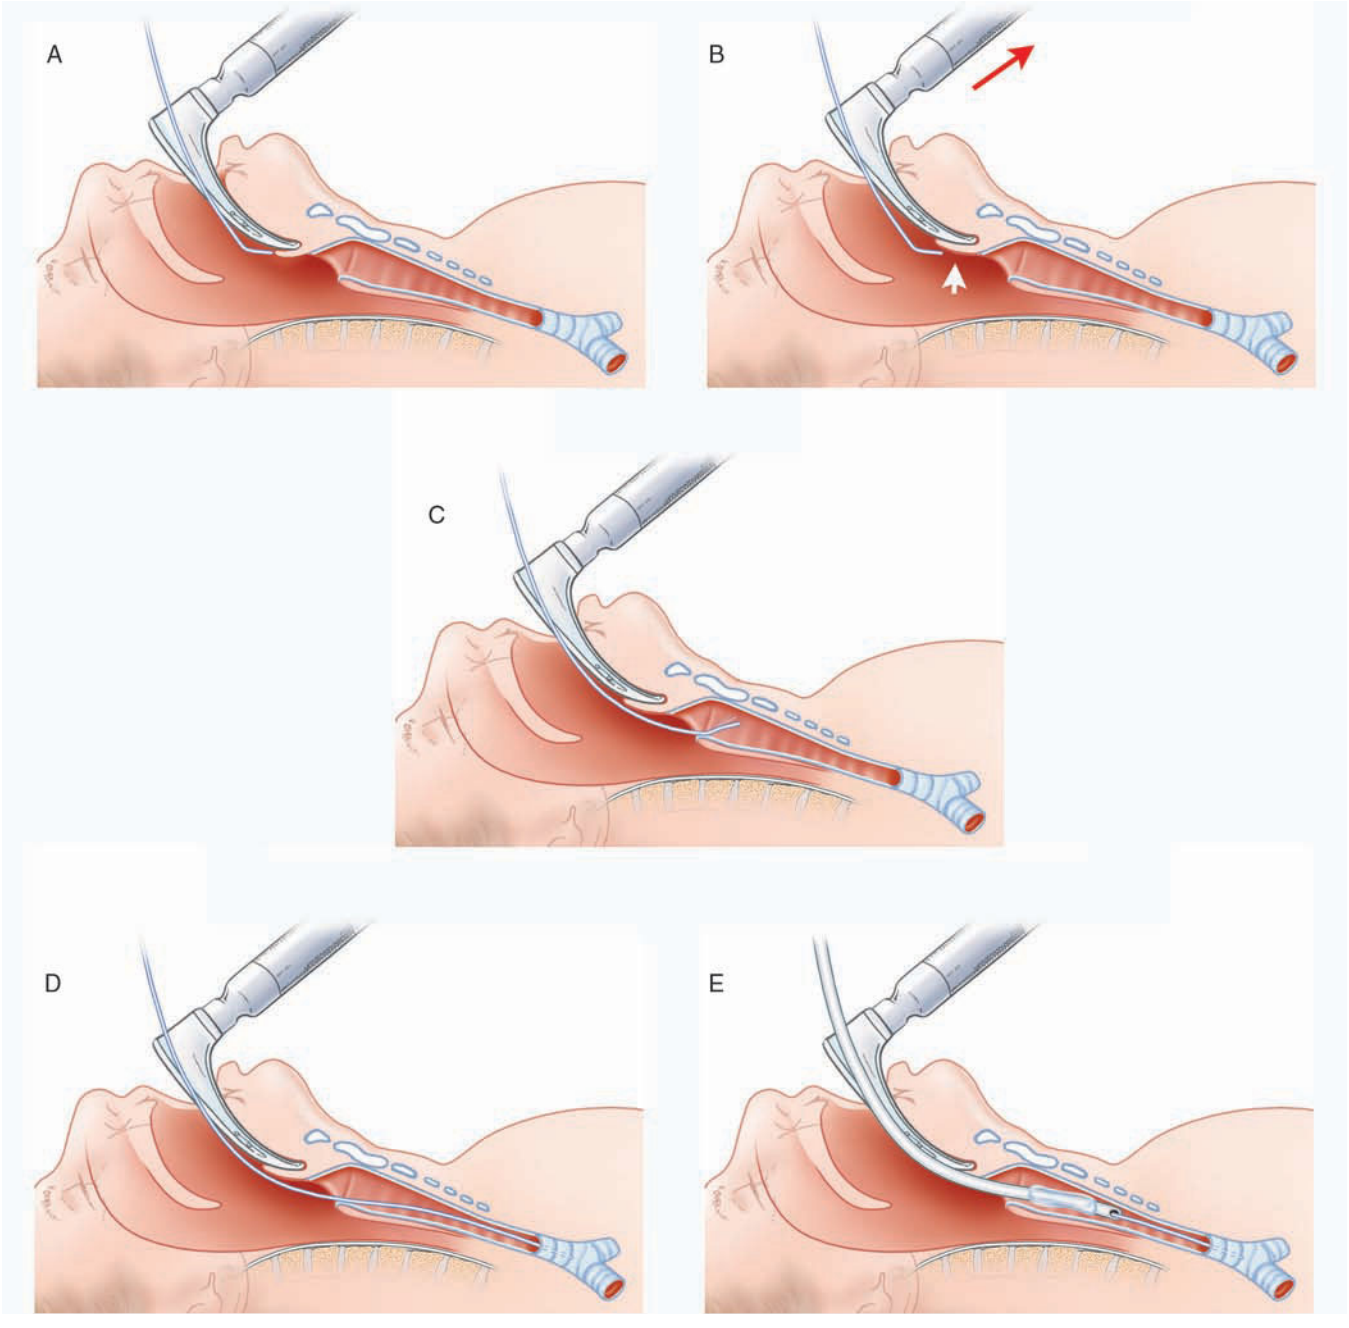

FIGURE 15-6. Intubation using a bougie. **A.** The laryngoscope has been inserted and the bougie advanced into the hypopharynx. **B.** The bougie is advanced under the epiglottis. **C.** The bougie is inserted into the trachea and advanced over the tracheal rings. **D.** The bougie is advanced until its tip is at the carina or mainstem bronchus. **E.** The endotracheal tube is advanced over the bougie and into the trachea.

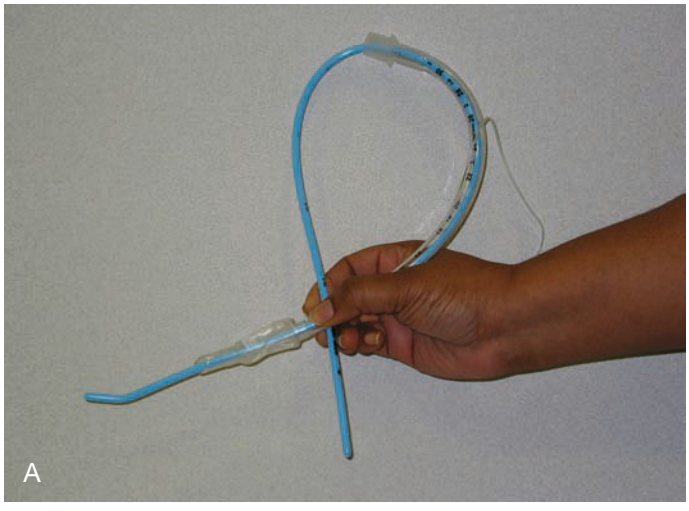

available than a retrograde guidewire kit. A bougie can be inserted through the skin and airway incision, laceration, or defect and advanced superiorly to exit the patient's mouth. The endotracheal tube can then be loaded over the bougie and advanced into the trachea. Refer to Chapter 23 for the complete details of retrograde guidewire intubation.

BOUGIE-ASSISTED CRICOTHYROIDOTOMY

Various medical and surgical specialities have used the bougie as an aid when performing a cricothyroidotomy.[26,27] It was found using a bougie as an aid to be easier and faster to teach how to perform a cricothyroidotomy in an animal lab than a traditional cricothyroidotomy.[28] The military describes this as the preferred technique of combat airway management.[29] The three-step technique using the bougie can be quickly taught to combat medics and performed in complete darkness using night vision goggles. A bougie placed through the incision maintains the open tract, provides tactile confirmation of tracheal placement, and serves as a guide for the endotracheal tube insertion.

ALTERNATIVE USES

Various other applications of the bougie have been described.[30–33] The bougie can be used as an adjunct in nasal intubation in the adult and pediatric populations.[30,31] The bougie has been successfully used

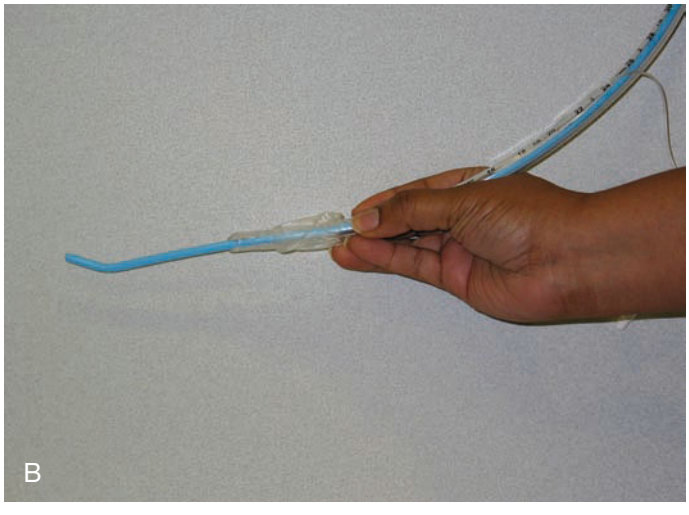

FIGURE 15-7. Two methods to preload an endotracheal tube onto a bougie. **A.** The curved hold. **B.** The straight hold.

to aid in correct placement of a double-lumen airway tube in a difficult airway.[32] It has also been described and tested as a back-up device during extubation to allow for a quick reintubation in case of the need to re-secure the airway.[33]

COMPLICATIONS

There are some complications specific to the use of a bougie. The bougie can cause trauma to the airway soft tissues.[9–11,34,35] The Frova causes significantly more complications than other bougies (5% incidence vs. rare).[34] This difference is most likely due to using the metal cannula, making the Frova quite stiff. The Frova with the metal cannula exerts more force on the airway tissues than other bougies.[15,35] Using the Frova without the metal cannula will reduce the incidence of tissue trauma. Single-use bougies may be more prone to cause soft tissue trauma when compared to multiple-use bougies, especially if they are held close to the distal end.[13,35] A false passage can be created by the tip of the bougie penetrating the soft tissues.[9] Insertion of an endotracheal tube over the bougie and into a false passage can increase the amount of soft tissue damage and hemorrhage. Insufflation of air into the surrounding soft tissues can compress the trachea and cause an external airway obstruction. A bougie can perforate the airway and result in a tension pneumothorax.[36] Advancement of the bougie into the trachea or mainstem bronchus can induce bronchospasm.[34] The remainder of the complications is similar to those of orotracheal intubation (Chapter 11).

SUMMARY

Bougies are widely used to aid in intubation with traditional direct laryngoscopy when the glottic opening cannot be adequately visualized. They have been successfully used both in the adult and pediatric population, with devices available for use with endotracheal tubes as small as 3.0 mm in size. They are also used to aid in placement of supralaryngeal devices, blind nasotracheal intubations, placement of double-lumen airway tubes, retrograde intubation, and cricothyroidotomies. A bougie should be a required device in any emergency or difficult airway cart.

16 Digital (Tactile) Orotracheal Intubation

O. John Ma and Amanda Munk

INTRODUCTION

For patients who require orotracheal intubation, digital (tactile) intubation is an alternative technique to traditional direct laryngoscopy.[1–12] This procedure involves using the index and middle fingers as a guide to blindly place the endotracheal tube into the patient's larynx. Digital tracheal intubation has been demonstrated to be a safe, simple, and rapid method.[1] It should be considered as a secondary method of intubation when other methods prove difficult or impossible.[1] It is particularly suited for prehospital and aeromedical use, where equipment and alternate intubation techniques are limited or unavailable. One study demonstrated an 88% success rate among paramedics who intubated with this technique.[2]

ANATOMY AND PATHOPHYSIOLOGY

For this procedure, the only two significant anatomic structures that the intubator will encounter are the patient's tongue and the epiglottis. The epiglottis is the cartilaginous structure that is located at the root of the tongue and serves as a valve over the superior aperture of the larynx during the act of swallowing.[3]

INDICATIONS

Digital orotracheal intubation is an ideal alternative technique for intubating the comatose or chemically paralyzed patient when other more conventional methods for intubation have failed. In particular, this procedure is useful when oral secretions or blood inhibit the direct visualization of the upper airway.[1] Since this technique involves minimal movement of the head and neck, it may be a suitable method for intubating patients with known or suspected cervical spine injuries. Digital intubation may be a useful procedure for paramedics and aeromedical personnel in the out-of-hospital setting, when trapped patients require intubation but are not in a position for more conventional methods.[2] It is an alternative technique for out-of-hospital intubation where other techniques and equipment are unavailable or limited.

This procedure has also been performed successfully in intubating neonates.[4,11,12] One study comparing neonatal digital intubation with direct laryngoscopy demonstrated digital intubation to be more rapid and more successful on the first attempt.[5]

CONTRAINDICATIONS

There are no absolute contraindications to digital intubation. The main danger of this procedure is to the healthcare worker performing the intubation, who is at risk for having his or her fingers bitten by the patient. **This technique should not be performed on any patient who is awake or semiconscious. It should be performed only on patients who are paralyzed or unconscious.** Relative contraindications would be performing this procedure on a patient with multiple fractured teeth that may abrade or cut the intubator's fingers, or a patient whose ingestion may present a biochemical hazard to the intubator.

EQUIPMENT

- Endotracheal tubes, various sizes
- Wire stylet, malleable (optional)
- 10 mL syringe
- Water-soluble lubricant or anesthetic jelly
- Bag-valve device
- Oxygen source and tubing
- Gauze, 4 × 4 squares

PATIENT PREPARATION

Endotracheal intubation in the Emergency Department is commonly performed on an emergent or urgent basis. If there is time, explain the risks, benefits, and complications of the procedure to the patient and/or the patient's representative.

The use of gloves, a bite block, and gauze over the teeth as guards are recommended when performing this procedure. The patient should be lying supine. If the patient has sustained a concerning mechanism of injury, the cervical spine should be immobilized. An assistant can help hold the patient's head to maintain in-line immobilization. Place the patient on continuous cardiac monitoring, pulse oximetry, and supplemental oxygen.

TECHNIQUE

Prepare the endotracheal tube. Attach a 10 mL syringe to the cuff's inflation port. Inflate the cuff and inspect it for any air leaks. Deflate the cuff and leave the syringe attached to the inflation port. The use of a stylet is optional, but commonly used by most practitioners in this procedure.[6] It may be used if the patient's larynx is anterior, the intubator has short fingers, or it is the physician's preference. Lubricate and insert the stylet until it is 1 cm proximal to the distal end of the endotracheal tube. Bend the malleable stylet just as it enters the endotracheal tube. This will prevent it from migrating distally and injuring the patient. Gently bend the distal end of the endotracheal tube into a "J."[1] Liberally lubricate the distal end of the endotracheal tube. Induce anesthesia (Chapters 8 and 10) if the patient is conscious.

The intubator should stand at the patient's right side and be facing the patient. Insert the index and middle fingers of the right hand into the right angle of the patient's mouth (**Figure 16-1**).[1,5] Slide the fingers along the surface of the tongue until the epiglottis is palpated. The metacarpophalangeal joints of the index and middle fingers will usually be at the level of the patient's incisors in an adult. The tip of the epiglottis is approximately 8 to 10 cm from the incisors. Elevate the epiglottis with the index finger (**Figure 16-2**). The thumb of the left hand may be used to provide cricoid pressure if needed.[7]

With the left hand, insert the endotracheal tube along the left side of the patient's mouth and between the two fingers (**Figures 16-1 & 16-2**).[1,5] Alternatively, the endotracheal tube can be advanced between the two fingers and the tongue. Gently advance the tip of the endotracheal tube into the patient's trachea (**Figure 16-2**). Do not advance the endotracheal tube if any resistance is encountered. Partially withdraw the endotracheal tube and reattempt to insert it into the patient's trachea. Alternatively, withdraw the endotracheal tube completely, bend it more sharply, and then attempt to insert it into the trachea. Have an assistant withdraw the stylet if one was used. Advance the endotracheal tube approximately 3 to 4 cm.[1,8] While securely holding the endotracheal tube with the left hand, gently withdraw the right hand from the patient's mouth. Inflate the cuff of the endotracheal tube. Begin ventilating the patient while securely holding the endotracheal tube and confirming proper placement.

The technique of digital orotracheal intubation is not as simple as some may think. A patient's mouth may appear too small to allow an

FIGURE 16-1. The index and middle fingers are placed in the right side of the patient's mouth and advanced until the epiglottis is palpated. The endotracheal tube is inserted into the patient's mouth between the two fingers.

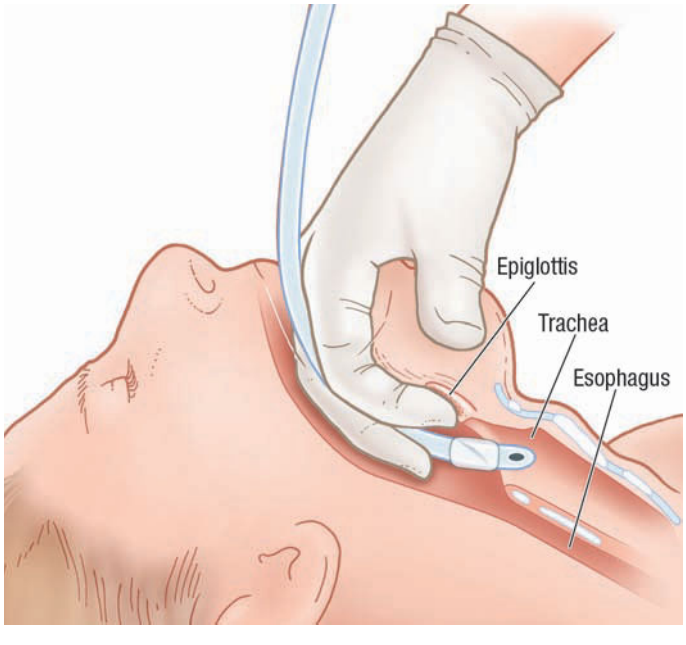

FIGURE 16-2. Advancing the endotracheal tube. The epiglottis is elevated with the index finger. The endotracheal tube is advanced between the fingers and into the larynx.

endotracheal tube and two fingers of the intubator. Use the fingers in the patient's mouth to push their jaw and tongue forward. If the patient's mouth still appears small, apply gauze squares over their mandibular incisors and push their mouth open further with the bases of the fingers in their mouth.

It may be difficult to blindly identify the patient's epiglottis. Insert your fingers in the midline of the patient's mouth and slowly push them posteriorly. The fingers will roll off the posterior portion of the tongue and allow you to palpate the epiglottis. Be careful to not push the epiglottis posteriorly. Once identified, move your fingers to the right side of the patient's mouth while the fingertips are in constant contact with the epiglottis. Continue the procedure as described above.

Some may be concerned their fingers are not long enough to palpate the epiglottis. Push the soft tissue in the right angle of the patient's mouth posteriorly while inserting your fingers posteriorly in their mouth. This will allow your fingers to reach more posteriorly.

This technique can be used in patients of all ages, including neonates.[11,12] Use only the index finger of little finger when performing this procedure in young children. Use the appropriate size suction catheter or endotracheal tube as would be used to orally intubate the child. Do not insert the catheter or endotracheal tube if the child is breathing using this technique or their vocal cords can be damaged.

ASSESSMENT

The placement of an endotracheal tube should be followed by an assessment to ensure its proper positioning (Chapter 12). This includes visual inspection of chest rise and lack of abdominal movement with ventilation, fogging in the endotracheal tube for at least six breaths, auscultation, and end-tidal CO_2 monitoring. This should be followed by a chest X-ray to confirm proper positioning of the endotracheal tube within the trachea.

AFTERCARE

The steps of ensuring proper placement of the endotracheal tube and securing the tube are the same as for any patient who has undergone orotracheal intubation (Chapter 11).

COMPLICATIONS

No significant complications to the patient have been identified with digital intubation. One study involving a small number of cadavers found that digital intubation predisposes to left mainstem intubation.[9] The investigators concluded that decreased right-sided breath sounds after tactile intubation may represent an easily corrected left mainstem intubation rather than other pathology. An awake or semiconscious patient may gag, with subsequent vomiting and aspiration and injury to the intubator's fingers. For added safety, insert a bite block between the patient's molars if its placement still allows enough space in the patient's mouth for two fingers and the endotracheal tube. The possibility of esophageal intubation is significant, especially if the intubator has small fingers or the airway is anterior. Hypoxemia can result from numerous attempts at intubation without any intervening ventilations. The endotracheal tube should be inserted gently to prevent traumatic injury to the patient's hypopharynx, vocal cords, or trachea.[6]

SUMMARY

Digital (tactile) intubation remains a viable alternative technique for management of the airway. Every Emergency Physician should become familiar with this technique. It is a rapid and safe method to intubate a patient. It is an ideal method for intubating a comatose or paralyzed patient if the upper airway cannot be visualized because of trauma, secretions, or blood. Digital intubation should also be considered when intubating the patient with a known or suspected cervical spine fracture, since this technique requires minimal head and neck movement. It is also a viable method for out-of-hospital intubation.

17 Lighted Stylet Intubation

Philip Bossart and Michael Wallace

INTRODUCTION

Direct laryngoscopy is the most common method of tracheal intubation in the Emergency Department. However, in about 1% to 3% of Emergency Department patients requiring intubation, direct laryngoscopy will be very difficult or impossible.[1,2] This may be due to many different causes including jaw immobility, limited cervical spine mobility, or excessive airway bleeding. In these situations, blind intubation using a lighted stylet is a proven valuable technique.[3–7] Lighted stylet intubation relies on the transillumination of the soft tissues of the anterior neck to indicate intratracheal endotracheal (ET) tube placement. A bright, well-defined glow is seen in the anterior neck when the light is in the trachea. However, a diffuse, less intense glow is seen with esophageal intubation. Lighted stylet intubation is a relatively easy technique to learn and rapid to perform.

The first published report of using a light source to guide intubation was in 1959.[8] They described the device and technique in order to perform blind nasal intubations in the operating room. However, this technique did not receive much attention until the late 1970s when the Flexi-lum light wand (Concept Corporation, Clearwater, FL) was introduced.[9] Over the years, more powerful and less heat emitting light sources have been developed along with more flexible stylets. Today there are at least four currently available devices, all of which are inserted into an ET tube instead of a standard stylet. These include the Trachlight (**Figure 17-1**), the Light Wand (**Figure 17-2**), the Flexible Lighted Stylet (**Figure 17-3**), and the Tube-Stat (**Figure 17-4**). Although there are slight differences in design, they all rely on using a lighted stylet to transilluminate the anterior neck and guide blind intubation of the trachea.

ANATOMY AND PATHOPHYSIOLOGY

The trachea lies anterior to most structures of the neck and is covered anteriorly only by skin, subcutaneous tissue, and pretracheal fascia. A light source positioned within the trachea will transilluminate a bright and discrete glow that can easily be seen on the surface of the neck. In contrast, the esophagus lies posteriorly and is surrounded by numerous soft tissue structures. A light source directed within the esophagus will be diffused by the surrounding tissue and appears dull. At the bedside, the Emergency Physician can easily discriminate between the dull, diffuse transillumination of an esophageal light source and the more discrete, intense signal transmitted from within the trachea. A submental, superior to the hyoid bone, glowing light indicates that the tip is positioned in the vallecula. A lateral glowing light indicates placement in the pyriform sinus.

TABLE 17-1 Indications for Intubating with a Lighted Stylet

Anatomic abnormalities	**Limited jaw mobility**
Congenital head and neck anomalies	Temporomandibular immobility
Pierre Robin syndrome	Trismus
Treacher Collins syndrome	
Midface hypoplasia	**Trauma**
	Dental trauma
Excessive secretions	Maxillofacial trauma
Blood	
Vomitus	**Miscellaneous**
	Unable to intubate by other methods
Limited cervical spine movement	
Known or suspected cervical spine injury	
Cervical arthritis	
Burn strictures of the neck	

INDICATIONS

There are numerous indications for lighted stylet intubation (**Table 17-1**). Lighted stylet intubation is a valuable rescue technique in patients who can be ventilated and oxygenated but are unable to be intubated with direct laryngoscopy. It is particularly useful in patients that have cervical spine immobilization or restricted neck movement, limited jaw opening, extensive oral trauma, loose teeth, or extensive blood or secretions in the hypopharynx that limit visibility. It can be used as a backup technique or primarily if direct laryngoscopy is predicted to be difficult. There are limited data comparing lighted stylet intubations to other rescue techniques.[10–12] However, there is literature to suggest that lighted stylet intubations are faster and have fewer complications than blind nasotracheal and fiberoptic bronchoscopy-assisted intubations.[6,11,12] In addition, lighted stylets are easier to use, less expensive, and more portable than fiberoptic bronchoscopes.[12]

Lighted stylet intubations can be performed as part of rapid sequence intubation as well as on sedated, spontaneously breathing patients with topical airway anesthesia. Lighted stylets can be used for oral or nasal intubations.[13] This technique can also be used for pediatric patients and infants.[14–16]

CONTRAINDICATIONS

Intubation with lighted stylets is relatively safe and simple. There are few contraindications to this technique. **Patients with laryngeal trauma should have direct laryngeal visualization for intubation rather than a blind technique that may cause additional trauma.** As a blind technique, it should not be used if there is any active infection or known tumor of the posterior pharynx or upper airway. The presence of epiglottitis, a retropharyngeal abscess, tracheal stenosis, a laryngeal polyp or tumor, or an airway foreign body precludes the use of this technology. It may be less successful in bright sunlight, in those with very dark skin, and particularly in the obese patient.[17,21,22]

It is relatively contraindicated in patients who cannot be oxygenated and ventilated. However, it could be used in this situation by very experienced physicians while simultaneous preparations are underway for a cricothyroidotomy. Lighted stylets should be used only by physicians who have sufficient experience and training with the equipment and the technique.

If the lighted stylet meets resistance, it should be withdrawn, redirected, and advanced only if it passes with ease. **Should unexpected difficulty occur during passage of the lighted stylet, the technique should be abandoned and an alternative method used to intubate the patient.**

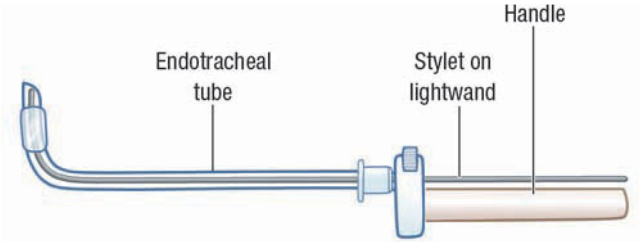

FIGURE 17-5. The Trachlight brand lighted stylet

EQUIPMENT

- Lighted stylet
- ET tubes, various sizes (ETT)
- 10 mL syringe
- Water-soluble lubricant
- Bag-valve device
- Equipment for orotracheal intubation (Chapter 11)

The basic unit of a lighted stylet is quite simple. It consists of a handle, a malleable stylet, and a light on the end of the stylet (**Figure 17-5**). Numerous variations exist on the basic unit. The handle contains the battery, an on–off switch, and sometimes an on–off indicator light. They may be reusable or single-use disposable devices. The stylet is malleable and available in numerous sizes. Longer stylets allow for nasal and oral intubation in adults. Stylets are also available in smaller lengths and widths to allow for use in the small ET tubes for infants and children. The stylet is inserted into the ET tube instead of a standard stylet.

PATIENT PREPARATION

Once the decision is made to intubate, the patient should be prepared as for any other intubation (Chapter 11). The patient should have intravenous access secured and routine hemodynamic monitoring, including an automatic blood pressure monitor, a cardiac monitor, and a continuous pulse oximetry monitor. Suction should be immediately available. Rapid sequence intubation with an induction agent and paralytic agent is the most common technique used in the Emergency Department. However, lighted stylet intubations can be performed with mild sedation and topical anesthesia in cooperative patients.

As with all intubations, the patient should be preoxygenated prior to airway manipulation. Unlike the case with other techniques, the position of the neck can be neutral. The "sniffing" position is not required for this technique. If the patient is in a cervical collar, the anterior half must be opened or removed to be able to visualize the glowing light. An assistant can maintain in-line stabilization of the cervical spine when the collar is opened.

TECHNIQUE

OROTRACHEAL INTUBATION

The exact technique will depend upon the type of lighted stylet or lightwand used. Since this technology varies by the manufacturer, anyone employing these airway adjuncts should be familiar with the equipment and manufacturer's instructions prior to adopting them for use clinically. This text describes the general guidelines for the lighted stylets available at the time of this writing. The reader is urged to take advantage of the teaching videos supplied by some manufacturers.

Check that the light source is working and apply a water-based lubricant to the stylet. Attach a 10 mL syringe to the ET tube cuff inflation port and ensure the integrity of the cuff. Insert the stylet through the ET tube. **The tip of the stylet should remain just inside the ET tube so that the stylet does not damage soft tissues.**

Bend the tip of the ET tube and stylet just proximal to the cuff or about 3 to 6 cm from the distal end (**Figure 17-5**). The bend may have to be a little more proximal or distal depending on the length of the patient's neck. Measure the mandibular–hyoid distance in the patient. Place the index finger in the submental space below the chin and determine the number of finger breadths between the mandible and the hyoid bone.[5] Typical measurements are one to three finger breadths. Bend the tip of the ET tube and stylet sharply at a site that approximates the mandibular–hyoid distance between the bend and the junction of the lighted tip of the stylet. This is usually 3 to 6 cm from the distal end of the ET tube and just above the cuff. Avoid making the bend at the cuff, if possible, to prevent damaging the cuff. **Be sure the bend is about 90° to allow the maximal light intensity to be directed anteriorly.**

Stand above or to the side of the patient's head. The lighted stylet, unlike the traditional laryngoscope, can be held in either hand. Lower the bed to facilitate insertion of the lighted stylet. Grasp the patient's jaw with your nondominant hand. Place your thumb on the mandibular molars and your fingers under the body of the mandible. Lift upward and inferiorly to open the jaw, elevate the tongue, and elevate the epiglottis. Grasp the lighted stylet with your dominant hand and turn it on. It is best held with a "pencil-grip" over the proximal ET tube.

Introduce the ET tube from the side of the patient's mouth and bring it to the midline. As the hockey stick-shaped tip is placed over the tongue, the handle will project toward the patient's feet (**Figure 17-6A**). Advance the tip by moving the handle in a vertical arc toward the patient's head (**Figure 17-6B**). This will bring the ET tube tip toward the vocal cords. A bright light will be seen in the midline of the neck just below the hyoid bone (**Figure 17-7A**). **If the light is in the submental space, the tip of the ET tube is in the vallecula (Figure 17-7B). If the light is lateral, the tip of the ET tube is lodged in the pyriform sinus (Figure 17-7C). A dull, faint light in the midline signifies that the tip of the ET tube is in the esophagus (Figure 17-7D).** If the glowing light is malpositioned, simply withdraw the ET tube, reposition it in the midline, and advance it again.

Once a bright and discrete light is detected in the midline at the level of the thyroid cartilage (Adam's apple), it is safe to advance the ET tube. If you are using the Trachlight, the manufacturer suggests withdrawing the stylet 10 cm before advancing the ET tube. This makes the distal tip of the ET tube more flexible and helps it make the acute turn before advancing down the trachea.

Advance the ET tube while observing the transilluminating light march down the neck to the suprasternal notch (**Figure 17-7A**). The light will disappear as the tube passes behind the suprasternal notch. If the glowing light is in the midline and the ET tube is resistant to advancement, the epiglottis is obstructing its advancement. Slightly rock the unit in the sagittal plane (from the patient's head to the feet) to slip the tip of the ET tube under the epiglottis. If resistance is still encountered, remove the lighted stylet. Ventilate the patient with a bag-valve-mask device. Load a smaller ET tube onto the lighted stylet and try again. At the point the light is lost, the tip of the ET tube is appropriately positioned midway between the vocal cords and carina.[25] Remove the stylet, inflate the ET tube cuff, confirm proper ET tube placement, secure the ET tube at the lips, and begin ventilating the patient.

Special caution should be used in very thin or very obese patients. In the thin patient, a bright light may be visible even when the stylet

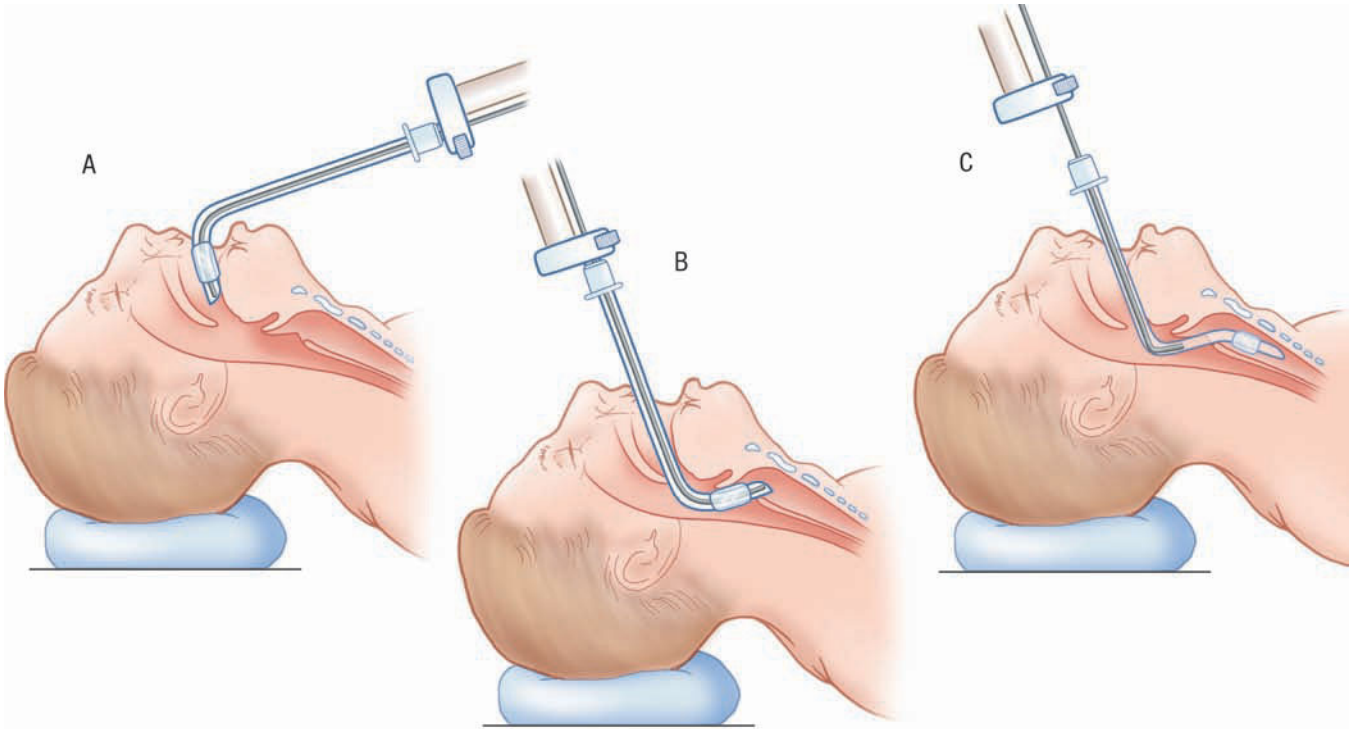

FIGURE 17-6. Insertion of the Trachlight lighted stylet. **A.** Insert the hockey stick-shaped ET tube and the stylet over the tongue. **B.** Move the tube in a vertical arc toward the patient's head. As the lighted stylet approaches the trachea, the bright light transilluminates the anterior neck. **C.** The ET tube is advanced into the trachea.

is in the esophagus. When the patient is thin, gently rock the light off midline to compare the diffuse dull light to that seen when the light is truly midline. In the obese patient, the extra soft tissue may dull the light. Dim the room lights to facilitate adequate visualization.

The glowing light must maintain a continual brightness to demonstrate tracheal intubation. If the glowing light is briefly lost or dulls and then returns, the ET tube has been misplaced in the esophagus. The brief loss or dulling of the glowing light corresponds to its passage behind the larynx. The return of the bright glowing light corresponds to the ET tube advancing past the larynx and into the esophagus. This is commonly seen in infants, small children, and very thin adults. Gently withdraw the lighted stylet while applying anteriorly directed traction to the tip of the stylet. Stop withdrawing the lighted stylet when the glowing light suddenly intensifies after it exits the esophagus. Readvance the lighted stylet, as previously described, while applying anterior traction on the unit to help it enter the larynx.

NASOTRACHEAL INTUBATION

The procedure for nasotracheal intubation is similar to orotracheal intubation with the lighted stylet with a few differences. The nasal passages should be treated with a topical anesthetic and a topical decongestant to vasoconstrict the mucosal tissue. The nasal passage may need to be dilated to accommodate the ET tube. Please refer to Chapter 22 for a complete discussion on the preparation of the nasal cavity for intubation. The lighted stylet should have a more gentle curve of about 100° to 120°. The bend to tip length should correspond to the distance from the posterior nasopharynx to the cricothyroid membrane.

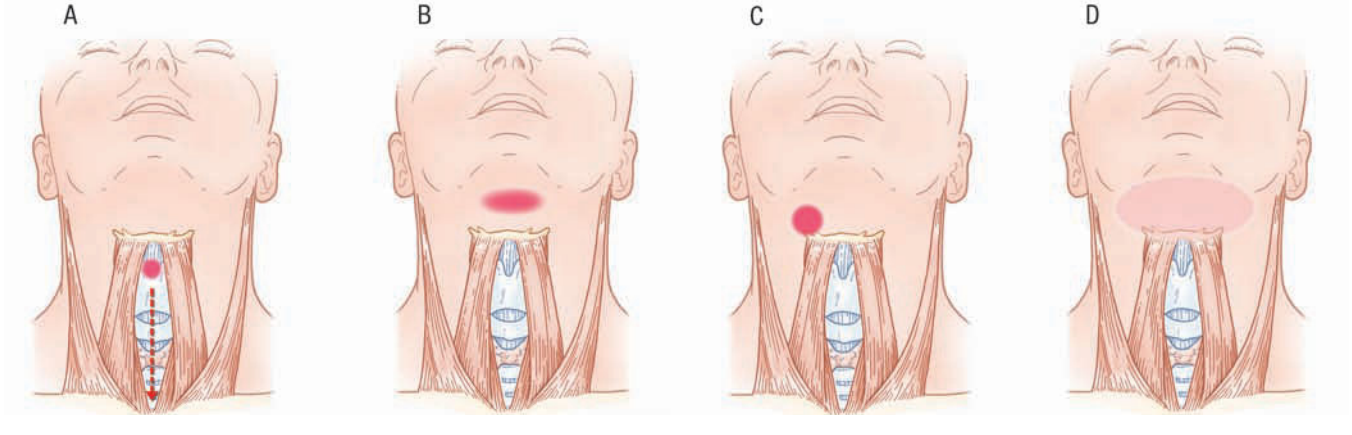

FIGURE 17-7. Appearance of the transilluminated light of the lighted stylet based on the location of the tip. **A.** Proper placement in the larynx with a bright distinct light in the midline at the level of the thyroid cartilage. With advancement of the ET tube, the light moves down the anterior neck and disappears behind the sternal notch (*dashed arrow*). **B.** Incorrect placement in the vallecula causes a submental glow, superior to the hyoid. **C.** Incorrect placement in the pyriform sinus causes a glow off the midline. **D.** Incorrect esophageal placement causes a diffuse, dull, or absent light.

ASSESSMENT

The patient should be assessed continuously at every step of the procedure to assure adequate oxygenation and ventilation. The position of the ET tube should be confirmed by end-tidal CO_2 monitoring, esophageal detector device, fogging in the ET tube for at least six ventilations, auscultation, and chest X-ray. Please refer to Chapter 12 for a more complete discussion regarding the confirmation of ET intubation.

AFTERCARE

The ongoing care of the patient should proceed as with any other intubation technique. Routine care of the ET tube is no different. The manufacturer's guidelines should be followed for maintenance of the equipment.

COMPLICATIONS

Intubation with a lighted stylet is a very safe procedure with a very low complication rate.[6,17] In over 30 years of use, there are only a small number of reported complications. These include two reports of accidental bulb dislodgment, two arytenoid dislocations, one case of stylet fracture, a lacerated frenulum, and varied reports of mild soft tissue trauma.[18–20] However, sore throat, hoarseness, and dysphagia seem to occur less frequently with lighted stylets than with direct laryngoscopy.[7] The cases of equipment failure noted above have been in older models of lighted stylets. There are data to suggest that lighted stylet intubations are less traumatic than direct laryngoscopy.[7] No complications were noted in 253 patients intubated with light stylets.[17] In addition, intubation with lighted stylets may cause less cervical spine motion compared with direct laryngoscopy.[25]

Success rates with lighted stylet intubation are comparable to those with other techniques. First attempt success rates are reported to be from 70% to 92%.[4,6,7] When multiple attempts were allowed, success rates approached 100%. In the prehospital setting with suboptimal intubating conditions, success rates of 88% have been reported.[21] Hung *et al.* reported successful intubation with lighted stylets in 95 out of 96 patients who had known difficult airways.[22] This series included patients with difficult or failed intubations by direct laryngoscopy, patients with unstable cervical spines, severe jaw immobility, and morbid obesity. Holzman *et al.* reported successful intubation of 30 out of 31 children with anatomic airway abnormalities.[14]

Intubation times with lighted stylets are comparable to those with other techniques and range from 16 to 45 seconds.[3,4,22] There does not appear to be any significant difference in degree of sympathetic stimulation and hemodynamic alterations between intubations with direct laryngoscopy and those with lighted stylets.[23,24] The skill level of the intubator is an important factor in the success rate, time to intubation, and possible complication rate.[14] Experience leads to faster intubation times and skills most likely will improve with practice in a cadaver lab or with a patient simulator.[5,10]

SUMMARY

Lighted stylet intubation is an easily learned technique that is a valuable adjunct for securing difficult airways. It is particularly useful in patients with limited jaw opening, limited neck movement, and marked airway bleeding. The American Society of Anesthesiologists includes use of lighted stylets in its recommendations for the management of difficult airways. The American Heart Association encourages instruction in alternative airway approaches, including lighted stylets, for difficult airways. The use of lighted stylets has proven to be rapid, safe, and effective in emergent and difficult settings.

The success of lighted stylet techniques is determined by the experience of the Emergency Physician. Since this technique is likely to be of greatest benefit in the occasional unexpected airway emergency, maintaining sufficient skills to use it in the emergent setting is a challenge. In order to be of use in the acute situation, Emergency Physicians will need to devote time and effort to developing and maintaining the skills they will need to cope with an airway emergency when it presents.

18 Supraglottic Airway Devices

Fred A. Severyn

INTRODUCTION

Airway management remains one of the cornerstones of the clinical practice of Emergency Medicine in both the Emergency Department and the prehospital environment. The majority of advanced airway placements in the prehospital environment occur in the cardiac arrest or trauma patient. Advances in the science of performing better cardiopulmonary resuscitation (CPR) aim to limit the "no-flow-time" associated with resuscitation. Most supraglottic airway devices aim for an insertion time under 30 seconds. Some Emergency Medical Service (EMS) systems have emphasized the use of an alternative airway device over endotracheal intubation.[1,2]

In the overall performance of airway management, the provider often begins with the basic life support (BLS) skill subset such as airway positioning, suctioning, and assisting spontaneous respirations with the use of a bag-valve-mask (BVM) device. They then jump to the advanced life support (ALS) skill subset such as placement of cuffed endotracheal tubes and surgical airway management. Traditional ALS management has revolved around the concept of placing an endotracheal tube. Over time, this has rolled out to the prehospital environment of care and is now firmly established into the current scope of practice for EMS professionals. The literature remains controversial and divided, with multiple recent studies suggesting limited benefit of prehospital endotracheal intubation in a variety of clinical settings. Even more disheartening are numerous studies demonstrating a significant percentage of unrecognized esophageal airway placement or endotracheal tube migration out of the airway upon Emergency Department arrival. Such therapeutic misadventures guarantee bad outcomes.[3] Most of these studies describe relatively busy EMS systems with clearly defined medical oversight. With inexperienced hands, the success rate is lower and the complications rates are high, and aggressive airway management has been linked to a decreased odds ratio for patient survival. In between BLS and ALS lies a very large grey area, with many airway adjuncts available to help with airway management.

The creation of a wide variety of airway adjuncts termed "supraglottic airway devices" (SADs) has occurred in order to facilitate airway management. Simplistically, SADs function as a bridge between the mouth and the vocal cords, allowing for air movements while bypassing tongue-induced airway obstruction.[4] Some recommended the term "extraglottic" to replace supraglottic in order to better define the relationship between function and not define anatomic position. For the purposes of this chapter, the two terms will be considered synonymous.

The classic laryngeal mask airway (LMA) is a common example of a SAD. It is utilized daily in operating room cases with a cumulative record of over 200 million episodes of use in patient care.[4,5] Most Emergency Physicians in training will get some exposure to the use of SADs as a result.[5] Not surprisingly, the logical migration

of airway devices from the operating room to the prehospital and Emergency Department environments has also begun. Each SAD comes with manufacturing claims as to their device superiority over the competition in a very competitive marketplace. It is difficult for Emergency Physicians to keep up with the industry explosion of these airway adjuncts. The disadvantages of SADs are that they are only temporary airway devices and must be removed or replaced with another airway device within a few hours.

The Emergency Physician will be on the receiving end of patients in which a wide variety of SADs have been used by EMS agencies. **There is also a need for SADs in the event of airway rescue after a failed intubation in the Emergency Department.** The American Society of Anesthesiologists has incorporated SADs into their "Can't ventilate, Can't intubate" difficult airway algorithm. The American Heart Association has also included their use in the algorithms for airway management in association with CPR. It is a reasonable expectation for the Emergency Physician to develop expertise and experience with SADs. This chapter discusses some of the many commonly available SADs. The LMAs and supraglottic dual lumen airway tubes (i.e., Combitube and EasyTube) are discussed in Chapters 19 and 20, respectively.

ANATOMY AND PATHOPHYSIOLOGY

Endotracheal intubation relies upon the placement of a ventilation tube between the vocal cords and into the trachea in order to provide a low resistance bridge between the trachea and the ventilation circuit. This bypasses the most common airway obstruction, the posteriorly directed lax tongue. SADs do not pass between the vocal cords. **SADs offer low resistance to air flow, protect the respiratory tract from gastric and oropharyngeal secretions to a variable degree, and are suitable for positive pressure ventilation in the nonspontaneously breathing patient while limiting potential adverse events.**[5] They rely on the close anatomic relationship between the laryngeal inlet and the upper esophagus. Many SADs allow the insertion of an introducer or an endotracheal tube to be passed through the airway tube and into the trachea.

INDICATIONS

The use of SADs is reserved for the unconscious patient without an intact gag reflex. They can be used in the unconscious patient who is difficult to ventilate with a face mask while preparations are being made for endotracheal intubation. The patient's mouth must be able to open at least 1.5 to 2.0 cm to allow for the insertion of the SAD. They can be used as either a primary or secondary airway. They are used more commonly as a primary airway, replacing the endotracheal tube, in the prehospital environment. They are used in the prehospital environment, and more often in the Emergency Department, as a secondary airway or rescue airway management device in cases of difficult or failed intubations. They should be considered in the "can't ventilate, can't intubate" patient when time is of the essence. Their use as a rescue airway device can "buy time" until additional airway assistance, equipment, and/or expertise can be brought to the patient. Consider using SADs during the initial resuscitation of the cardiac arrest patient as they are quick to insert and do not require stopping chest compressions during CPR.

CONTRAINDICATIONS

The presence of an intact gag reflex is an absolute contraindication to the use of SADs, regardless of which device is used. The inability to open the patient's mouth at least 1.5 to 2.0 cm will prevent the insertion of most SADs. Oral, pharyngeal, and laryngeal trauma are relative contraindications to using a SAD. These devices are contraindicated in the patient with known esophageal disease, a caustic ingestion, or airway burns. Many SADs require the patient to be over a certain height and/or weight to be used. Refer to the specific manufacturer recommendations when choosing a SAD and the appropriate size.

EQUIPMENT

- SADs, various types and sizes
- Endotracheal tubes
- Water-soluble lubricant
- Syringes, various sizes
- Oxygen source, tubing, and regulator
- Face masks
- Bag-valve device
- Pulse oximeter
- Cardiac monitor
- Noninvasive blood pressure monitor
- ALS medications
- Advanced airway equipment
- Surgical airway equipment

There are at least 17 variations of SADs on the market today. They are conceptually divided into three broad categories based on the primary separation between the respiratory and gastrointestinal tracts. These include cuffless anatomic preshaped sealers, cuffed perilaryngeal sealers, and cuffed pharyngeal sealers.[6,7]

The cuffless anatomic preshaped sealers are flexible devices whose shape is based on spiral computed tomography (CT) scan investigations of normal subjects of varying heights and weights.[8] These studies created a design template for a device that when inserted will accommodate the "normal" airway in the majority of cases.[8] Without an inflatable separation between the respiratory and gastrointestinal tracts, there is less flexibility to their design and use. **These devices offer less protection from aspiration of gastric contents than other SADs.** SADs in this category include the single use liner of pharyngeal airway or SLIPA (Hudson RCI, Research Triangle Park, NC) and the I-gel (Intersurgical Ltd., Berkshire, England). The SLIPA (**Figure 18-1**) is more commonly used in the operating room

FIGURE 18-1. The SLIPA.

FIGURE 18-2. The I-gel.

than the Emergency Department. The I-gel (**Figure 18-2**) can often be found in the Emergency Department difficult airway cart. The I-gel performs as well as the LMA-Supreme in both ventilation and protecting the airway from aspiration.[9]

Cuffed perilaryngeal sealers include the LMA (LMA North America, San Diego, CA), its many variations, and other manufacturers' laryngeal mask devices. These balloon sealers impact above the laryngeal inlet. The narrowest part of the inflatable lumen wedges into the upper esophagus, theoretically limiting gastric inflation during positive pressure ventilation. Design advances have allowed for inclusions of a potential gastric channel in the tip of the laryngeal mask that allows for placement of a narrow (typically 14 French or smaller) gastric tube for gastric suction and decompression. Refer to Chapter 19 for the complete details regarding LMAs.

Cuffed pharyngeal sealers utilize a design in which a balloon seals the hypopharynx at the base of the tongue, preventing passive air escape through the mouth. Downstream from the hypopharyngeal occluding balloon are a number and variety of ventilation apertures that allow air to pass into both the trachea and esophageal lumens. This category of SADs can be subdivided into those devices with and without a second balloon for the esophagus. Those devices without distal downstream esophageal balloons have a less specific anatomic placement. This may require more device manipulation to allow for easy ventilation, with a theoretically lower aspiration protection. Devices in this category include the cuffed oropharyngeal airway or COPA (Covidien, Mansfield, MA), PAexpress or PAX (Vital Signs Inc., Totowa, NJ), and the CobraPLA and CobraPlus (Pulmodyne Inc., Indianapolis, IN). Of these, the CobraPLA (**Figure 18-3**) may be found in the Emergency Department difficult airway cart.

Cuffed pharyngeal sealers with esophageal balloons not only occlude the airway at the base of the tongue, but the esophageal balloon theoretically isolates the esophageal lumen from the respiratory tract. Devices in this category include the Combitube (Kendall Sheridan, Mansfield, MA), the EasyTube (Teleflex Medical, Kernen, Germany), and the King Laryngeal Tubes (King Systems, Noblesville, IN). All of these SADs may be found in the Emergency Department difficult airway cart. Refer to Chapter 20 regarding the complete details of the Combitube and EasyTube. These two SADs are more commonly used in the prehospital environment for a primary or secondary airway. The King Laryngeal Tubes (**Figure 18-4**) are available in several models.

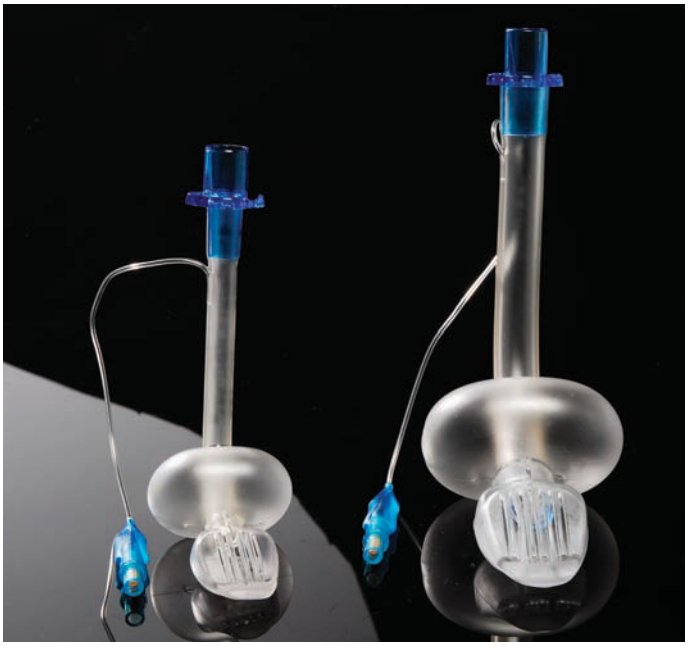

FIGURE 18-3. The CobraPLA (Photo courtesy of Pulmodyne Inc., Indianapolis, IN).

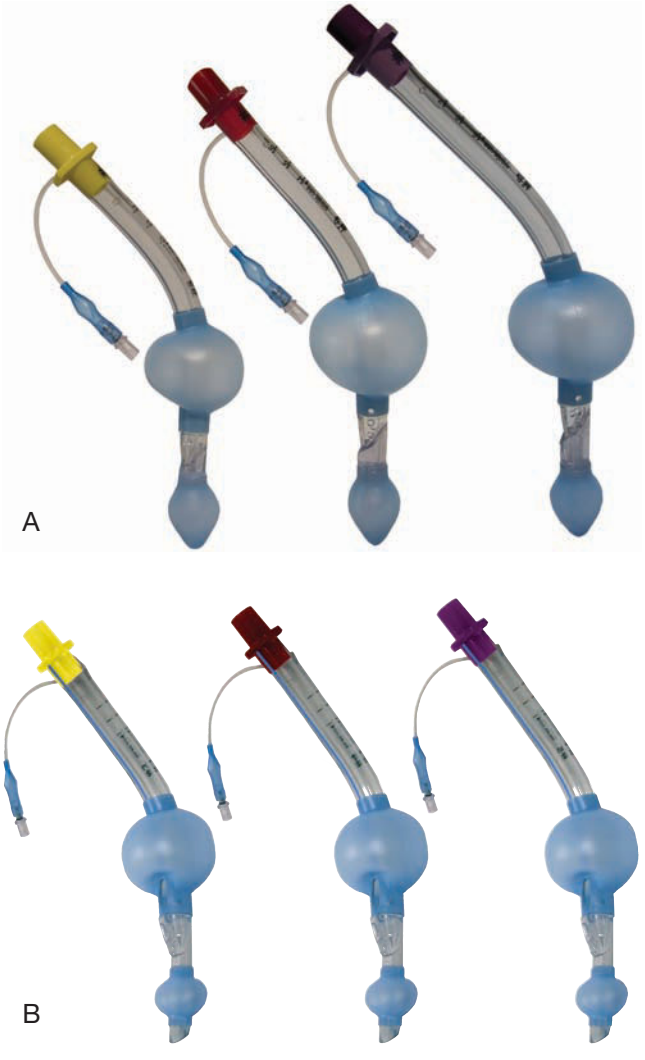

FIGURE 18-4. The King Laryngeal Tubes. **A.** King LTD models. **B.** King LTS-D models (Photos courtesy of King Systems Inc., Noblesville, IN).

The specific equipment needed for the various SADs will vary slightly according to the device used, but is relatively similar. The majority of the airway adjuncts are silicone based, and require the use of a water-soluble sterile lubricant to help ease airway placement without mucosal trauma from abrasion. Size appropriate airway adjuncts must be chosen for the individual patient's anatomy.

PATIENT PREPARATION

The patient should be appropriately monitored with electrocardiography (ECG), end-tidal CO_2 monitoring, noninvasive blood pressure cuff, and pulse oximetry. The patient preparation is exactly the same as that for orotracheal intubation. As for any situation where airway manipulation is to occur and the patient's protective airway reflexes are blunted or ablated, a fully functioning suction apparatus with a variety of catheters must be immediately available. Insertion of the SAD requires an anesthetic depth similar to that which allows placement and acceptance of an oropharyngeal airway. Successful placement of the SAD is much more likely if the patient is premedicated. The optimal induction agent should produce jaw relaxation and attenuation of airway reflexes, permitting insertion of the SAD within 30 to 60 seconds of loss of consciousness. A variety of induction agents may be used.

Select the appropriately sized SAD. Inflate the cuff(s), if present, to ensure that there are no air leaks. Deflate the cuff(s) and leave the air-filled syringe(s) attached to the SAD. Liberally lubricate the SAD with a water-soluble lubricant to aid in its insertion.

TECHNIQUE

The basic insertion technique begins with choosing the appropriate SAD and size. Gently access the airway. Use the nondominant thumb and forefinger in a scissors-like manner to open the patient's mouth, allowing for device insertion. Insert the liberally lubricated SAD. Insert the SAD until either resistance is noted, markers on the airway tube are at the incisor level, or the airway sealing balloon is situated in the hypopharynx and cannot be advanced any further depending on the device.[10]

Most SADs utilize a balloon cuff surrounding the air lumen that limits leakage of instilled air back into the oropharyngeal cavity and into the environment. The cuffless preshaped pharyngeal sealers do not have a cuff that requires inflation. Each cuffed SAD has a range of air required for cuff inflation. **Inflate the cuff with the recommended volume of air. Injection of higher volumes of air above the recommended volume risks SAD migration, airway or esophageal trauma, balloon herniation over the airway passage ports, or device rupture.**

The success rate for first pass insertion of SADs varies depending on the device, the indication for placement, the setting, and the person performing the procedure. Success rates between 72% and 95% are documented throughout the literature.

Begin ventilating the patient. Attach a bag-valve device to the SAD airway tube and begin ventilations. Minor manipulations of the SAD may be required to maximize the ease of ventilation in each particular patient. Slightly rotate or withdraw the SAD with the nondominant hand while ventilating through the device until ventilations are smooth and without resistance. Repositioning of the airway device during its use over time may be required in up to 18% of patients.[10]

ASSESSMENT

The SAD allows for air movement into the trachea, with varying degrees of potential air leakage into the digestive system during positive pressure ventilation. Successful placement will allow for relatively effortless air movement between the patient and the bag-valve device. Successful placement of the SAD is most accurately demonstrated by auscultation of bilateral breath sounds, chest wall movement, and end-tidal CO_2 monitoring. One may also gain a sense of accuracy of placement during insertion.

There exists the possibility of failure to insert, migration of placement after insertion, or the failure to maintain an adequate internal seal that prevents effective patient positive pressure ventilation.[3] If the patient cannot effectively be ventilated or oxygenated, remove the SAD and fall back to BLS skills until either additional expertise arrives or another airway option is available and successful.

AFTERCARE

Secure the SAD similar to that of an endotracheal tube. Place the patient on a ventilator. **Periodically reevaluate the SAD to ensure its position has not changed and it is still providing appropriate ventilations. The SAD may need an occasional position adjustment during ventilation.**

The SAD does not protect against aspiration as well as an endotracheal tube. It should be replaced with an endotracheal tube or a surgical airway. The method of securing the airway with a device other than a SAD will be determined by the patient's condition, if they have a "difficult airway," available equipment, and experience of the Emergency Physician. Some SADs allow the passage of an endotracheal tube through the airway tube similar to the LMAs.

COMPLICATIONS

There are numerous documented complications associated with the use of SADs. One of the most obvious of these and potentially the most devastating is the failure to place the device successfully or to obtain a satisfactory seal. Fortunately, even in inexperienced hands, the incidence of failure to achieve satisfactory ventilation is quite low. Failure to place a SAD appropriately with inadequate ventilation has been estimated to occur in up to 5% of all insertions. The SAD can be displaced if the patient moves their head or their head and neck is moved during transportation and transfers.

The insertion can result in mucosal damage and abrasions, especially if not properly lubricated or forcefully inserted. Unilateral vocal cord paralysis can occur secondary to traumatic insertion. Bilateral vocal cord paralysis has not been reported. Dental trauma may occur during the insertion or during maintenance of the airway. The cuffs are large and thin, thus they may be torn during use.[11,12]

Overinflation of balloons and cuffs can result in tissue ischemia, erosion, and rupture. Herniation of pharyngeal and airway structures into the SAD has been documented utilizing fiberoptic airway evaluation.[13] Trapping of the epiglottis in the distal aperture of the SAD may result in edema of the epiglottis. The oropharyngeal balloons have been linked to the development of tongue swelling secondary to venous congestion as a potential complication with prolonged use.[11,14,15] Lingual nerve injury, tongue numbness, parotid gland swelling, and hypoglossal nerve palsy are sometimes noted.

SAD placement in the patient with an intact gag reflex can induce emesis and aspiration. Emesis and aspiration are associated with a decreased survival.[1,16,17] Always be vigilant to suspect, prevent, and identify aspiration. When the SAD permits, provide gastric decompression via a suction tube prior to device removal or additional airway manipulation.[18]

SUMMARY

Supraglottic airway devices can be effectively utilized for both primary and secondary airway management in both the Emergency Department and the prehospital environment. A highly competitive

marketplace has allowed for a wide variety of constructions. These devices are relatively simple and quick to insert. They provide an effective bridge between the tracheobronchial tree and the ventilating device. Many EMS agencies utilize SADs as either a primary or secondary airway. The Emergency Physician must be familiar with their use and limitations.

19 Laryngeal Mask Airways

Katrin Takenaka and Theltonia Howard

INTRODUCTION

The laryngeal mask airway (LMA) is a device that fills the gap in airway management between that of endotracheal (ET) intubation and the use of a face mask. It was introduced in the United Kingdom in 1983 by British anesthesiologist A. I. J. Brain. His goal was to develop an airway apparatus that could rapidly overcome an obstructed airway, is simple to use, and is atraumatic to insert. In 1991, the LMA was approved for use in the United States by the Food and Drug Administration.

The LMA was designed primarily as a means of providing ventilatory support while avoiding the fundamental disadvantage of the need to visualize and penetrate the vocal cords with an ET tube.[1] The LMA is introduced into the hypopharynx without direct visualization. It forms a low-pressure seal around the laryngeal inlet and permits positive-pressure ventilation. With the introduction of the LMA ProSeal, pressures of up to 30 cmH_2O may be administered safely (A.I.J. Brain, M.D., personal communication). Once inserted, the LMA may be used as a conduit for fiberoptically guided ET intubation or to place an ET tube blindly.[2] The LMA has come to be viewed as a viable method of airway management, with over 800 articles and case reports describing the advantages and disadvantages of the device.[3] A more recent Medline search for articles involving the use of LMAs yielded over 3500 results.

Many disadvantages of the standard LMA became apparent with widespread use of the device. More than 10 years after its introduction, Dr. Brain and colleagues began to work on a new airway system with better intubation characteristics than the standard LMA. The intubating laryngeal mask airway (ILMA) was developed through the aid of analysis of magnetic resonance images of the human pharynx and laboratory testing of ET tubes.[4] The new and more "anatomically correct" ILMA effects more precise placement. The design of the ILMA also avoids head and neck manipulation and insertion of the intubator's fingers into the patient's mouth, both of which occur during the placement of the standard LMA.[4,5]

There are approximately nine different models of the LMA. The term "laryngeal mask airway" is specific to one brand of laryngeal mask devices produced by LMA North America, San Diego, CA. Several other manufactures also make laryngeal mask devices. Some of these will also be described in this chapter. The LMA Classic (LMA-C) is the original and most commonly used version. The LMA Classic Excel (LMA-CE) is more durable than the original LMA-C and can be reused up to 60 times. The LMA Unique (LMA-U) is a single-use disposable version of the LMA-C. The LMA Flexible is a wire-reinforced version of the LMA that is more flexible than the original version and resists kinking. It is used by Anesthesiologists for patients undergoing head and neck procedures. It is not used in the Emergency Department. The LMA Fastrach is a modified version of the LMA that allows ET intubation through the unit. It is also referred to as the ILMA. It allows ventilation during intubation attempts. Its advantages include the following: no manipulation of the head and neck is required, it can accommodate up to a size 8 ET tube, it facilitates one-handed insertion, it can be inserted from the patient's side or from above the head, and it can be used in conjunction with fiberoptic intubation. The LMA ProSeal (LMA-PS) features a cuff deflator, modified cuff design, dual tubes, and a bite block. Similar to the LMA-PS, the LMA Supreme (LMA-S) has a built-in drain tube and a bite block. However, the LMA-S is intended for a single-use and has a more curved airway tube than the LMA-PS. The LMA CTrach (LMA-CT) includes an insertion site for an ET tube and allows for direct visualization of the larynx using built-in fiberoptics. The Ambu laryngeal mask (Ambu LM) has an airway tube that is curved more acutely than the LMA-Cs. This curve follows the anatomy of the upper airway and allows for easier insertion without having to manipulate the head or neck.

The standard LMA, ILMA, LMA-PS, LMA-CT, or Ambu LM may be available in the Emergency Department. The techniques for inserting these devices are discussed in this chapter. The anatomic differences between these devices produce subtle differences in their insertion methods. The indications, contraindications, assessment, and complications associated with these devices are largely identical.

ANATOMY AND PATHOPHYSIOLOGY

The anatomy of the airway is briefly reviewed (**Figure 19-1**). Refer to Chapter 6 for the complete details of the airway anatomy. The oral cavity is bounded by the hard and soft palate above and the anterior portion of the tongue and the reflection of its mucosa onto the floor of the mouth below. Posteriorly, the mouth opens into the oropharynx through the oropharyngeal isthmus. The pharynx is a U-shaped tube extending from the base of the skull to the level of the cricoid cartilage, at which point it becomes continuous with the esophagus.[6]

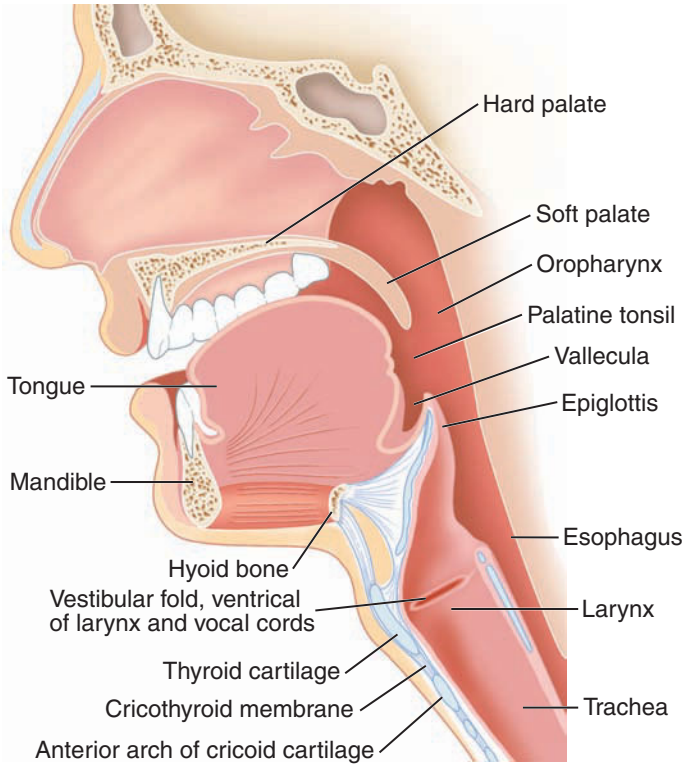

FIGURE 19-1. Midsagittal section of the head and neck demonstrating the airway anatomy.

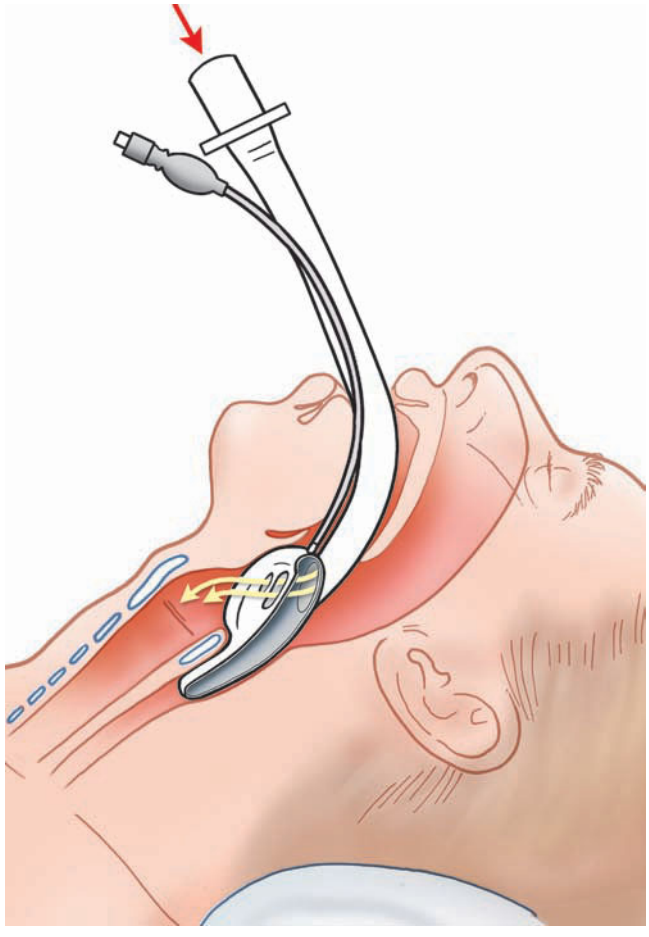

FIGURE 19-2. Sagittal view of the airway demonstrating correct placement of the LMA.

The larynx extends from its oblique opening bordered by the aryepiglottic folds, the tip of the epiglottis, and the posterior commissure to the base of the cricoid cartilage.[6] The esophagus lies posterior to the airway. When inflated and properly positioned, the tip of the device will lie in the esophagus at the level of the upper esophageal sphincter and directly posterior to the cricoid cartilage (**Figure 19-2**).

INDICATIONS

The indications for the use of an LMA device parallel the general indications for active airway management. These include the correction of hypoxemia or hypercarbia, the provision of controlled hyperventilation, the provision of a secure airway in the presence of obstruction, and the provision of airway access for pulmonary hygiene and bronchoscopy. An LMA may aid in supporting airways that are difficult to manage as well as being an invaluable aid to blind and fiberoptic intubation. The success rate of correct placement in inexperienced hands approaches 90%.[7] This makes the LMA superbly suited for use by medical personnel who have had only a minimal amount of training in airway management.

Airway control also facilitates emergent radiographic investigations, for example, computed tomography (CT) or magnetic resonance imaging (MRI) scans without motion artifact.[6] The standard LMA contains no ferromagnetic components and is a suitable alternative to an ET tube in many situations. It is ideal for use in patients emergently requiring diagnostic MRI scans. Use of the LMA does not require a metal laryngoscope, which is contraindicated if a patient requires airway management in the MRI suite.

LMA devices may be used in the event of a failed ET intubation. They have a role in securing the airway presumptively in patients with an "anteriorly" situated larynx, a situation whereby direct laryngoscopy and ET intubation are historically difficult. In emergent situations, the LMA is a safe alternative to the esophageal obturator airway, King tube, Combitube, and EasyTube. The LMA has also proved to be useful in burn patients requiring repeated dressing changes, especially of the face. Finally, the LMA may well be the airway technique of choice for professional singers who require short-term airway management since there is less likelihood of causing vocal cord or laryngeal nerve injury with this approach.[7]

However, in all its uses, there is a conspicuous absence of airway protection from aspiration. The LMA-PS and LMA-S are being marketed as superior to the LMA-C for use in nonfasting patients. These versions feature an improved laryngeal seal for permitting positive-pressure ventilation at pressures up to 30 cmH_2O and a drain tube in tandem with the airway tube. The drain tube facilitates blind insertion of a gastric tube for decompressing the stomach. An introducer aids insertion of the LMA-PS while obviating the need to introduce fingers into the patient's mouth.

CONTRAINDICATIONS

There are no absolute contraindications to the use of LMAs. However, there are several relative contraindications. These devices should not be used in individuals who are at an increased risk of regurgitation or aspiration unless the benefit of securing an airway outweighs the risk of aspiration (e.g., when other techniques for securing the airway have failed).[8] This is supported by uncontrolled studies using fiberoptic bronchoscopy, which have shown that the esophagus is visible within the LMA mask in 6% to 9% of patients.[7] Patients at high risk for aspiration include those with previous upper gastrointestinal surgery, known or symptomatic hiatal hernia, gastroesophageal reflux disease, women more than 10 weeks pregnant, patients with intestinal ileus or peptic ulcer disease, obese patients, or those individuals who are not fasted.[5,9,10]

In emergent situations where cricoid pressure is needed to prevent active or passive regurgitation of stomach contents prior to airway placement, the LMA is not an appropriate airway device. It will not prevent subsequent aspiration of stomach contents as efficiently as will a cuffed ET tube. The act of placing an LMA after the application of cricoid pressure (i.e., the Sellick maneuver) has been shown to have a significantly high failure rate.[7] The LMA-PS and LMA-S feature dual tubes (i.e., airway and drain) as well as a modified cuff designed to provide separation of the respiratory and alimentary tracts. As a result, they may prove invaluable in negating this "Achilles' heel" of the standard LMA.

These devices should not be used in individuals with severe respiratory diseases.[2,9,10] Specifically, individuals with airway obstruction at or below the larynx and those with low pulmonary compliance or high airway resistance (e.g., morbid obesity, bronchospasm, pulmonary edema, pulmonary fibrosis, or thoracic trauma) are not appropriate candidates for LMAs. **The only possible exception is that it can be inserted as a temporary airway rescue device in preparation of another method of ET intubation or a surgical airway.**

Patients must be able to assume the "sniffing" position, analogous to that of individuals positioned for direct laryngoscopy prior to ET intubation. Patients who cannot passively or actively extend their head and flex their neck are not candidates for the LMA-C, LMA-CE, LMA-U, or LMA-S. The ILMA, LMA-CT, LMA-PS with an introducer, or the Ambu LM are more appropriate for these patients. Patients should not receive these devices if they cannot open their mouth at least 1.5 cm due to anatomic limitations (e.g., ankylosing spondylitis, severe rheumatoid arthritis, cervical spine

instability, etc.).[7] This is one situation where blind nasotracheal intubation or fiberoptically guided nasotracheal tube placement has an advantage over the LMAs.

Finally, the LMA is relatively contraindicated in cases of pharyngeal pathology. This includes but is not limited to abscesses, caustic ingestions, hematomas, and tissue disruptions. These processes make the use of the LMA difficult. The device may rupture abscesses and hematomas, causing the patient to aspirate. The use of an LMA after a caustic ingestion can result in perforation of the eroded upper esophageal or hypopharyngeal walls from the pressure of the inflated cuff.

EQUIPMENT

- LMAs, various types and sizes
- ET tubes
- Water-soluble lubricant
- Syringes, 10 and 20 mL
- Oxygen source, tubing, and regulator
- Face masks
- Bag-valve device
- Pulse oximeter
- Cardiac monitor
- Noninvasive blood pressure monitor
- Advanced Cardiac Life Support (ACLS) medications
- Advanced airway equipment
- Surgical airway equipment

LMA CLASSIC (LMA-C) AND UNIQUE (LMA-U)

The standard LMA preceded the ILMA by more than a decade. The prototype of the LMA was constructed by forming a shallow mask with an inflatable rubber cuff joined to a tube communicating with the lumen of the mask at an angle.[1,2] The modern LMA is made of flexible silicone, is completely latex-free, and has a more tapered appearance. It has a variably sized, internally ridged tube fused at a 30° angle to a spoon-shaped mask with a flexible rim.

The LMA-C is a disposable unit that can be used multiple times. It must be sterilized between uses following specific manufacturer recommendations. The LMA-U is similar in construct to the LMA-C. However, the LMA-U is a single-use device. These LMAs are designed to conform to the contours of the hypopharynx, with the lumen facing the glottic opening (**Figure 19-2**).

They consist of an airway tube, an inflation line, and a mask (**Figure 19-3**). Overall, they resemble a giant spoon. The airway tube has a large bore and is clear, like an ET tube.[2] The proximal end contains a standard 15 mm airway adapter that can connect to a bag-valve device or a ventilator. A black line along the posterior border is used as a marker for proper positioning. The distal end of the airway tube connects to the mask.

The mask is elliptical in shape (**Figure 19-4**). The outer rim of the mask contains an inflatable cuff. When inflated and properly

FIGURE 19-3. The LMA-C (Photo courtesy of LMA North America, San Diego, CA).

FIGURE 19-4. The distal end or mask of the LMA-C. **A.** The deflated cuff. **B.** The inflated cuff.

TABLE 19-1 LMA-C and LMA-U Size Selection

Patient's weight (kg)	LMA size	Maximum cuff inflation volume (mL)	Largest ET tube size*	Fiberoptic bronchoscope size (mm)
<5	1.0	4	3.5	2.7
5–10	1.5	7	4.0	3.0
10–20	2.0	10	4.5	3.5
20–30	2.5	14	5.0	4.0
30–50	3.0	20	6.0 (cuffed)	5.0
50–70	4.0	30	6.0 (cuffed)	5.0
70–100	5.0	40	7.0 (cuffed)	5.0
>100	6.0	50	7.0 (cuffed)	5.0

*The inner diameter in millimeters.

positioned, the tip of the LMA will lie in the esophagus at the level of the upper esophageal sphincter and directly posterior to the cricoid cartilage (**Figure 19-2**). The lateral edges of the mask rest in the pyriform fossae. The upper edge rests against the base of the tongue. The LMA provides a seal against the upper esophageal sphincter, aryepiglottic folds, and distal epiglottis so as to direct air into the trachea and avoid insufflation of the stomach (**Figure 19-2**).[2,3]

The distal end of the airway tube opens into the mask. This opening is covered by two vertical aperture-bars that prevent the epiglottis from obstructing the lumen of the airway tube (**Figure 19-4**). The aperture bars should be cut off prior to inserting the LMA if an ET tube is to be inserted through the LMA.

The inflation line is used to inflate and deflate the cuff (**Figure 19-4**). The distal end of the inflation line attaches to the upper border of the cuff. The proximal end contains an inflation port and balloon, similar to an ET tube. An air-filled syringe attaches to the inflation port to inflate the cuff.

The correct size of the LMA is based on the patient's weight and is crucial to ensure a proper seal and reduce complications (**Table 19-1**).[8] The distal end assumes a different shape when the cuff is inflated and deflated. The distal end is pentagon-shaped when deflated (**Figure 19-4A**). It is oval-shaped when inflated (**Figure 19-4B**).

LMA CLASSIC EXCEL (LMA-CE)

Although similar in construct to the standard LMA, the LMA-CE has been designed as an "enhanced" version of the LMA-C (**Figure 19-5**). The airway tube has been reinforced, allowing the LMA-CE to be used up to 60 times. It must be sterilized between uses following specific manufacturer recommendations. The inflatable cuff is made of soft silicone to minimize throat stimulation and irritation. The LMA-CE is available in three sizes (**Table 19-2**).

FIGURE 19-5. The LMA-CE. (Photo courtesy of LMA North America, San Diego, CA).

TABLE 19-2 LMA-CE Size Selection

Patient's weight (kg)	LMA size	Maximum cuff inflation volume (mL)	Largest ET tube size*
30–50	3.0	20	7.0 (cuffed)
50–70	4.0	30	7.5 (cuffed)
70–100	5.0	40	7.5 (cuffed)

*The inner diameter in millimeters.

Several modifications have been made in order to facilitate ET intubation with the aid of a fiberoptic bronchoscope. Proximally, the airway tube has a 15 mm connector that can be easily removed to allow for access. The airway tube has been designed to accommodate up to a 7.0 cuffed ET tube. It is short enough that the cuff of the ET tube can pass through the LMA-CE and beyond the vocal cords. The mask aperture includes a vertically oriented epiglottic elevating bar, also known as the EEB (**Figure 19-5**). The EEB is free at the caudal end and fixed at the cephalad end, effectively creating a hinge mechanism. An ET tube passed through the mask aperture swings the EEB backward and elevates the epiglottis away from the path of the advancing ET tube.

LMA FASTRACH (ILMA)

The LMA Fastrach is also known as the intubating LMA or ILMA (**Figures 19-6 & 19-7**). The form of the ILMA was derived from head and neck sagittal MRI studies in 50 normal subjects whose

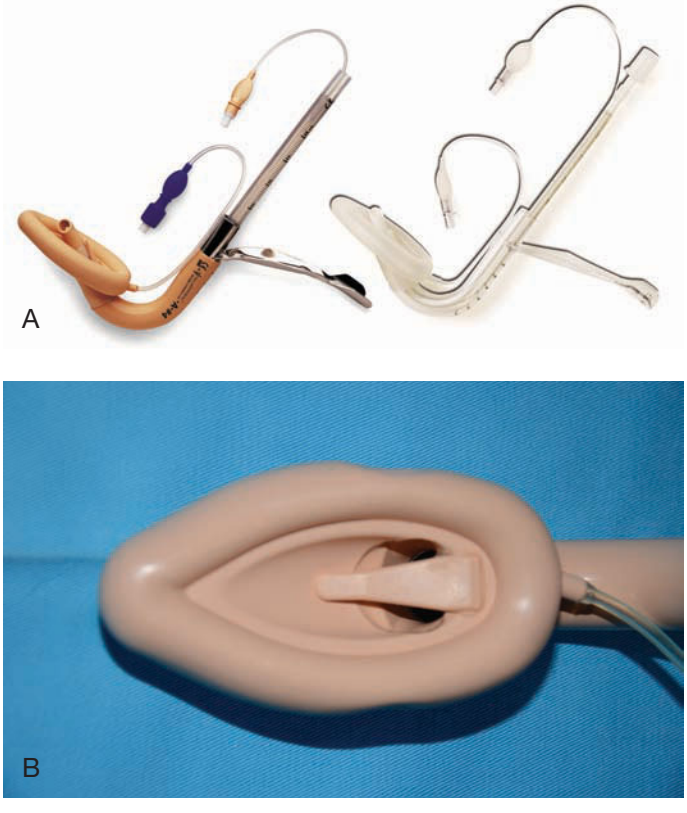

FIGURE 19-6. The ILMA. **A.** The reusable device (left) and the single-use device (right) (Photo courtesy of LMA North America, San Diego, CA). **B.** The mask.

FIGURE 19-7. An ET tube is inserted through the ILMA. The tip of the ET tube is guided by the V-shaped EEB.

heads were held in a neutral position. The convex radius of the curve of the silicone-covered steel tube represents a value close to the best-fit curve derived from the MRI studies.[4] The new prototype consists of an anatomically curved steel tube connected to standard LMA cuff sizes 3, 4, and 5.[5,9]

The ILMA has several significant modifications that make it different from the LMA-C (**Figures 19-6 & 19-7**). It is available in a reusable stainless steel version and a plastic single-use disposable version (**Figure 19-6A**). Both versions are available in three sizes (**Table 19-3**). The airway tube is stainless steel covered with silicone rubber. The proximal end has a handle fused to the airway tube to facilitate insertion, manipulation, and removal of the ILMA. It is curved to follow the curve of the hypopharynx and position the mask aperture over the glottic aperture. It has a larger diameter (13 mm vs. 9 mm) than the LMA.[9] This allows the ILMA to accommodate a cuffed ET tube with an inner diameter up to 9.0 mm.[5,11] It is significantly shorter (14.5 vs. 20 cm) than the LMA-C.[9]

The mask of the ILMA is similar to that of the LMA with two major modifications. The ILMA contains a ramp inside the distal airway tube as it meets the mask and continues into the mask aperture. It is designed to direct the ET tube into the center of the aperture and into the patient's airway. It also has a large, single, and stiff EEB designed to lift the epiglottis out of the way of the advancing ET tube (**Figures 19-6B & 19-7**).

The ILMA was designed to be used with a wire-reinforced cuffed silicone ET tube with an 8.0 mm inner diameter (**Figure 19-8**).[5] The ILMA ET tube is available in 6.0, 6.5, 7.0, 7.5, and 8.0 mm sizes. The molded tip allows atraumatic insertion through the vocal cords. It has a transverse block line along its posterior surface. This line serves as a marker to let the intubator know when the tip of the ET tube is positioned at the EEB. This occurs when the ET tube is inserted through the ILMA, and the transverse bar is located at the proximal end of the airway tube. While it is ideal to use the wire-reinforced silicone ILMA ET tube, a standard ET tube may also be used.

TABLE 19-3 LMA Fastrach or ILMA Size Selection

Patient's weight (kg)	LMA size	Maximum cuff inflation volume (mL)	Largest ET tube size*
30–50	3.0	20	7.0 (cuffed)
50–70	4.0	30	7.5 (cuffed)
70–100	5.0	40	8.0 (cuffed)

*The inner diameter in millimeters.

FIGURE 19-8. The silicone ET tube and pusher used with the ILMA (Photo courtesy of LMA North America, San Diego, CA).

LMA CTRACH (LMA-CT)

The LMA-CT is basically an ILMA with built-in fiberoptics that allow direct visualization of airway anatomy (**Figure 19-9**). Two fiberoptic channels lie along the lateral edges of the airway tube. These channels merge and exit under the EEB. The properly positioned LMA-CT fiberoptics project an image of the laryngeal inlet directly in front of the mask aperture. A portable color display, the LMA CTrach Viewer, attaches magnetically to the top of the LMA-CT airway tube. This allows the intubator to monitor the passage of the ET tube through the vocal cords. The LMA-CT Viewer lies just above the patient's chin and in line with the actual airway anatomy, making intubation easier from a hand-eye coordination standpoint. Images may be recorded and downloaded onto a computer for later documentation and teaching purposes.

FIGURE 19-9. The LMA-CT (Photo courtesy of LMA North America, San Diego, CA).

FIGURE 19-10. The LMA-PS (Photo courtesy of LMA North America, San Diego, CA).

LMA PROSEAL (LMA-PS)

The LMA-PS has been designed to be inserted manually or with the aid of a metal introducer (**Figure 19-10**). The use of the introducer obviates the need for the intubator to place their fingers in the patient's mouth. The LMA-PS has been modified to allow for ventilation at higher airway pressures. A combination of a softer silicone cuff, an additional rear cuff in larger sizes, and a deeper bowl mask permit higher seal pressures up to 30 cmH_2O. This is approximately 50% higher than with the LMA-C. The LMA-PS provides a tighter seal without increasing mucosal pressure or the risk of complications. It is a reusable device that is available in numerous sizes (**Table 19-4**).

The LMA-PS features a dual tube (i.e., drain tube and airway tube) system that decreases the risk of rotational dislodgement of the device. The drain tube communicates with the upper esophageal sphincter, allowing for blind insertion of an orogastric tube and for venting of gastric gases and liquids. The drain tube is positioned in the cuff to prevent the epiglottis from blocking the airway tube. The LMA-PS has been designed to decrease the risk of aspiration. Despite this, the manufacturer cautions that the LMA-PS does not provide complete protection against aspiration.

LMA SUPREME (LMA-S)

The LMA-S, like the LMA-PS, is a dual tube system that provides some separation of the respiratory and digestive tracts. The LMA-S is a single-use device and has an airway tube that is more curved and anatomically shaped (**Figure 19-11**). It has a more rigid airway tube than the LMA-PS, thus it requires no digital or metal introducer for placement. It can be used for the blind passage of an orogastric tube. The drain tube can help monitor correct positioning of the LMS-S. Gases will audibly leak from the drain tube if the LMA-S does not have a tight airway seal. The LMA-S incorporates a bite block. It is available in numerous sizes (**Table 19-5**).

*The inner diameter in millimeters.

AMBU LARYNGEAL MASK (AMBU LM)

The Ambu LM (Ambu Inc., Glen Burnie, MD) consists of an airway tube, spoon-shaped mask, and inflatable cuff similar to the LMA-C (**Figure 19-12**). However, the airway tube of the Ambu LM is bent into a smooth curve of approximately 90° to conform to the anatomy of the upper airway and to facilitate easier insertion. Because of this anatomically correct curve, the device can be placed without manipulating the patient's head or neck. The airway tube is D-shaped and easier to grip than other tubes. The distal tip of the Ambu LM is reinforced so that the cuff does not fold over during insertion.

KING LARYNGEAL AIRWAY DEVICE (KING LAD)

The King LAD (King Systems, Noblesville, IN) is a disposable, single-use, silicone device similar to the LMA-C. It is available in two

FIGURE 19-11. The LMA-S (Photo courtesy of LMA North America, San Diego, CA).

styles (**Figure 19-13**), and a wide range of sizes in each style. The standard model has a curved airway tube while the flexible model has a straight and easily bendable airway tube.

AIR-Q MASKED LARYNGEAL AIRWAY (AIR-Q)

The Air-Q Masked Laryngeal Airway or Air-Q (Mercury Medical, Clearwater, FL) is another commonly used device (**Figure 19-14A**). It is available in a full range of sizes (**Table 19-6**). The airway tube shape and mask inlet have a different shape than the LMAs. An ET tube can be inserted through the Air-Q similar to the ILMA.

The Air-Q Blocker Masked Laryngeal Airway or Air-Q Blocker (Mercury Medical, Clearwater, FL) has been modified from the Air-Q to include a soft guide tube along side of the airway tube (**Figure 19-14B**). A lubricated suction catheter or nasogastric tube (up to size 18 French) can be inserted and directed into the posterior pharynx and esophagus to suction secretions. A proprietary suction catheter with an inflatable balloon near the distal end can be inserted through the guide tube (**Figure 19-14B**). The inflated balloon blocks the upper esophagus to prevent aspiration. The tip of this catheter has multiple holes to allow esophageal venting while the balloon prevents aspiration. The Air-Q Blocker is available in three sizes (**Table 19-6**).

The Air-Q Self-Pressurizing Masked Laryngeal Airway or Air-Q SP (Mercury Medical, Clearwater, FL) is similar to the Air-Q except for one major structural change. The Air-Q SP has a self-pressurizing cuff that does not require a pilot balloon, a inflation line, or a syringe to inflate the cuff (**Figure 19-14C**). Positive-pressure ventilation provided by a bag-valve device or ventilator inflates and self-pressurizes the cuff. The Air-Q SP is available in a full range of sizes (**Table 19-6**).

FIGURE 19-12. The Ambu LM.

FIGURE 19-13. The King LAD standard model (left) and flexible model (right).

PATIENT PREPARATION

The patient should be appropriately monitored with electrocardiography (ECG), end-tidal CO_2 monitoring, noninvasive blood pressure cuff, and pulse oximetry. The patient preparation is exactly the same as that for orotracheal intubation. As for any situation where airway manipulation is to occur and the patient's protective airway reflexes are blunted or ablated, a fully functioning suction apparatus with a variety of catheters must be immediately available. Insertion of the LMA requires an anesthetic depth similar to that which allows placement and acceptance of an oropharyngeal airway.[7] Successful placement of the standard LMA is much more likely if the patient is premedicated. In the case of the ILMA, the successful placement of the ET tube is highly dependent on adequate sedation and/or muscle relaxation. The optimal induction agent should produce jaw relaxation and attenuation of airway reflexes, permitting insertion of the LMA device within 30 to 60 seconds of loss of consciousness. A variety of induction agents may be used.

There is some controversy as to what physical examination findings represent the endpoint for judging when to insert the LMA. The consensus is that the first attempt at insertion should occur following the loss of the eyelash reflex (seventh cranial nerve) as when the jaw is relaxed.[10,12] This typically occurs 30 to 60 seconds after administration of the ultra-short-acting induction agents. Some practitioners also rely on the onset of apnea and/or loss of response to verbal stimuli as signs of adequate depth of anesthesia.[12]

TECHNIQUES

LMA CLASSIC, UNIQUE, AND CLASSIC EXCEL

Prior to insertion, carefully inspect the cuff for leaks with the cuff slightly overinflated. Completely deflate the cuff so that it forms a smooth wedge shape. The technique for inserting the LMA-C, LMA-U, and LMA-CE is rather simple (**Figure 19-15**). Lubricate the

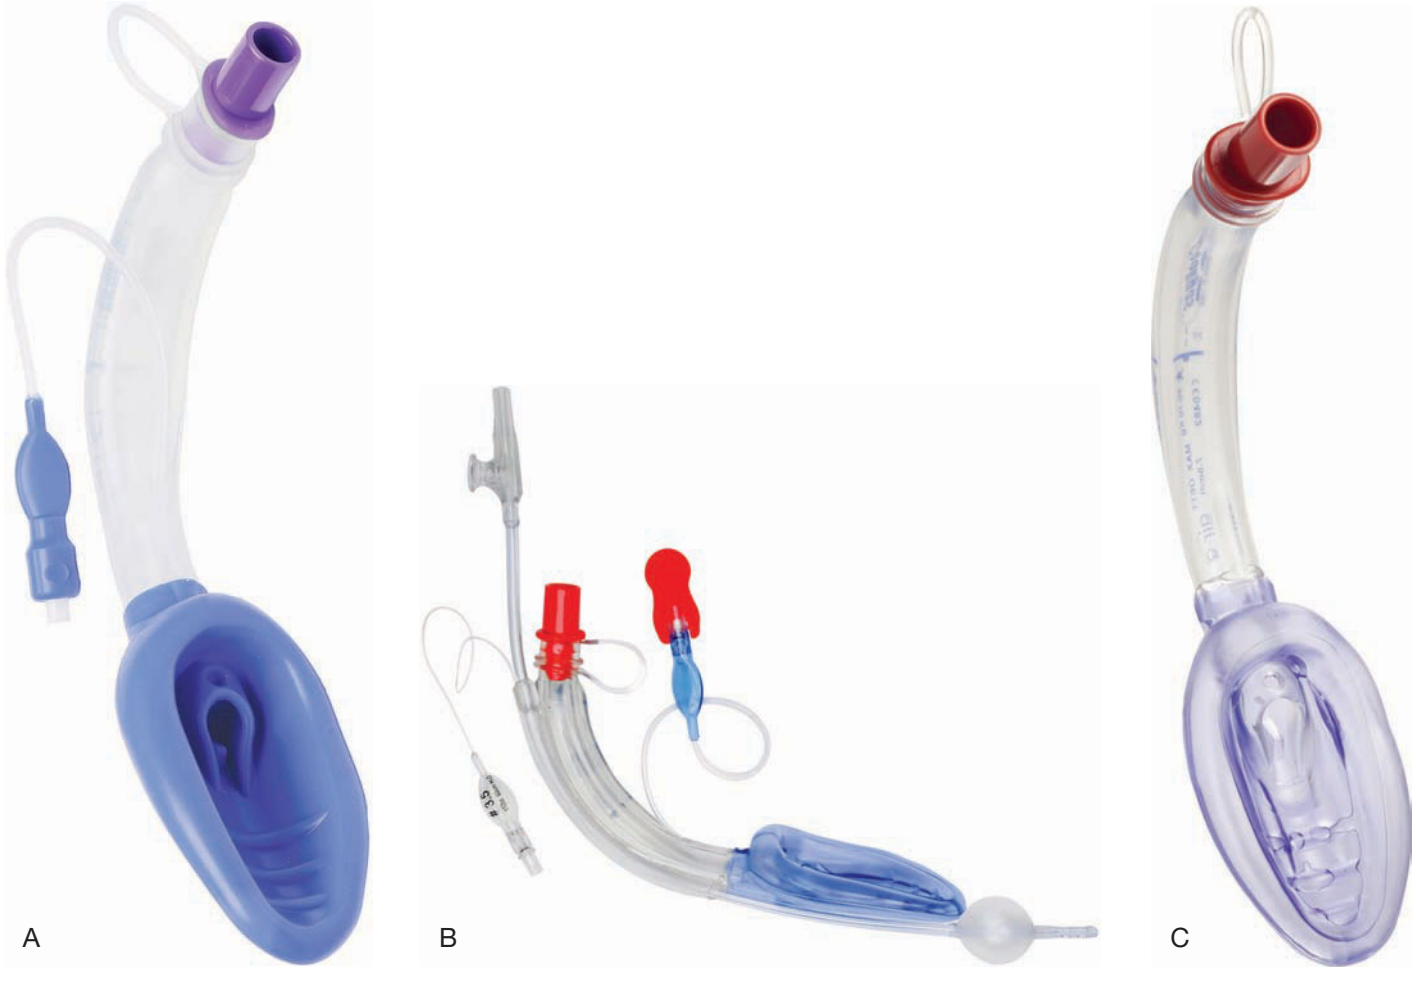

FIGURE 19-14. The Air-Q Masked Laryngeal Airway. **A.** The Air-Q. **B.** The Air-Q Blocker with the proprietary suction catheter inserted. **C.** The Air-Q SP. (Photos courtesy of Mercury Medical Inc., Clearwater, FL).

posterior surface of the LMA with a water-soluble lubricant. Care must be taken to avoid lubricating the anterior surface of the device, as the gel might obstruct the distal aperture or trickle into the larynx and provoke laryngospasm.[7] Avoid using silicone-based lubricants that may degrade the cuff.[8] Avoid lubricants containing lidocaine as they may provoke an allergic reaction or decrease laryngeal protective reflexes.[8]

Position the patient's head as for ET intubation in the sniffing position. Place the nondominant hand behind the patient's head to stabilize the occiput and slightly flex the neck (**Figure 19-15A**). Allow the patient's jaw to fall open. An assistant may be required to help open it.

TABLE 19-6 Air-Q, Air-Q Blocker, and Air-Q SP Size Selection

Patient's weight (kg)	Size	Maximum cuff inflation volume (mL)	Largest ET tube size*	Air-Q sizes	Air-Q Blocker sizes	Air-Q SP sizes
<7	1.0	3	4.5	X		X
7–17	1.5	5	5.0	X		X

30–50	2.5	12	6.5	X	X	X
50–70	3.5	18	7.5	X	X	X
70–100	4.5	25	8.5	X	X	X

*The inner diameter in millimeters.

Insert the LMA into the oral cavity with the aperture facing but not touching the tongue (**Figure 19-15A**). **It is essential that the leading edge of the cuff be smooth, wrinkle-free, and shaped like a wedge.** This facilitates passage of the cuff around the posterior pharyngeal curvature and into the hypopharynx while avoiding the epiglottis. Place the index and middle fingers of the dominant hand against the junction between the LMA and the cuff (**Figure 19-15B**). Advance the LMA in one smooth movement following the curvature of the pharynx until it enters the hypopharynx (**Figure 19-15B**). The fingers should lie almost horizontally when the LMA is properly positioned.[13,14] Grasp and stabilize the airway tube with the nondominant hand, then remove the index and middle fingers of the intubating hand (**Figure 19-15C**). **Slightly advance the LMA further downward until resistance is felt. At this point, it is important to not push further.** If difficulty is encountered, a rotational movement of the tube, slight inflation of the cuff, a jaw-thrust maneuver, or, in rare cases, the use of a laryngoscope may be helpful.[7]

Inflate the cuff with the recommended volume of air (**Figure 19-15D**). **Do not overinflate the cuff. Inflation usually causes a characteristic outward movement of the airway tube of up to 1.5 cm as the cuff centers itself around the laryngeal inlet.** A slight forward movement of both the thyroid and cricoid cartilages will be noted. **The longitudinal black line on the shaft of the tube should lie in the midline against the upper lip. Any deviation may indicate the wrong size device was used or misplacement of the cuff**

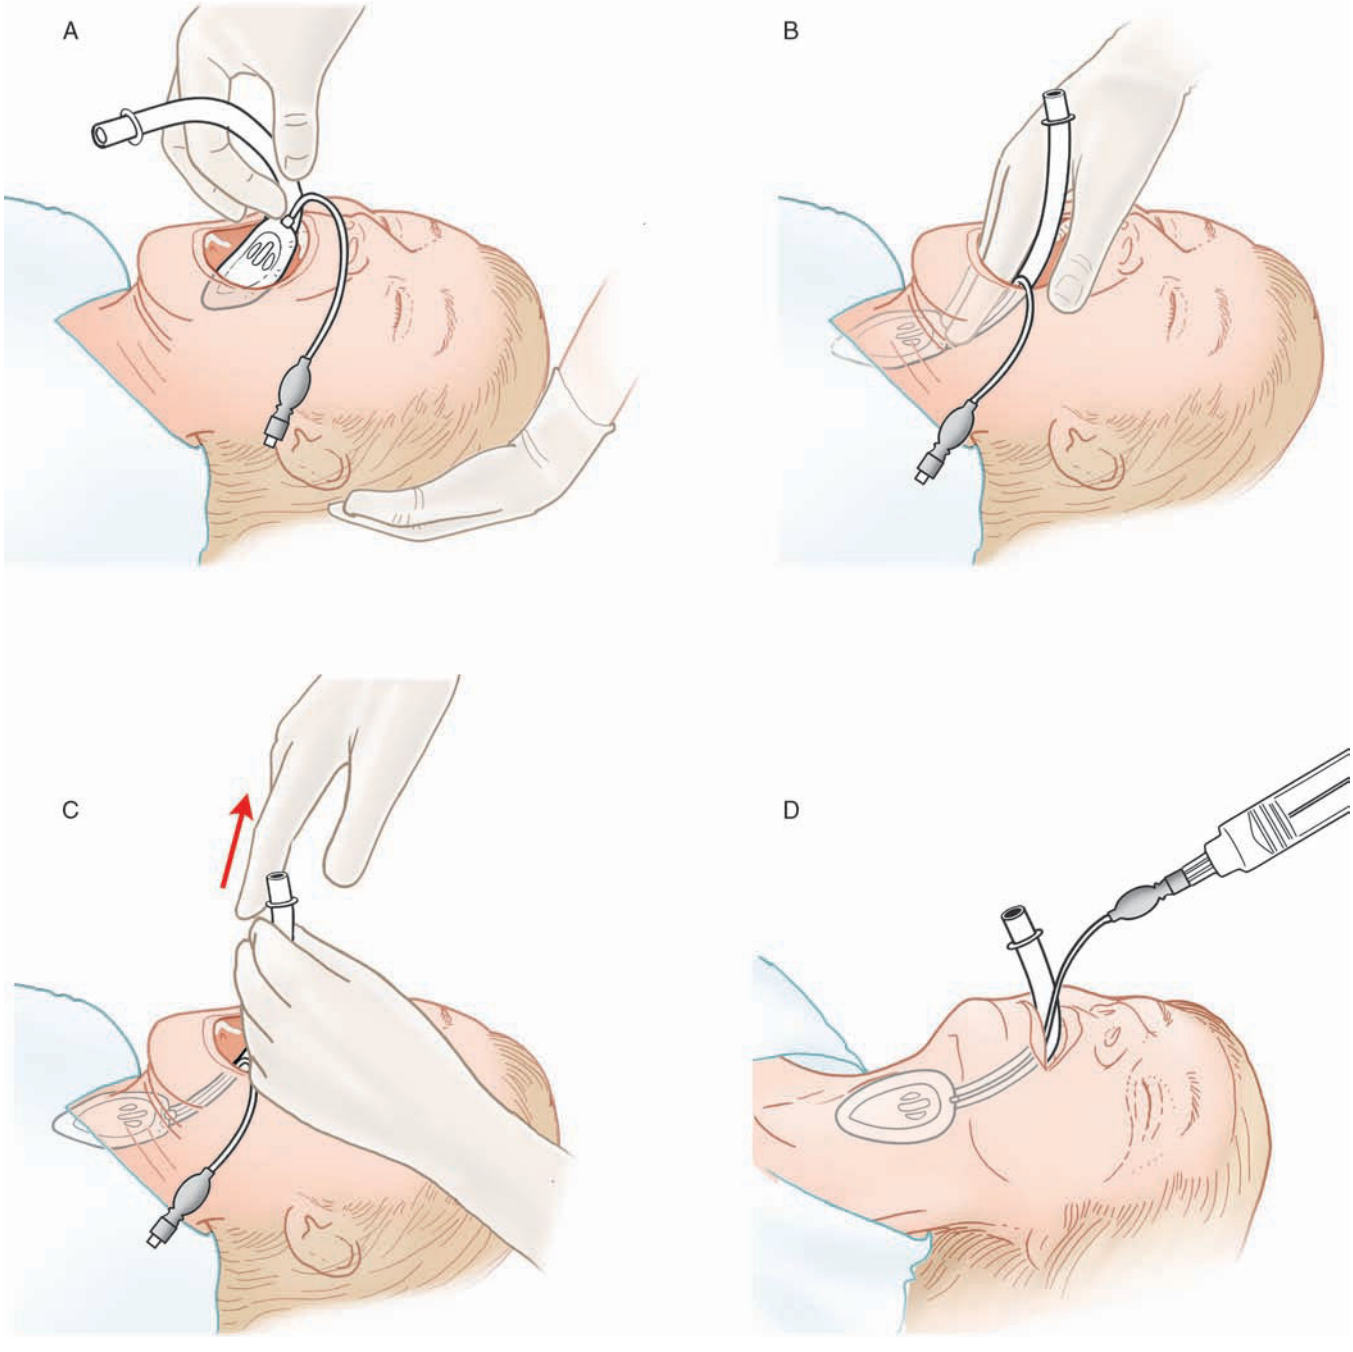

FIGURE 19-15. Insertion of the LMA. **A.** The patient's head is properly positioned and the LMA is inserted into the patient's mouth. **B.** The LMA is advanced with two fingers. **C.** The LMA is stabilized while the insertion hand is removed. **D.** The cuff is inflated.

and a partial airway obstruction.[7] When correctly positioned, the tip of the LMA cuff lies at the base of the hypopharynx against the upper esophageal sphincter, the sides lie in the pyriform fossae, and the upper border of the mask lies at the base of the tongue, pushing it forward.[7] Even when grossly malpositioned, the mask may still create a useful airway.[8] Secure the LMA like an ET tube.

LMA PROSEAL

Prior to insertion, carefully inspect the cuff for leaks with the cuff slightly overinflated. Completely deflate the cuff so that it forms a smooth wedge shape. The LMA-PS features a cuff deflator, which is a compact, portable instrument for assuring complete removal of air without causing the silicone to wrinkle. Lubricate the posterior surface of the LMA with a water-soluble lubricant. Insert the LMA-PS like that described above for the LMA-C. The only difference is that the fingertip should be pushed into the introducer strap at the rear of the cuff.

An alternative method of insertion involves a metal introducer. When using the introducer, head and/or neck manipulation may not be required. Place a properly sized introducer into the strap. Fold the tubes around the convex surface of the introducer and fit the proximal end of the airway tube into the matching slot. Insert the LMA-PS into the oral cavity with the aperture facing, but not touching, the tongue. The back of the mask must remain in constant contact with the hard palate. Rotate the LMA-PS inward in one smooth movement following the curvature of the introducer until it enters the hypopharynx and resistance is felt. Grasp and stabilize the

airway tube with the nondominant hand. Remove the introducer. Inflate the cuff and secure the LMA-PS. The LMA-PS includes a built-in bite block.

LMA SUPREME

Prior to insertion, carefully inspect the cuff for leaks with the cuff slightly overinflated. Completely deflate the cuff so that it forms a smooth wedge shape. Lubricate the posterior surface of the LMA-S with a water-soluble lubricant. Position the patient's head in a semi-sniffing position. The neutral position or a full "sniffing" position may preclude proper placement of the LMA-S.

Insert the LMA-S. Grasp the LMA-S by the connector end. Insert the LMA-S into the oral cavity with the aperture facing, but not touching, the tongue. Briefly rub the mask tip across the palate in order to lubricate the area. Rotate the LMA-S inward in one smooth movement following the curvature of the pharynx until it enters the hypopharynx and resistance is felt. Directing the distal tip toward the right or left side of the throat may facilitate placement. Grasp and stabilize the airway tube with the nondominant hand. Inflate the cuff and secure the LMA.

LMA FASTRACH (ILMA)

The technique for inserting the ILMA is not very different from that for the standard LMA. It involves a one-handed rotational movement in the sagittal plane with the patients head supported to achieve a neutral position.[5] The ILMA may be inserted from above the patient's head (like the LMA) or standing to the side of the patient's head. It may be inserted with the right or left hand.

Prior to insertion, slightly overinflate the cuff and check it for leaks. Completely deflate the cuff. Lubricate the posterior surface of the airway tube and the mask liberally. Grasp the ILMA by its handle. Place the patient in the sniffing position if no contraindications exist. Open the patient's mouth with the nondominant hand. Position the ILMA over the patient with the tip of the mask in the patient's mouth (**Figure 19-16A**). Slowly insert the mask while the posterior aspect of the mask remains in constant contact with the hard palate. When the entire mask is inside the patient's mouth and against the hard palate, rotate the ILMA inward along the natural curve of the hard palate and pharynx (**Figure 19-16B**). The airway tube should maintain constant contact with the upper central incisors as the unit is advanced. Stop advancing the unit when resistance is felt. This signifies that the tip of the mask is in the upper esophagus (**Figure 19-16B**).

Inflate the cuff with the recommended volume of air (**Figure 19-16C**). **Inflation usually causes a characteristic outward movement of the airway tube, up to 1.5 cm, as the cuff centers itself around the laryngeal inlet.** A slight forward movement of the thyroid and cricoid cartilages will be noted. The airway tube should lie in the midline against the upper central incisors. Any deviation may indicate the misplacement of the cuff and a partial airway obstruction. When correctly positioned, the tip of the ILMA cuff lies at the base of the hypopharynx against the upper esophageal sphincter, the sides lie in the pyriform fossae, and the upper border of the mask lies at the base of the tongue, pushing it forward.

Confirm proper placement of the ILMA. Have an assistant attach a bag-valve device to the proximal end of the airway tube and ventilate the patient. Observe the upper chest rise, auscultate bilateral breath sounds, and observe end-tidal CO_2 monitoring to confirm proper placement. An anterior movement, or bulging, of the cricoid and thyroid cartilages during or after cuff inflation also indicates correct positioning of the ILMA.[1]

Insert an ET tube. Lubricate the wire-reinforced silicone ET tube (or a standard ET tube) liberally. Insert the silicone ET tube into the ILMA until the transverse black line on its posterior surface is at the proximal end of the airway tube (**Figure 19-16D**). At this point, the tip of the silicone tube will be just inside the distal end of the airway tube. If necessary, an assistant can connect a bag-valve device to the silicone ET tube and ventilate the patient. Make sure that the longitudinal black line on the posterior surface of the silicone ET tube is facing upward.

Slowly and gently advance the silicone ET tube 1.5 cm beyond the transverse black line. If no resistance is felt, the tip of the silicone tube is just past the vocal cords. Continue to advance the silicone ET tube an additional 4 cm (**Figure 19-16E**). The patient can be ventilated by an assistant during this procedure if necessary. Inflate the cuff of the silicone ET tube and ventilate the patient through the silicone ET tube (**Figure 19-16F**). Confirm proper tube placement by the auscultation of breath sounds, observation of chest rise, and end-tidal CO_2 monitoring.

The ILMA should now be withdrawn. Deflate the cuff of the ILMA. Have an assistant remove the bag-valve device and the 15 mm adapter on the proximal end of the silicone ET tube. Withdraw the ILMA by gently reversing the ILMA over the silicone ET tube (**Figure 19-16G**). **Simultaneously apply slight pressure to the proximal end of the silicone ET tube so that it does not become dislodged (Figure 19-16G).** When the mask begins to exit the patient's mouth, stop withdrawing the ILMA. **Grasp the silicone ET tube firmly at the patient's mouth and hold it securely.** Withdraw the ILMA in a smooth curved motion (**Figure 19-16H**). Reattach the standard respiratory connector, ventilate the patient, and reconfirm proper placement of the silicone ET tube.

Some physicians prefer to use a "pusher" to prevent accidental extubation while the ILMA is being withdrawn. Cut a 25 cm length from a second silicone ET tube. Insert this into the ILMA as it is being removed. Apply slight pressure so it pushes against the first ET tube and prevents it from moving proximally. When the ILMA exits the patient's mouth, remove the ILMA and pusher as a unit. Secure and assess the proper positioning of the ET tube, as mentioned previously.

LMA CTRACH (LMA-CT)

The technique for inserting the LMA-CT is similar to that for the ILMA. The LMA-CT may be inserted from above the patient's head like the LMA-C or standing to the side of their head. Place the patient in the neutral position to avoid head extension. The manufacturer recommends only using the LMA-CT with straight, wire-reinforced cuffed silicone ET tubes with a 6.0 to 8.0 mm inner diameter. Standard curved plastic ET tubes may lead to an increased incidence of laryngeal trauma.

Insert the LMA-CT using the technique described for the ILMA. Inflate the cuff with the recommended volume of air and confirm proper placement of the ILMA. Have an assistant attach a bag-valve device to the proximal end of the airway tube and ventilate the patient. Observe the upper chest rise, auscultate bilateral breath sounds, and observe end-tidal CO_2 monitoring to confirm proper placement.

Attach the Viewer by placing the Viewer's socket onto the magnetic latch connector on the LMA-CT. Turn on the Viewer to visualize the glottis. Lubricate the wire-reinforced silicone ET tube. Grasp the LMA-CT by its handle and pass the ET tube back-and-forth through the airway tube several times in order to lubricate the entire airway tube. **Do not pass the lubricated silicone ET tube beyond the transverse black line on its posterior surface in order to avoid obscuring the fiberoptics with lubricant.** Make sure that the longitudinal black line on the posterior surface of the silicone ET tube is facing upward.

Slowly and gently advance the silicone ET tube 1.5 cm beyond the transverse black line. Gripping the handle and lifting a few

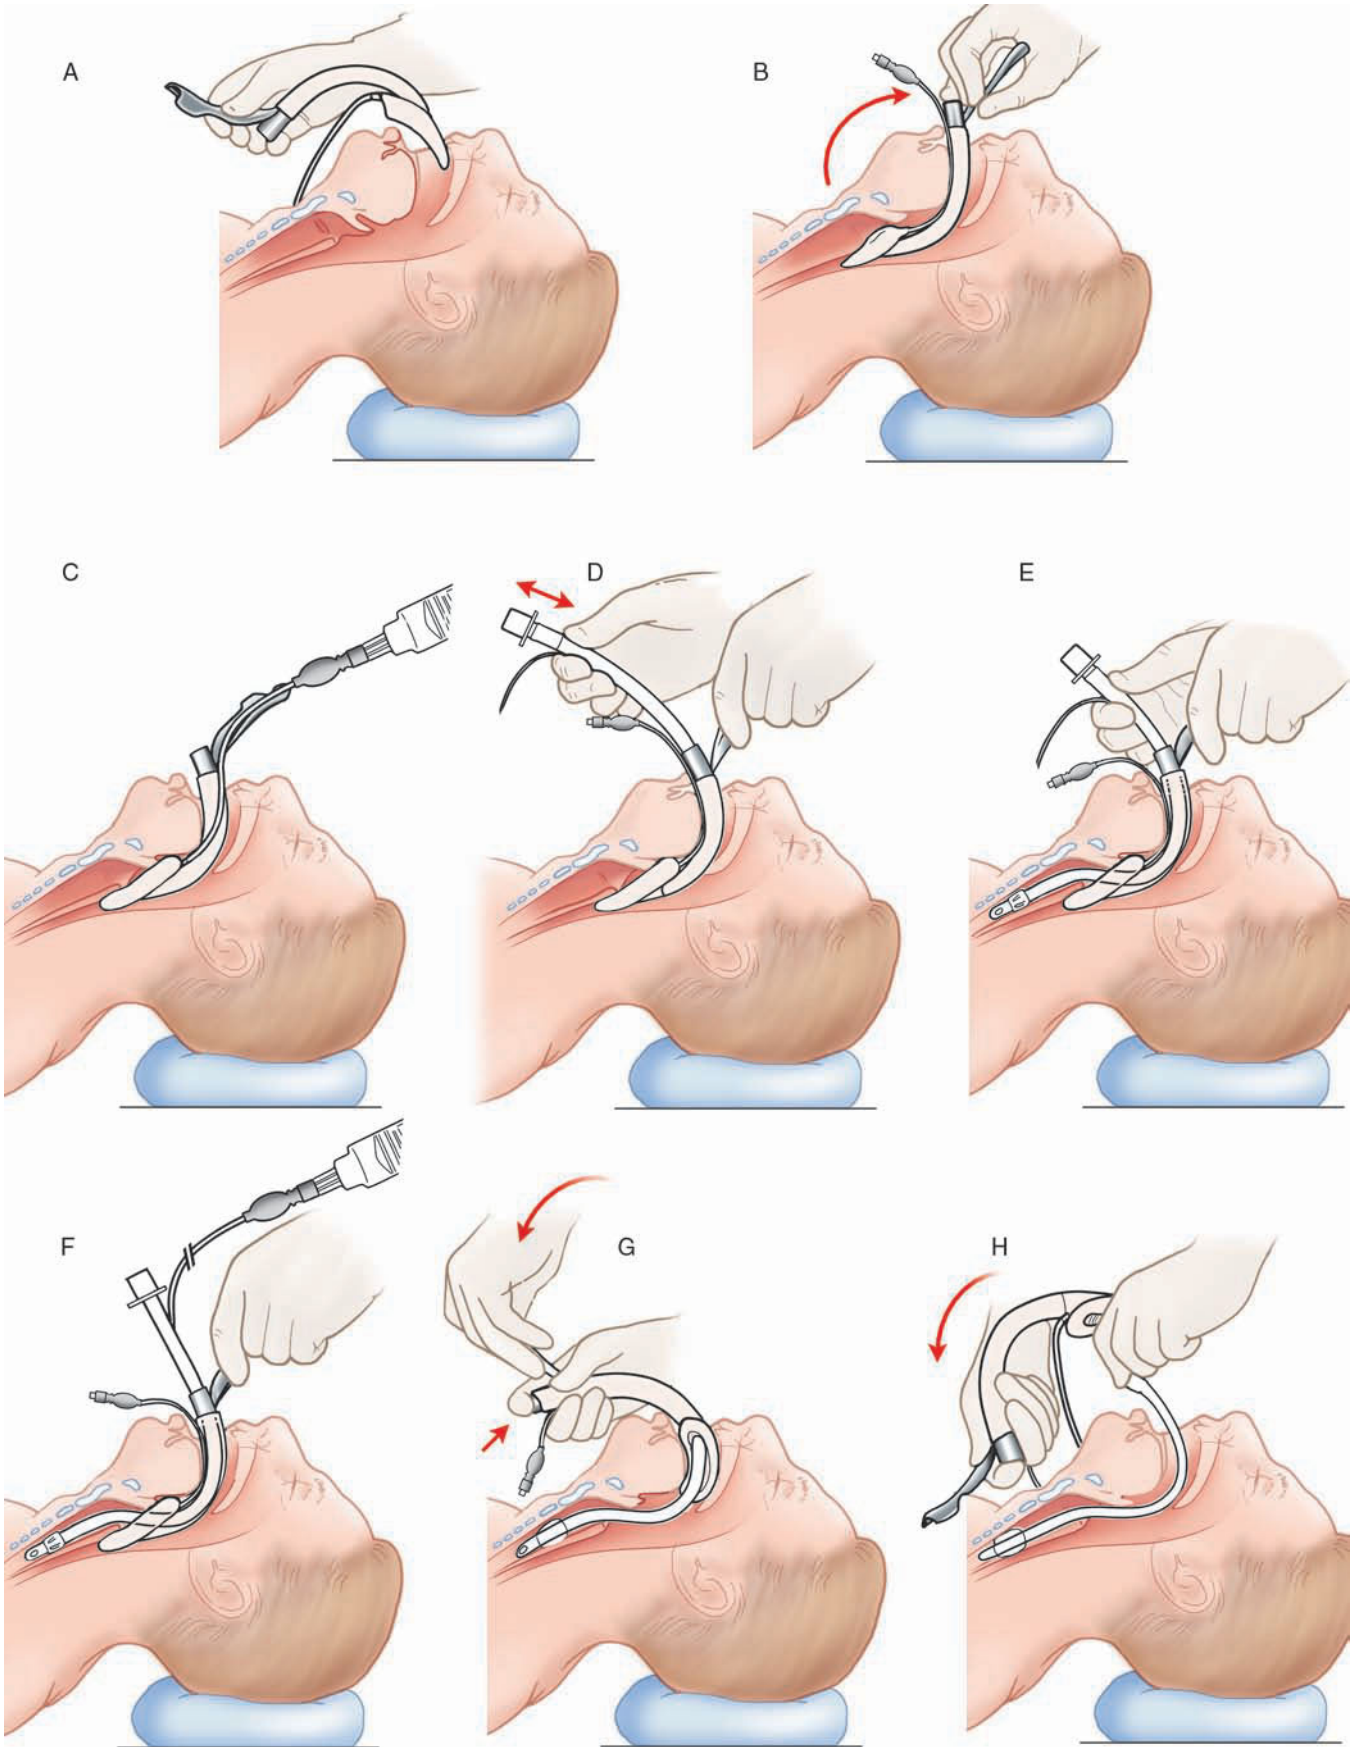

FIGURE 19-16. Insertion of the LMA Fastrach or ILMA. **A.** The ILMA is inserted. **B.** The ILMA is advanced until resistance is encountered. **C.** The cuff is inflated. **D.** The ILMA is stabilized and the ET tube is inserted. **E.** The ET tube is advanced into the trachea. **F.** The ET tube cuff is inflated. **G.** The ILMA is carefully removed. **H.** When the ILMA has exited the patient's mouth, grasp and stabilize the ET tube. Completely remove the ILMA.

millimeters optimize the alignment of the silicone ET tube and the trachea. As the silicone ET tube passes the mask aperture, the EEB will be seen to rise on the Viewer display. Continue to advance the silicone ET tube through the vocal cords. The patient can be ventilated by an assistant during this procedure if necessary. Detach the Viewer. Then, inflate the cuff of the silicone ET tube and ventilate the patient through the silicone ET tube. Confirm proper tube placement by the auscultation of breath sounds, observation of chest rise, and end-tidal CO_2 monitoring. Withdraw the LMA-CT similar to the technique described for the ILMA.

OTHER LARYNGEAL MASK DEVICES

The Ambu Laryngeal Mask (Ambu LM), King Laryngeal Airway Device (King LAD), and the Air-Q Masked Laryngeal Airway (Air-Q) can be inserted and secured similar to the LMA. An ET tube can be inserted through all the Air-Q models similar to the ILMA.

ALTERNATIVE TECHNIQUES

It is generally held that difficulty in insertion of the standard LMA occurs most frequently at the point where the tip of the mask passes just behind the tongue as it changes direction toward the hypopharynx.[15] Most of the suggested alternative methods for inserting the LMA involve the negotiation of direction change from the pharynx to the hypopharynx. Some authors suggest that a partially inflated mask is easier to place in the correct position.[15] Others employ a jaw-thrust maneuver. After adequate jaw relaxation has been established, the mask is positioned firmly and flatly against the hard palate, as recommended. Perform the jaw-thrust maneuver with the nondominant hand while firmly thrusting the mask into place with the dominant hand, in one motion.[16] The jaw-thrust creates a space in the hypopharynx for the mask. In rare cases, the use of a laryngoscope may help facilitate LMA placement, though this reduces the inherent simplicity of the technique of LMA insertion.

One study of the LMA-PS showed that a 90° rotation would improve rates of successful placement.[17] This technique was also associated with a lower incidence of mucosal bleeding and sore throat. After preparing the LMA-PS and the patient as usual, insert the device until the entire cuff is inside the mouth. Rotate the LMA-PS 90° counterclockwise and advance until resistance is felt. Once the LMA-PS is in the hypopharynx, straighten it out.

Given that there is less experience with the ILMA, few alternative methods of insertion exist. However, one must remember that the metal handle on the tip of the ILMA tube may be used to modify the position of the cuff within the hypopharynx.[9] Pulling back on the metal handle toward the intubator rotates the tube caudally in the sagittal plane. Pushing on the metal handle away from the intubator rotates the tube cephalad in the sagittal plane.

ASSESSMENT

Successful placement of an LMA device is most accurately demonstrated by auscultation of bilateral breath sounds, chest wall movement, and end-tidal CO_2 monitoring.[5,9] One may also gain a sense of accuracy of placement during insertion. During observation of the front of the neck while inserting an LMA, one may see a bulging of the tissues overlying the larynx. Visualization of this bulge, in addition to increased resistance to forward motion of the mask, indicates that the device is in the correct position.[1] A chest radiograph should be obtained if an ET tube has been placed through an LMA.

AFTERCARE

The LMA does not protect against aspiration as well as an ET tube. It should be replaced with an ET tube or a surgical airway. The method of securing the airway with a device other than an LMA will be determined by the patient's condition, if they have a "difficult airway," available equipment, and experience of the Emergency Physician.

COMPLICATIONS

There are numerous documented complications associated with the use of LMAs. One of the most obvious of these, and potentially the most devastating, is the failure to place the device successfully or to obtain a satisfactory laryngeal seal. Fortunately, even in inexperienced hands, the incidence of failure to achieve satisfactory ventilation is quite low. One large study, a retrospective review of 11,910 surgical cases where the standard LMA was used, noted an overall success rate of 99.81%.[18] Success rates have been classified as success on one single attempt and overall success. The overall success rate allows up to three attempts to be considered for successful placement. One investigator claimed a 99.5% single-attempt success rate in a retrospective analysis of 1500 cases.[10] Most studies imply correct LMA placement in 88% to 90% of first attempts.[7] Several studies have found success rates of 90% to 99% for ILMAs. Success rates appear to be higher if a wire-reinforced silicone ET tube is used rather than a standard ET tube.[19,20] Besides failure, there are other complications, which may be divided into minor complications and major complications.

MINOR COMPLICATIONS

Minor complications are those that may result in significant patient morbidity but usually are not associated with mortality or extremely deleterious outcomes. Stomach inflation can occur during positive-pressure ventilation at pressures greater than 20 cmH_2O for the standard LMA. Cuff herniation secondary to overinflation may result in failure of the cuff to seal effectively. Partial airway obstruction may occur in up to 10% of adults and 25% to 50% of pediatric patients when standard LMA cuffs are examined by fiberoptic bronchoscopy.[7] Trapping of the epiglottis in the distal aperture of the LMA may result in edema of the epiglottis. Air leaks around the cuff can occur during positive-pressure ventilation at pressures greater than 20 cmH_2O for the standard LMA and 30 cmH_2O for the LMA-PS. Forceful attempts to pass the LMA around the posterior pharyngeal curvature can result in uvular bruising.[7] Lingual nerve injury, tongue numbness, parotid gland swelling, and hypoglossal nerve palsy are sometimes noted. Unilateral vocal cord paralysis can occur secondary to traumatic insertion. Bilateral vocal cord paralysis has not been reported. Dental trauma may occur during the insertion or during maintenance of the airway.

MAJOR COMPLICATIONS

Major complications are those from which significant patient morbidity may be expected, including patient mortality. Fortunately, as regards the LMA, major complications are exceedingly rare. In a report of 11,910 surgical cases where the standard LMA was used, there were a total of 18 critical events related to the LMA, for an overall incidence of 0.15%.[18] These events included regurgitation of stomach contents (0.03%), vomiting of stomach contents (0.017%), pulmonary aspiration (0.009%), laryngospasm (0.07%), bronchospasm (0.025%), cardiac dysrhythmias (0.09%), and cardiac arrest (0.06%). While there appears to be a higher incidence of critical events when the device is used for controlled ventilation and positive-pressure ventilation, the incidence has not proved to be statistically significant.

In general, the complication rate (defined as events not attributable to the patient's underlying condition or to surgical or other interventions) should be equivalent to that seen during placement

of either a Guedel or Berman type oropharyngeal airway. Referring to standard anesthesiology textbooks, one realizes that the complication rate in each of the aforementioned categories when using the LMA is significantly lower than that occurring during direct laryngoscopy and ET intubation, potentially due to the intense autonomic nervous system stimulation occurring with the latter procedures.

SUMMARY

A major advancement in airway management was made with the introduction of the LMA. It is superior to a face mask in that it prevents supraglottic obstruction and reduces the likelihood of gastric insufflations.[2] However, it does not provide protection from aspiration. The LMA-PS and LMA-S, with their dual tube system, may help decrease the risk of aspiration.

The standard LMA has clearly earned a valuable place in the armamentarium of clinicians who provide airway management. The technique is easy to learn, easy to teach, and requires no specialized equipment. The LMA causes minimal autonomic nervous system activation and less of a response from the cardiovascular system than with direct laryngoscopy. The LMA is not associated with a risk of esophageal or endobronchial intubation. Both, however, are possible complications following use of the ILMA. The LMA has minimal effects on the intraocular pressure response to airway manipulation. The LMA may be of use in cases of suspected cervical spine injury.

The use of an LMA in place of a face mask avoids many risks, such as injury to the eyes, supraorbital and facial nerves, nose, and lips. There is less risk of hand fatigue than with the bag-valve-mask device. The LMA provides a safer and more secure airway in children and adults than does a face mask, with fewer episodes of hypoxemia as detected by pulse oximetry.[7]

The introduction of the ILMA more than a decade after the standard LMA further defined and expanded the role of this apparatus in airway management. It allows for precise ET tube placement, therefore ensuring airway protection. It is anatomically designed to ensure more accurate placement of the cuff. Given the ease of placement of the ILMA without the need for the rescuer to be positioned behind the head, there may be a significant place for the ILMA in future airway management algorithms.[4] The advent of the LMA-CT allows for direct fiberoptic visualization of the vocal cords prior to intubation.

20 Double Lumen Airway Tube Intubation

Joseph Weber

INTRODUCTION

The Esophageal-Tracheal Combitube (ETC; Kendall Sheridan, Mansfield, MA) and the EasyTube (EzT; Teflex Medical [Ruesch], Kernen, Germany) are double lumen airway devices that can be blindly inserted into the unconscious and unresponsive patient. The ETC and EzT function to adequately ventilate and oxygenate a patient while simultaneously protecting the airway from aspiration.[1,2] They are most often used in the prehospital setting by emergency medical technicians not trained in standard orotracheal intubation and by paramedic-level rescuers as an alternative airway device when standard orotracheal intubation fails.[3–5] These are the only two double lumen devices used in the prehospital setting and the Emergency Department. The Emergency Physician should be familiar with these devices so that it can be removed and exchanged with an endotracheal tube if placed in the prehospital environment or if required in the Emergency Department to manage a difficult airway.

ANATOMY AND PATHOPHYSIOLOGY

The ETC is a double-tube, double lumen, and double-cuffed device (**Figure 20-1**). The ETC starts as two distinct tubes that fuse into one, but remain functionally separated by a partition. The shorter clear tube is continuous with the distal open port, also known as the tracheoesophageal lumen. At its distal end is the distal tracheoesophageal cuff, similar to that of an endotracheal tube. It is a high-volume, low-pressure balloon that is inflated through the white inflation port. The longer blue tube is continuous with the eight perforations known as the proximal ports. A large pharyngeal cuff is just proximal to the perforations. This cuff is positioned between the base of the tongue and the palate, separating the oral and nasal cavities from the remainder of the airway. It is inflated through the blue inflation port.

The EzT is also a double-tube, double lumen, and double-cuffed device with a structure similar to the ETC (**Figure 20-2**). However, it has several differences in comparison to the ETC. First, the shorter clear tube ends as a conventional single lumen 7.5 mm endotracheal tube. Second, the longer blue tube ends in an open aperture, rather than multiple perforations. Third, the EzT is latex free.[6]

Both the ETC and EzT may be inserted blindly into a patient's airway. If the distal tip enters the trachea, the patient is ventilated through the shorter clear tube and the distal cuff prevents aspiration of gastric contents into the trachea. If the distal tip enters the esophagus, the patient is ventilated through the longer blue tube, whose proximal ports lie in the hypopharynx, while the distal cuff will occlude the esophagus.

The EzT may also be used as a primary airway device under direct laryngoscopy. When placed successfully into the trachea, it functions as a 7.5 mm endotracheal tube. If unable to pass it into the trachea, it can be advanced into the esophagus and the patient ventilated through the blue tube.[6,7]

Both devices are available in two sizes. The 37 French SA model of the ETC is meant for small adults. The manufacturer recommends its use in patients with a height of 122 to 168 cm (4.0 to 5.5 ft). The 41 French model of the ETC is meant for larger adults with a height of 152 cm (5 ft) and greater. Patients in the intermediate range of 152 to 168 cm (5.0 to 5.5 ft) can use either model. A recent study demonstrated that the 37 French SA model can be used in patients up to 183 cm (6 ft, 1 in) in height. The EzT is available in a 28 French model for patients with a height from 90 to 130 cm (3.0 to 4.3 ft) and a 41 French model for patients over 130 cm (4.3 ft).

Several attributes specific to these devices contribute to their usefulness in the acute setting. Both are effective as either a primary or backup airway management device. A patient can be ventilated with the tip positioned in either the esophagus or the trachea. Minimal training is necessary. There is no need for a laryngoscope. They are easily inserted with patient's head and neck in a neutral position. The dual lumens and balloons also offer certain advantages. When placed in the esophagus, the distal lumen of both allow for gastric suctioning. The proximal lumen of the EzT is an open lumen rather than perforations as in the ECT. This allows for the passage of a suction catheter, fiberoptic scope, or endotracheal tube changer (maximum diameter 3.99 mm) into the trachea.[6] The balloons firmly secure the device, making dislodgment unlikely. The proximal balloon can functionally tamponade oropharyngeal bleeding and serve to minimize the risk of

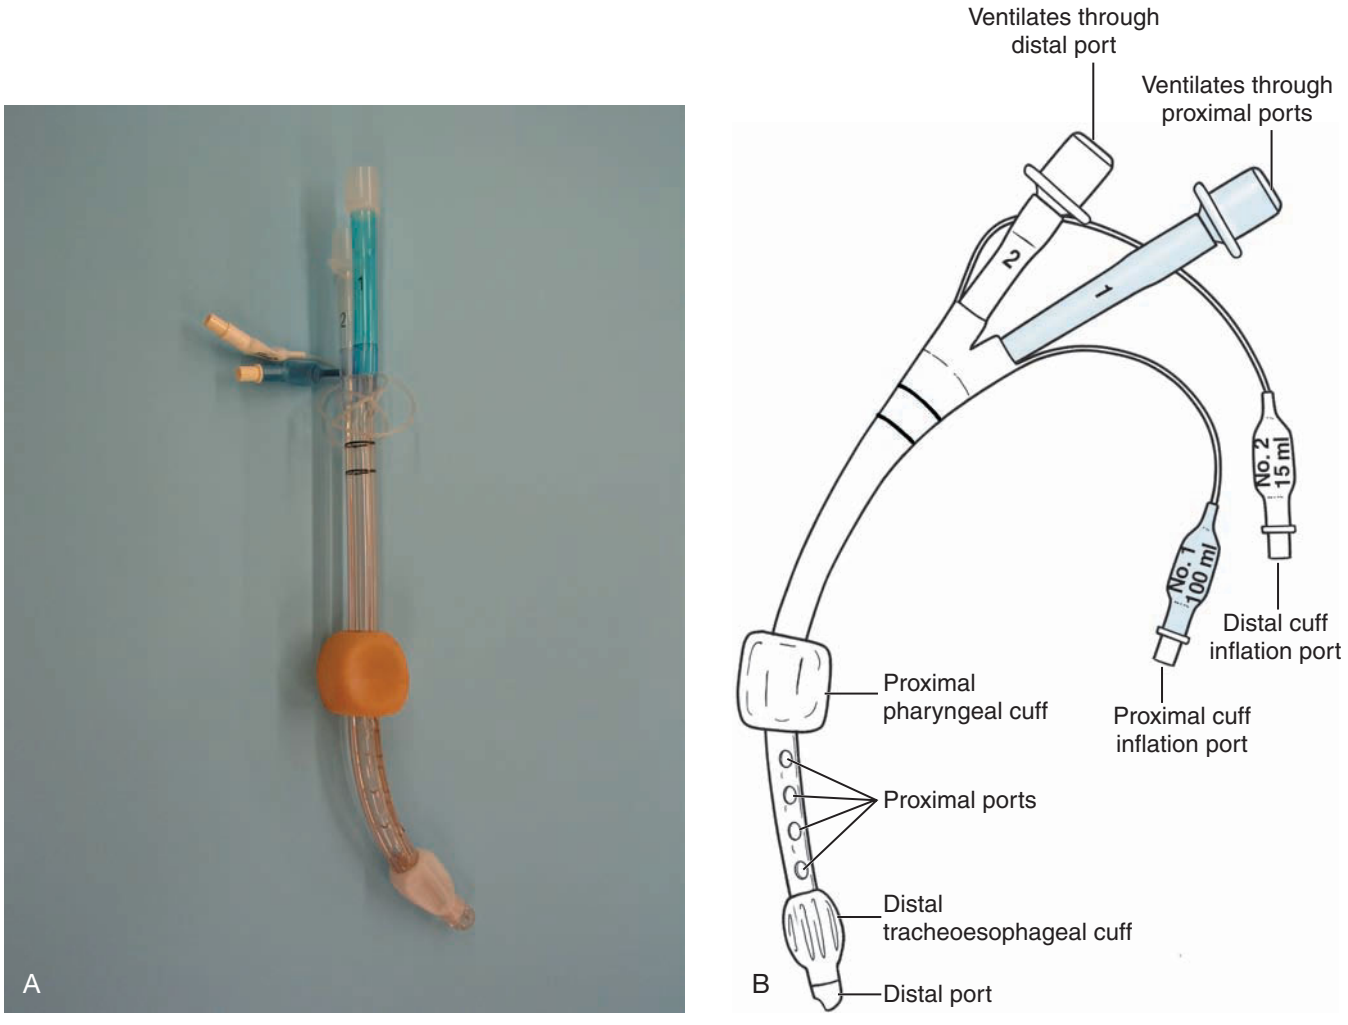

FIGURE 20-1. The Combitube. **A.** Photograph. **B.** Illustration.

aspirating oral debris.[8] These attributes make these devices suitable for rescuers of all skill levels.

INDICATIONS

The primary indication for an ETC or an EzT is as a backup device for airway management in and out of the hospital. It can be used for difficult or failed orotracheal intubations. It should be placed on crash carts for use by individuals not skilled with orotracheal intubation. In situations with limited access to the patient's head (e.g., extrication situations), they can be used where standard orotracheal intubation cannot be performed. They should be considered in situations of potential cervical spine injury as the device can be inserted with the patient's head and neck in a neutral position. The ETC is an appropriate device for management of the airway when visualization is limited due to bleeding or secretions. All Emergency Physicians should become familiar with these devices if they are used by emergency medical technicians in their region as well as considering it as an alternative airway device for difficult airways in the Emergency Department.[8,9]

CONTRAINDICATIONS

Certain contraindications exist and should be addressed. **These devices should not be used on patients with an intact gag reflex.** If intubation is anticipated, there should be enough time to premedicate the patient and induce anesthesia before inserting them. Size limits apply to both the ETC and the EzT. The standard ETC cannot be used in patients under 5 feet tall. The smaller ETC SA model cannot be used in patients under 4 feet tall. The EzT cannot be used in patients under 3 feet tall. The ETC cannot be used in patients with a latex allergy. The EzT is latex free and can be used in all patients.

Their use is contraindicated if the patient has known esophageal disease or an airway obstruction. Patients with known esophageal disease (e.g., strictures, cancer, or victims of caustic ingestions) are at an increased risk of complications such as perforation and failed performance of the device. Patients with known upper airway obstruction (e.g., secondary to congenital disorders, cancer, or other anatomic abnormalities) are also at increased risk for complications and performance failure.

EQUIPMENT

- Gloves, gown, and mask
- Eye protection, goggles or a face mask with an eye shield
- Pulse oximeter
- Noninvasive blood pressure cuff
- Cardiac monitor
- IV access equipment

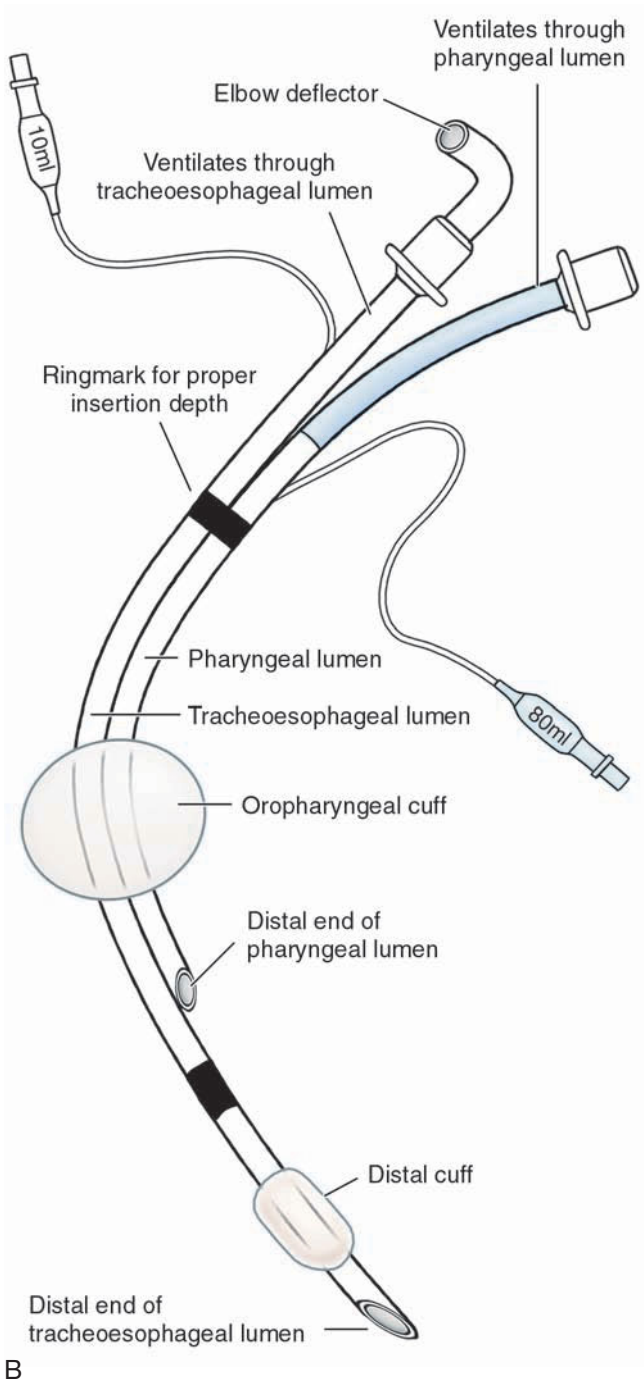

FIGURE 20-2. The EasyTube. **A.** Photograph. **B.** Illustration.

- ETC or EzT kit
- Oxygen source and tubing
- Suction source and tubing
- Water-soluble lubricant
- Bag-valve-mask device
- Advanced Cardiac Life Support equipment and medications
- Surgical airway equipment

The ETC and the EzT are prepackaged in a kit form with the dual lumen airway tube, two syringes for balloon inflation, a 90° elbow, and a flexible suction catheter (**Figures 20-3A & B**). The ETC kit also contains a vomit deflector that is not routinely used, as it may be associated with significant complications and gastric contents directed at the healthcare professional. The suction catheter included is designed to be inserted through the smaller tube and to exit the tracheoesophageal port.

PATIENT PREPARATION

Preoxygenate the patient with a bag-valve-mask device using 100% oxygen. Establish IV access. Apply the pulse oximeter, noninvasive blood pressure cuff, and the cardiac monitor. Place the patient in the supine position, or in any position that may be required. The neutral position is not required. Prepare the equipment while an assistant is ventilating the patient. Remove the ETC or EzT and equipment from the package. Attach the syringes to their respective ports and inflate the cuffs (**Figure 20-4**). If a leak of air is present or if the cuff does

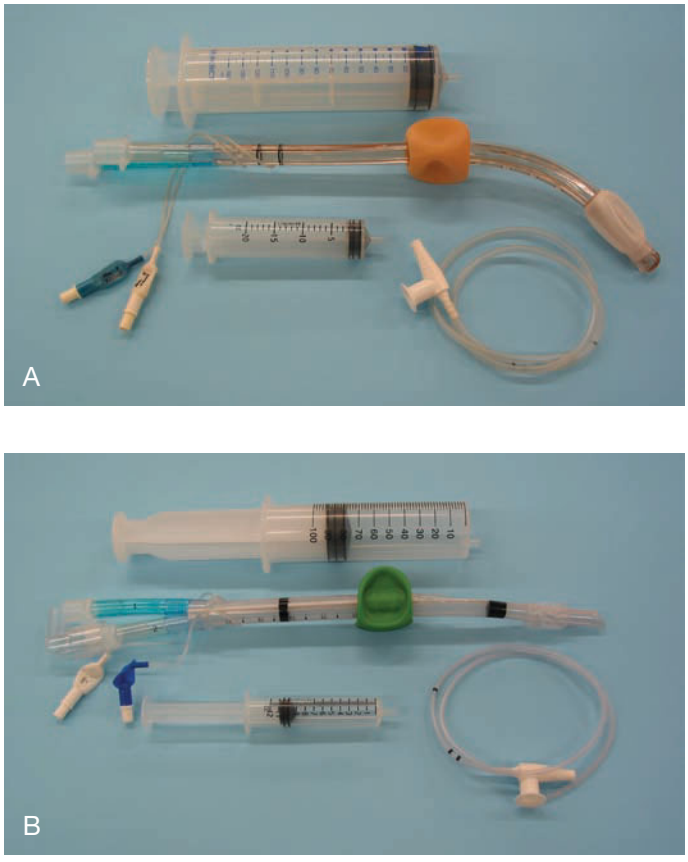

FIGURE 20-3. The contents of the double lumen kits. **A.** The Combitube kit. **B.** The EasyTube kit.

not inflate properly, discard the device and open another kit. Deflate the cuffs and leave the syringes attached to the ports. Liberally lubricate the tip of the device with a water-soluble lubricant.

TECHNIQUE

Insert the thumb of the nondominant hand into the patient's mouth and over their tongue (**Figure 20-5A**). Place the nondominant fingers under the chin. Depress the tongue and open the jaw simultaneously. Remove any dental devices and foreign bodies. Grasp the device with the dominant hand. The curve of the device should be in the same direction as the natural curve of the pharynx. Insert the device into the midline of the patient's mouth. Advance it in a downward curved motion until the patient's teeth or alveolar ridge lies between the two printed bands of the ETC (**Figure 20-5B**) or the black stripe of the EzT (**Figure 20-6**). **Do not insert the device forcefully as significant injury can occur.** If it does not advance easily, redirect it and then reinsert the device. Inflate the pharyngeal cuff with the volume of air marked on the blue port (100 mL for the ECT, 85 mL for the ECT SA, or 80 mL for the EzT). The device will withdraw slightly from the patient's mouth as the pharyngeal cuff is inflated. Inflate the distal cuff with the volume of air marked on the white port (15 mL for the ECT, 12 mL for the ECT SA, or 10 mL for the EzT).

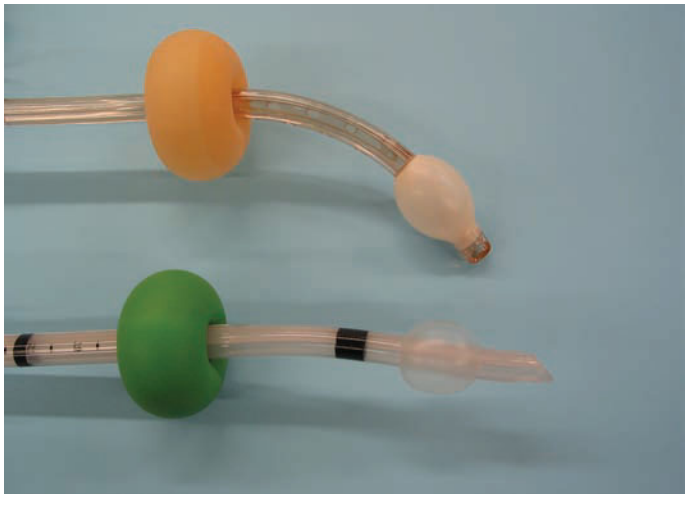

FIGURE 20-4. The Combitube (above) and the EasyTube (below) with their cuffs inflated.

Because most blind intubations are esophageal, begin ventilation through the longer blue tube (**Figures 20-5C & 20-6**). Auscultation of breath sounds, symmetric rise of the chest, fogging in the tube for more than six breaths, and lack of gastric insufflation confirm placement within the esophagus and ventilation through the proximal ports/aperture (**Figures 20-5C & 20-6**). If no breath sounds are auscultated and gastric insufflation occurs, the trachea is intubated (**Figure 20-5D**). Begin ventilation through the shorter clear tube and verify by auscultation the presence of breath sounds.

If breath sounds cannot be auscultated when ventilating through either tube, the device may be too far into the pharynx. Deflate the pharyngeal cuff and withdraw the device 2 to 3 cm. Reinflate the pharyngeal cuff. Ventilate through the longer tube and confirm tube placement as noted above.

AFTERCARE

Secure the device. This is accomplished using the standard method of taping or a commercially available endotracheal tube holder. Although there are reports of short-term (e.g., 4 to 6 hours) ventilator use with these devices, it should be replaced with a standard endotracheal tube for long-term ventilation.[10]

Several methods for replacing the device are available. The first is to remove the device entirely and intubate the patient orotracheally. Deflate the pharyngeal cuff. Suction the patient's mouth and oropharynx. Tilt the device to the left side of the patient's mouth. Deflate the distal cuff. Remove the device. Intubate the patient orotracheally.[11]

Alternative methods of intubation are also possible. Deflate the pharyngeal cuff. Suction the mouth and oropharynx. Tilt the device to the left side of the patient's mouth. Insert the laryngoscope and visualize the tip of the device. If it is in the esophagus, orotracheally intubate the patient, deflate the distal cuff of the device, and remove the device. This method will prevent aspiration, especially if endotracheal intubation is unsuccessful. If it is in the trachea, instruct an assistant to deflate the distal cuff of the device and remove it slowly. After the device clears the patient's vocal cords, immediately insert the endotracheal tube.

The EzT has a significant advantage over the ECT when attempting to replace it with a conventional endotracheal tube. If the distal end is in the trachea and the patient is being ventilated through the short clear tube, it can be left in place as it is functioning as a 7.5 mm endotracheal tube. If the distal end is in the esophagus and the patient is being ventilated through the long blue tube, a fiberoptic scope or an endotracheal tube changer can be passed through the blue tube and into the trachea. The EzT can then be removed and an endotracheal tube passed over the endotracheal tube changer. This cannot be done with the ECT because it has perforations rather than an open aperture.[6,7]

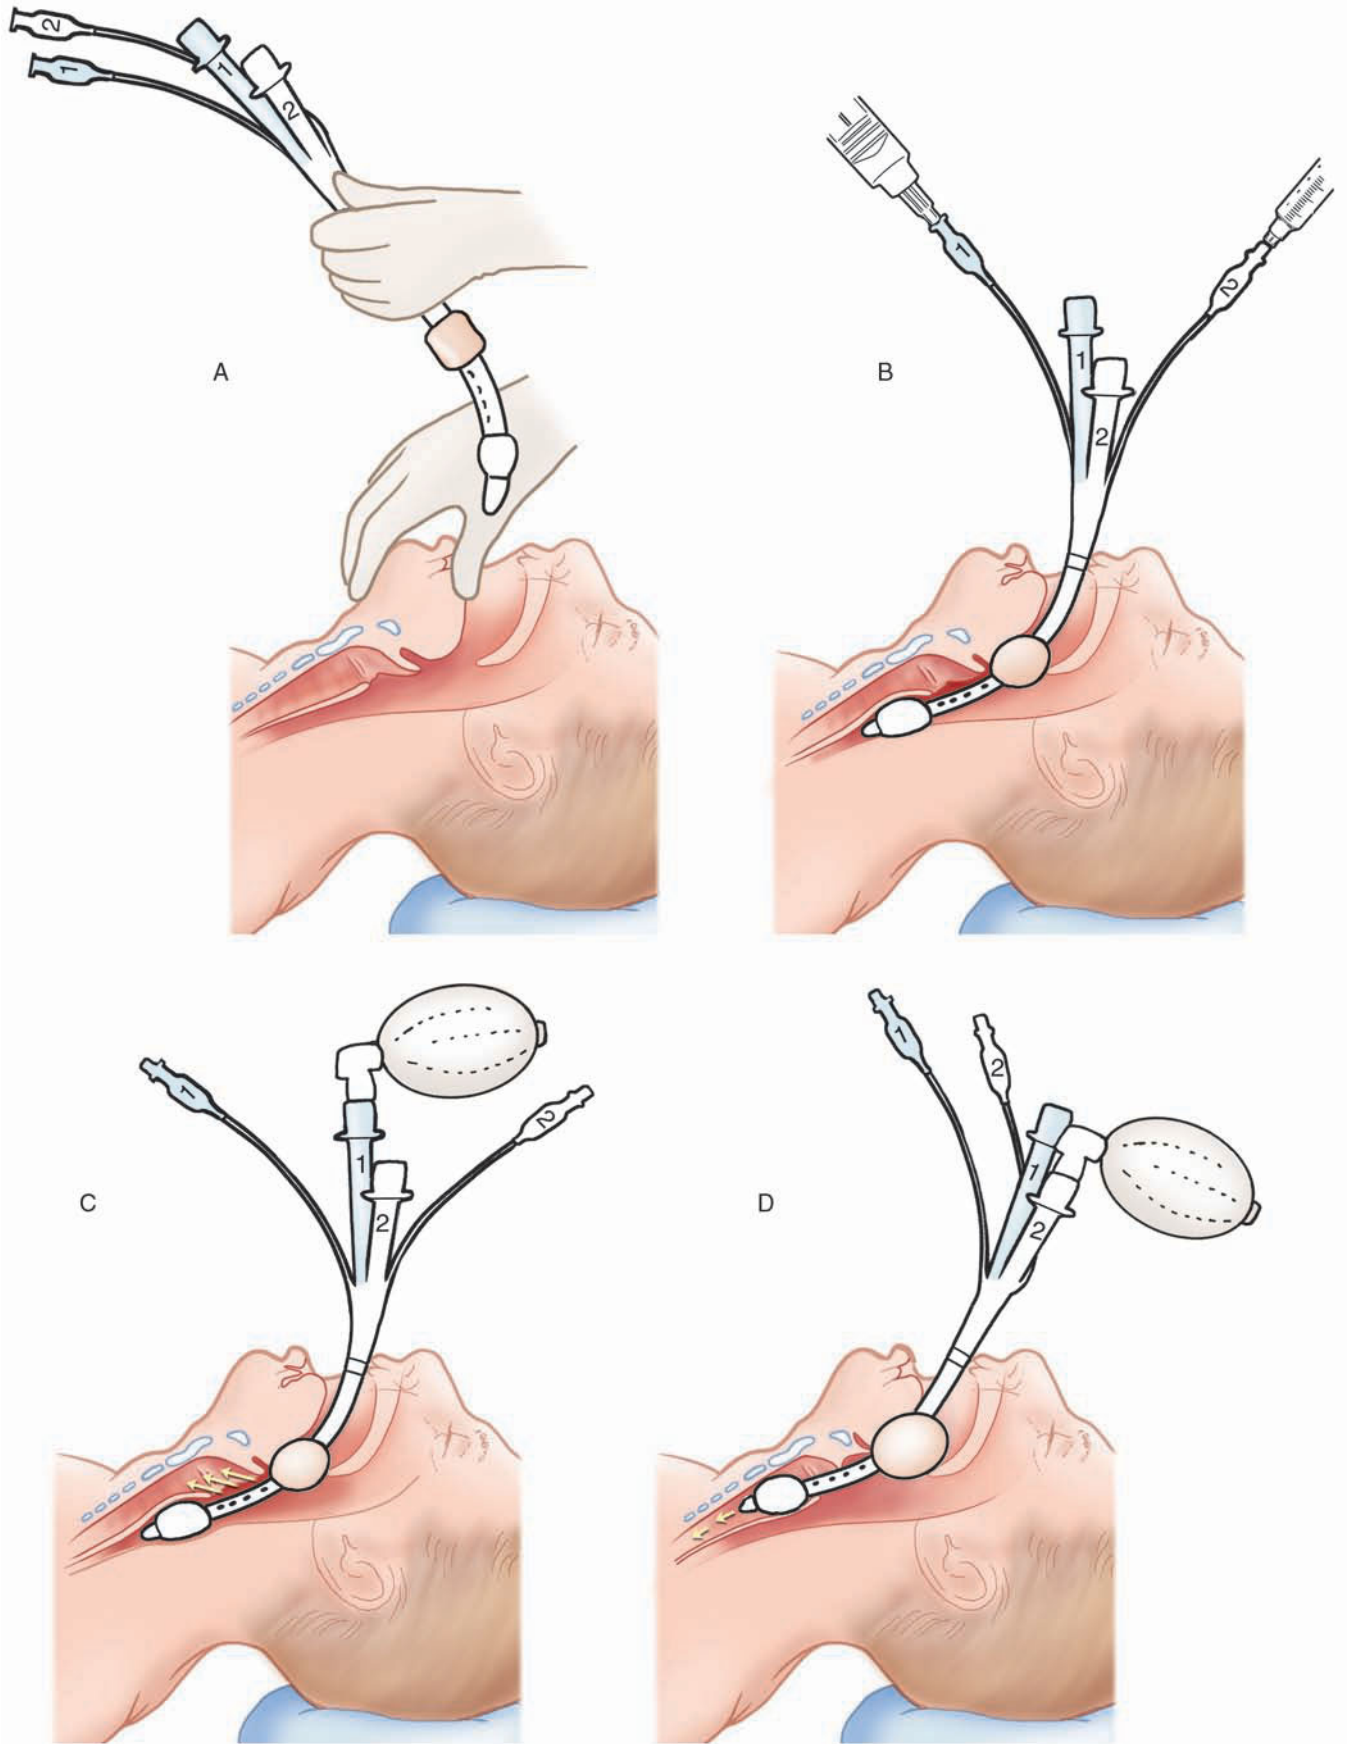

FIGURE 20-5. Insertion of the ETC. **A.** Positioning of the patient and the physician. **B.** The tube is inserted until the patient's teeth are between the black lines and the cuffs are inflated. **C.** The tube is inserted into the esophagus. The patient is ventilated through the longer tube (1) and air is directed from the proximal ports (*arrows*). **D.** The tube is inserted into the trachea. The patient is ventilated through the shorter tube (2) and air is directed through the distal port (*arrows*).

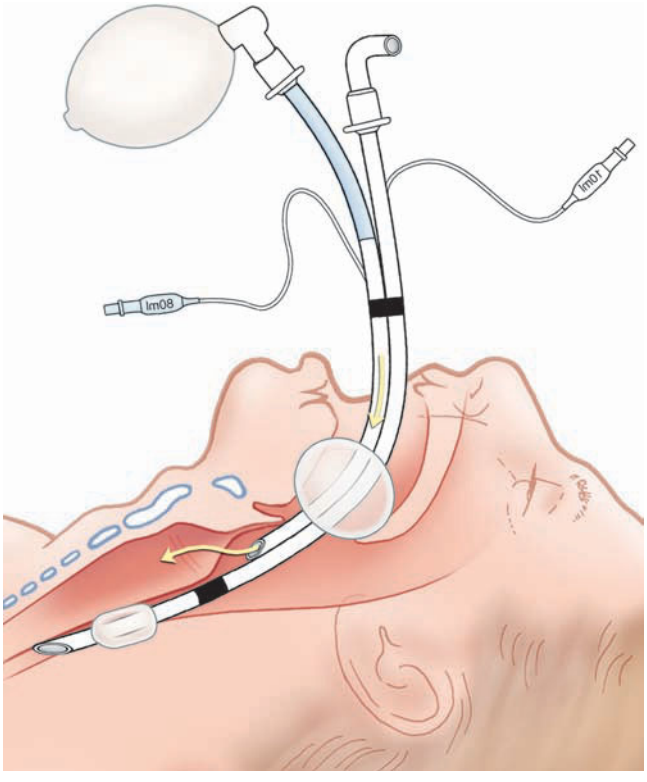

FIGURE 20-6. Insertion of the EzT with the distal end in the esophagus.

COMPLICATIONS

Despite the potential utility of the ETC or EzT in the acute setting, several disadvantages must be kept in mind. These include the high cost, bulky packaging, and the fact that the ETC detachable "vomit deflector" can expose providers to gastric contents if improperly managed. It is best not to use the vomit deflector, as it can be associated with aspiration. Several risks are also inherent to the insertion and mechanics of the devices. It should be recognized that the presence of a rigid cervical collar can cause great difficulties in the proper placement of this device.[12] The device is most frequently inserted into the esophagus. Therefore, there is a risk of esophageal injury.[13] **There is no way to suction the trachea with the open distal port in the esophagus. It is important to note that resuscitation drugs that can be routinely given through an endotracheal tube cannot be given through the device positioned with the tip in the esophagus.** Drugs will accumulate in the blind end of the tube or the hypopharynx. Significant soft tissue injury can occur due to the tip of the device or if the balloons contain too much air.[12,14] If forced, the tip can perforate the esophagus, piriform sinus, or vallecula. The increased cuff pressure of the ETC versus the EzT can result in mucosal injury.[15] An overinflated distal balloon located in the esophagus can compress the trachea and cause an airway obstruction.[16] **Always inflate the balloons with the recommended volume of air and not more.** Prolonged use of up to 4 hours can result in the proximal cuff obstructing the lingual veins and resultant tongue engorgement.[17] This can result in a difficult intubation when exchanging the device for an endotracheal tube.

SUMMARY

The Esophageal-Tracheal Combitube and the EasyTube can adequately ventilate a patient whether it is placed in the esophagus or trachea. It is relatively simple to use and requires minimal training. It offers an additional technique for emergency care providers to secure the airway in both the prehospital and hospital environment. It should be included in every armamentarium dedicated to the difficult airway.

21 Fiberoptic Endoscopic Intubation

Erika D. Schroeder, M. Scott Linscott, and Joseph Bledsoe

INTRODUCTION

The flexible fiberoptic bronchoscope is a useful instrument for placing endotracheal (ET) tubes in awake and nonparalyzed patients who may have contraindications to paralysis, as well as in patients undergoing rapid sequence intubation when other means of orotracheal intubation have failed. **The device is unique in that its flexible cord allows it to conform to the patient's anatomy, making intubation possible in a variety of clinical situations when intubation by direct laryngoscopy is likely to be difficult or impossible.** It is most useful in performing awake intubations as it is accepted by more patients and is associated with fewer complications than awake laryngoscopy.[1] Proficiency in the skills required for fiberoptic intubation requires both instruction and practice.[2] **Technical problems and failure to successfully intubate patients using this technique are usually due to a lack of familiarity and expertise with the fiberoptic bronchoscope, using it in the wrong clinical setting, and inadequate patient preparation.**

ANATOMY AND PATHOPHYSIOLOGY

A more detailed description of the airway anatomy is provided in Chapters 6 (Essential Anatomy of the Airway), 7 (Basic Airway Management), and 11 (Orotracheal Intubation). A brief description of the flexible fiberoptic bronchoscope is presented in this section. There are other sources for a more in depth description of the fiberoptic bronchoscope's anatomy.[3]

The basic anatomy of the flexible fiberoptic bronchoscope is shown in **Figure 21-1**. The major components are the handle, the insertion cord, and a light source. The handle contains the eyepiece for image viewing and a dial to bring the image into focus. A lever controls an angulation wire, which allows for movement of the bronchoscope's insertion cord tip in one plane.

The bronchoscope's insertion cord is composed of thousands of glass fibers, each approximately 10 μm in diameter. The fibers in the cord transmit an image to the proximal viewing lens. There is a side port that can be used for the insufflation of oxygen, instillation of local anesthetic or saline solution, limited suction (due to the small size of the port), passage of a guidewire, and end-tidal CO_2 monitoring. Any fiberoptic bronchoscope used for intubation should have a length of at least 55 to 60 cm.[4] Fiberoptic laryngoscopes or nasopharyngoscopes are usually unsuitable for intubation because of their short length.

INDICATIONS

Fiberoptic intubation of the airway is indicated in situations where an awake intubation technique is preferable to one that renders the patient unconscious. The awake technique is indicated when it is anticipated that direct laryngoscopy might be difficult to perform or if paralysis is contraindicated.[2] This would include morbidly obese

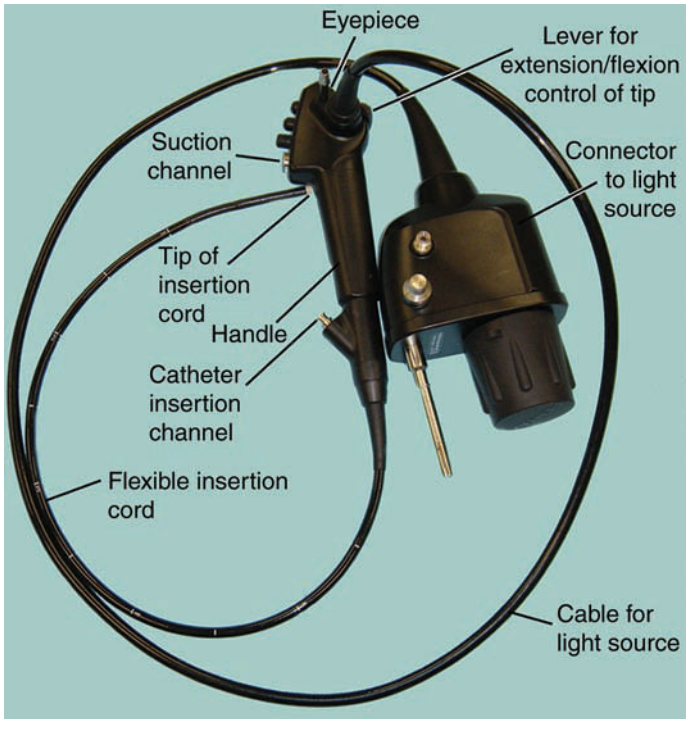

FIGURE 21-1. Anatomy of the flexible fiberoptic bronchoscope.

patients, those having limited mandibular opening, an unstable or immobile cervical spine, macroglossia, CHF, micrognathia, patients who appear to have pathologic airway anatomy (e.g., tracheal deviation, tracheal stenosis, tumors, and trauma), and those who appear to be at increased risk for dental damage.[5] Fiberoptic bronchoscopy has been used successfully in the case of a rapidly enlarging neck mass.[6] It should be considered in patients in whom neck extension should be avoided or who are at increased risk of aspiration of their gastric contents (e.g., those not fasted, pregnancy, alcohol intoxication, and bowel obstruction).[4]

CONTRAINDICATIONS

Fiberoptic intubation is not recommended for patients who are actively vomiting or have significant oropharyngeal bleeding. Opaque fluids cover the fiberoptic port and prevent adequate visualization through the bronchoscope. Patients who are hypoxic or require assisted ventilation by mask are poor candidates for fiberoptic intubation as the technique may require several minutes to perform. An exception may be made if the patient can be ventilated by a laryngeal mask airway (LMA) through which fiberoptic ET intubation may be performed.[7,8] Contraindications specific to nasal fiberoptic intubation would include coagulopathy, significant midface trauma, severe intranasal pathology, fracture of the cribriform plate, and leakage of cerebrospinal fluid.[9]

Relative contraindications to fiberoptic intubation of the airway are situations when instrumentation of the airway may further compromise airway patency, such as stridor resulting from airway edema, infection, or epiglottitis. **Some authors advocate fiberoptic intubation as an option to consider in these circumstances, but only by individuals extremely proficient at fiberoptic endoscopic intubation and only with a qualified physician standing by to perform an emergent tracheostomy or cricothyroidotomy if the need arises.**[10] In these circumstances, it would probably be prudent to establish a surgical airway in the operating room, under a more controlled setting, rather than attempt a fiberoptic bronchoscopic intubation. Occasionally, an emergent tracheostomy or cricothyroidotomy cannot be successfully performed in these patients before complete airway obstruction occurs. **Therefore, one should always be prepared to provide oxygen emergently by another route (e.g., transtracheal jet ventilation) to prevent hypoxic brain damage.**

EQUIPMENT

Nasal Anesthesia

- Cotton-tipped applicators
- 4% lidocaine
- 0.05% oxymetazoline (Afrin®)
- 4% cocaine

Oropharyngeal Anesthesia

- 1%, 2%, or 4% lidocaine or benzocaine spray
- Nebulizer device with tubing or a Mucosal Atomizer Device (MAD®, Wolfe Tory Medical, Salt Lake City, UT)
- Cotton 4 × 4 swabs soaked in 4% lidocaine
- Emesis basin
- Yankauer suction
- Tongue blade

Laryngeal Anesthesia

- Alcohol swabs
- 10 mL syringes
- 21 gauge needle, 1½ inches
- 2% lidocaine for atomization
- 1% and 4% lidocaine solution
- Nebulizer device with tubing

Fiberoptic Bronchoscopy and Intubation

- An assistant
- Fiberoptic bronchoscope with working channel
- Bite block
- Oral/nasopharyngeal airways
- Light source
- ET tubes, various sizes
- Suction source and catheters
- Cuffed tracheal tubes of various sizes, especially 5 and 7 mm
- Oxygen source
- Oxygen tubing
- Bag-valve device
- Face masks
- Water-soluble lubricant or anesthetic jelly
- Gauze 4 × 4 squares
- Antisialagogue (glycopyrrolate 0.3-0.4 mg IV or IM, atropine 0.5 mg IV)

Miscellaneous Supplies

- Povidone iodine solution or chlorhexidine
- Alternative intubation kit/devices (difficult airway cart)
- Cricothyroidotomy tray or kit
- Rapid sequence induction medications
- Crash cart
- Cardiac monitor
- Pulse oximetry

PATIENT PREPARATION

Fiberoptic intubation is best performed on awake and spontaneously breathing patients. Rendering the patient unconscious might relax and distort the airway anatomy, placing the patient at risk for more serious complications including apnea, airway obstruction, and aspiration of gastric contents.[11] **Proper patient preparation is essential to the successful completion of a fiberoptic intubation.** Proper patient preparation includes counseling the patient, clearing the airway of secretions and blood, judicious sedation, and airway anesthesia (nasopharynx, larynx, and trachea).[9] **Counseling is an important and often underestimated part of patient preparation.** Thoroughly explain the necessity for the procedure and the technique. The bronchoscopist can gain the patient's confidence and cooperation, which are invaluable aids for the performance of a successful fiberoptic intubation.

Before proceeding with fiberoptic bronchoscopy, monitors for electrocardiogram, blood pressure, and pulse oximetry should be placed along with an intravenous line for the administration of drugs. Supplemental oxygen should be administered and can be delivered either by nasal cannula, "blow-by," or through the side port of the fiberoptic bronchoscope. Delivering oxygen through the side port offers the additional advantage of blowing airway secretions away from the fiberoptic bronchoscope's tip and can be used to help visualize the vocal cords when redundant tissue is obscuring the view. Unfortunately, it has the potential disadvantage of causing gastric distention and rupture.[12,13]

The patient may be in a sitting, semirecumbent, supine, or left semilateral position during fiberoptic bronchoscopy.[14] In morbidly obese patients, the sitting position will, by virtue of gravity, displace redundant pharyngeal tissue anteriorly and open the pharyngeal space.[15] However, use of the sitting position also requires the bronchoscopist to stand at the patient's side, thus inverting the image seen through the fiberoptic bronchoscope. Alternatively, the bronchoscopist can stand on a platform in order to be of sufficient height to correctly perform the procedure. When performing the procedure with the patient in the supine position, the patient's head should lie flat against the table surface with the neck extended (if it is safe to do so). This head position brings the tracheal axis more in line with the nasal and oral passageways and elevates the epiglottis from the posterior pharyngeal wall. The "sniffing position," while optimal for direct laryngoscopy, increases obstruction of the glottis by the epiglottis during fiberoptic bronchoscopy and makes the passage of the fiberoptic bronchoscope more difficult.[15] Maneuvers performed by an assistant, such as the jaw thrust or pulling the tongue forward with a cotton swab, can help to move the pharyngeal soft issues anteriorly and allow increased maneuverability of the fiberoptic bronchoscope's tip.[9]

Instrumentation of the airway may cause the patient to produce copious secretions, making an otherwise straightforward fiberoptic bronchoscopy extremely difficult. Bronchoscopy via a "dry" airway devoid of secretions can be accomplished in most instances by administering 0.3 to 0.4 mg of glycopyrrolate. This is a potent antisialagogue and should be administered intravenously at least 10 minutes before or intramuscularly 30 minutes before fiberoptic bronchoscopy. Atropine is often more readily available in the Emergency Department than glycopyrrolate. It can be administered in a dose of 0.5 mg intravenously at least 10 minutes before fiberoptic bronchoscopy. The only disadvantage of atropine is that it crosses the blood–brain barrier and can cause central nervous system effects whereas glycopyrrolate does not. Please refer to Chapter 8 for a more complete discussion of these two antisialagogues.

Sedation can be extremely beneficial in gaining the patients cooperation during the performance of a fiberoptic bronchoscopy. **Sedative drugs, if used at all, should be judiciously titrated to the desired effect with continual assessment of the patient's level of consciousness, while at the same time avoiding respiratory depression.** Ketamine given in small doses (0.5 to 1.0 mg/kg) has the advantage of producing minimal respiratory depression and may be preferable to opioids in some cases. Other agents that have been successfully used for sedation during fiberoptic intubations include midazolam, propofol, fentanyl, dexmedetomidine, and remifentanil.[4,16] Please refer to Chapter 8 for a more complete discussion of the pharmacologic adjuncts to intubation. **Avoid sedation if the patient has a tenuous airway, labored respirations, a distended abdomen, or is vomiting.**

AIRWAY ANESTHESIA

Adequate anesthesia of the airway is extremely important when intubating an awake patient. In order to establish a quiet larynx devoid of reflexes, it is extremely helpful, prior to attempting fiberoptic bronchoscopy, to provide anesthesia of the airway. It is especially effective in improving the success rate of individuals who are less experienced at performing fiberoptic intubation. The regional anesthesia technique employed to anesthetize the larynx is the bilateral superior laryngeal nerve block.

Bilateral blockade of the superior laryngeal nerves will provide effective anesthesia of the supraglottic structures. Prepare a 5 mL syringe attaching a 21 gauge needle and filling it with 1% or 2% lidocaine solution. Identify the hyoid bone by palpation. Slide your finger laterally to identify the superior cornua. Clean and prepare the skin over the superior cornua bilaterally. Insert the needle and advance it until it contacts the superior cornua of the hyoid bone. Contact with the bone can be made easier by extending the patient's head and gently palpating the hyoid bone with the thumb and forefinger of one hand. By applying gentle pressure to one side, the opposite cornua comes into closer contact with the skin and is subsequently easier to contact with the needle. Walk the needle tip inferiorly and off the bone. Advance the needle 3 to 4 mm and through the thyrohyoid membrane (**Figures 21-2 & 21-3**). **Aspirate before injecting the local anesthetic solution to confirm that the needle has not entered the external carotid artery.** Inject 2 to 3 mL of lidocaine. Repeat the procedure on the contralateral side. The hyoid bone may not be palpated due to obesity, infections, or masses. In those instances, a superior laryngeal nerve block should not be attempted.[17]

It remains an unresolved controversy whether to abolish the laryngeal reflexes of a patient considered to have a "full stomach." In considering this option, one must weigh the risk of abolishing the laryngeal reflexes and rendering the patient potentially vulnerable to gastric aspiration versus leaving the laryngeal reflexes intact and thus causing significant discomfort for the patient. When deliberating whether or not to proceed with a regional block of the larynx in a patient considered to be at risk for gastric aspiration, bear in mind that aspiration of gastric contents occasionally does occur in patients with intact laryngeal reflexes. Instrumentation of the airway in patients with an intact gag reflex can induce vomiting.

The larynx and trachea can be effectively anesthetized by performing a transtracheal injection of 4 mL of lidocaine. Clean and prepare the surface of the skin over the cricothyroid membrane. Prepare a 20 gauge intravenous catheter-over-the-needle on a 5 mL syringe containing 2 to 3 mL of sterile saline. Prepare a second syringe containing lidocaine solution. Insert the catheter-over-the-needle on the syringe containing sterile saline perpendicular through the skin in the midline over the cricothyroid membrane (**Figures 21-2 & 21-4**). Advance the syringe until the tip of the catheter-over-the-needle is in the trachea. The lumen of the trachea is identified by the loss of resistance. Aspirate air into the syringe, as evidenced by the presence of bubbles in the saline, to confirm that the catheter-over-the-needle is within the trachea. **Care should be taken to not advance the catheter-over-the-needle too far and perforate the posterior**

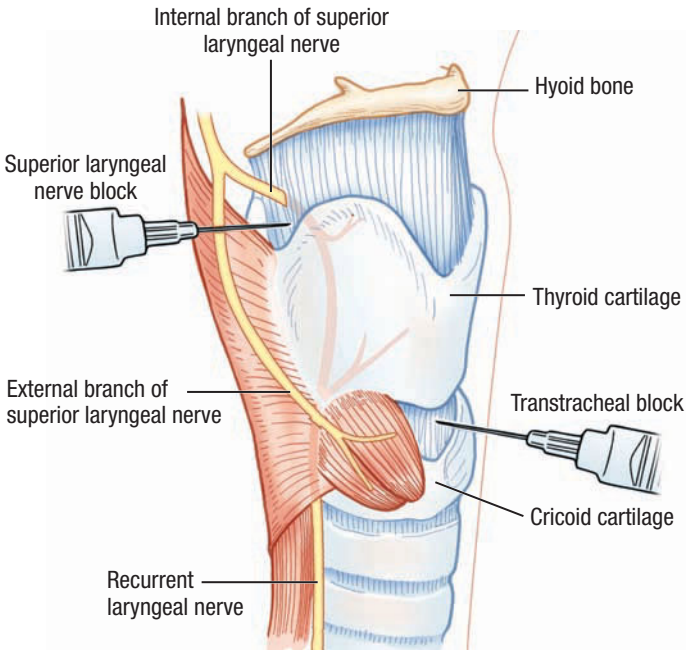

FIGURE 21-2. The anatomy of the larynx. The syringes demonstrate the superior laryngeal nerve block and the transtracheal block.

trachea, as this could result in a pneumomediastinum.[18] Securely hold the syringe in place and advance the catheter into the trachea. Securely hold the catheter hub at the skin. Withdraw the needle and syringe. Attach the syringe containing lidocaine to the catheter. Briskly inject 3 to 4 mL of lidocaine through the catheter and into the tracheal lumen. This will cause the patient to cough and disperse the local anesthetic solution throughout the trachea and larynx. Remove the syringe and catheter. The physician performing this block should be wearing a gown, a face mask, and eye protection to prevent exposure to the respiratory secretions when the patient coughs.

The nasal passages, pharynx, and larynx can be anesthetized by several other techniques. If the nasal passageways are the anticipated route for intubation, they should be prepared by shrinking and anesthetizing the nasal mucosa. Cocaine (4%) applied topically

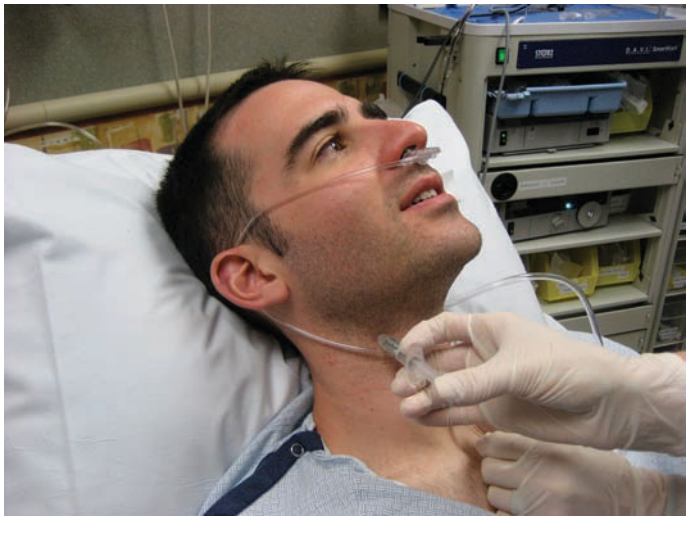

FIGURE 21-3. The recurrent laryngeal nerve block. The needle is inserted and advanced just below the superior cornua of the hyoid bone.

FIGURE 21-4. Transtracheal anesthesia of the trachea and larynx. The catheter enters the trachea through the midline of the cricothyroid membrane.

(maximum dose 200 mg) has the advantage of providing profound vasoconstriction and anesthesia to the nasal passageways. Similar effects can be provided by applying 0.25% to 1.0% phenylephrine topically to the nasal mucosa, followed by lidocaine 4% via cotton-tipped applicators. These applicators should be gently placed, one at a time, through the middle meatus and back to the inferior turbinate. A nasal passage that accommodates four to five single cotton-tipped applicators will usually allow passage of a 7.0 mm ET tube.[9] Also effective in providing profound vasoconstriction of the nasal mucosa is the use of three to four sprays of atomized oxymetazoline (Afrin®) into one or both nares.

Once the antisialagogues have taken effect, the tongue and pharynx can be anesthetized. Place a tongue blade on the patient's tongue and apply topical anesthetic spray (**Figure 21-5**). Benzocaine or lidocaine spray will usually provide effective anesthesia for the posterior pharynx within 30 seconds. They can be administered from a commercially available spray container or using an atomizer device. There are reports of methemoglobinemia from the overzealous use of benzocaine.[19] Its use should be limited to several short sprays.

Alternatively, the patient can swish 2% viscous lidocaine in their mouth for several minutes to provide effective anesthesia. One of the most effective methods of blocking the glossopharyngeal nerve is the "lollypop method." Create a lollypop by soaking sterile gauze in lidocaine ointment and taping it to a tongue depressor. Place the lidocaine lollypop into the patient's posterior mouth while setting up for the bronchoscopy. Advance the lollypop 1 cm every 2 minutes until the patient's posterior pharynx is completely anesthetized.

FIGURE 21-5. Anesthetizing the posterior oropharynx with atomized lidocaine solution.

As an alternative, nebulized 4% lidocaine administered at least 20 minutes prior to fiberoptic bronchoscopy will usually provide adequate anesthesia of the supraglottic structures. A second alternative is the "spray as you go" technique.[20] Once the epiglottis is visualized through the fiberoptic bronchoscope, instill 3 to 4 mL of 2% lidocaine through the working channel of the scope and onto the epiglottis and the surface of the vocal cords. This will induce coughing and temporarily obliterate the view of the laryngeal structures. Allow 2 to 3 minutes for the anesthetic solution to exert its effect before proceeding with fiberoptic bronchoscopy.

After anesthesia is accomplished, place a suction catheter into the oropharynx. This will clear the airway of secretions and blood that can impair the visual image. It will also determine the adequacy of the topical anesthesia for preventing coughing and gagging.

TECHNIQUES

Prepare the fiberoptic bronchoscope. Attach the light source. Check the focus of the image by holding the tip of the insertion cord 1 to 2 cm over a printed page. Adjust the eyepiece until the letters on the image are clear. Note how the image appears as you move toward and away from the page. Briefly use the angulation lever to move the tip of the insertion cord and learn its movements. **The most difficult aspect of mastering fiberoptic bronchoscopy is learning to simultaneously angle the tip, rotate the scope, and advance the insertion cord.**[21] It requires repetition and practice to develop these skills before attempting to intubate a patient.

Before placing of the fiberoptic bronchoscope insertion cord into the ET tube, let the insertion cord hang toward the floor to straighten the inner fiberoptic strands. Identify the plane in which the angulation lever moves the tip. When fiberoptic bronchoscopes are stored coiled in a case, over time the insertion cord may develop a curve. Slightly rotate the fiberscope to the right or left until the angulation of the tip is in the midline plane. Look through the eyepiece and note the position of the directional arrow (▼) on the anterior edge of the image that correlates with the midline.

To prevent fogging, apply an antifog solution to the insertion cord tip or place the tip in warm water before inserting the fiberoptic bronchoscope into the patient's nose. Warming the ET tube with warm water just prior to placing it on the insertion cord will soften the tube and may make the later advancement of the ET tube through the mouth or nares easier.

Apply a thin film of silicone spray or a water-soluble lubricant over the insertion cord to facilitate passage of the ET tube over the flexible cord. Insert the flexible insertion cord completely through the ET tube, taking care not to get any of the lubricant on the lens tip. The insertion tip should exit the distal tip of the ET tube. Do not place the tip of the insertion cord through the Murphy eye of the ET tube. Lubricate the ET tube liberally.

Estimate the distance from the patient's mouth to their glottis. Place the tip of the insertion cord by the patient's ear. Mark the point the insertion cord touches the patient's mouth. The distance from the mouth to the ear is approximately the distance from the mouth to the glottic opening. Add 3 cm to this length if performing the procedure through the nose instead of the mouth.

Hold the fiberoptic bronchoscope in your dominant hand with the angulation lever operated by the thumb and the suction port (if used) covered by the index finger. The other end of the scope should be held between the index finger and the thumb of the nondominant hand. Place the nondominant hand at the patient's nose or mouth. There should be no slack in the fiberoptic bronchoscope between the two hands. The removal of slack from the insertion cord makes more precise rotary movements of the tip possible.

NASAL INTUBATION

Nasal fiberoptic intubation has several advantages over the oral route. For those less experienced at fiberoptic bronchoscopy, nasal fiberoptic bronchoscopy is usually easier to perform because less angulation of the tip is required. Once inserted, nasal ET tubes are better tolerated by patients and are associated with a lower incidence of accidental extubation. Disadvantages include a higher incidence of bacteremia, middle ear infection, epistaxis, and alar necrosis.[9] **Nasal intubation, unlike oral intubation, may produce bacteremia; therefore appropriate endocarditis prophylaxis should be provided for those at risk.**

Examine the patient to determine which is the most patent nostril. Insert and navigate the insertion cord's tip along the posterior floor of the nares (**Figure 21-6**). Continue to advance the insertion cord and ET tube as a unit until the ET tube enters the oropharynx (**Figure 21-7**). This will serve to minimize patient discomfort and the risk of epistaxis early in the procedure. Occasionally, loss of view and maneuverability of the insertion cord tip occur in the oropharyngeal area as the tip encounters the pharyngeal mucosa. Pulling the patient's tongue forward with gauze, using the jaw-thrust maneuver, or simply advancing the insertion cord a few centimeters further will usually bring pharyngeal structures back into view. Continue to advance the tip of the insertion cord until the epiglottis is visualized (**Figure 21-7**). Maneuver the insertion cord tip with the lever until the glottis comes into view (**Figure 21-8**). Continue to advance the insertion cord tip through the vocal cords and to a point approximately 3 cm above the carina. Advance the ET tube over the insertion cord and into the trachea to the appropriate depth.

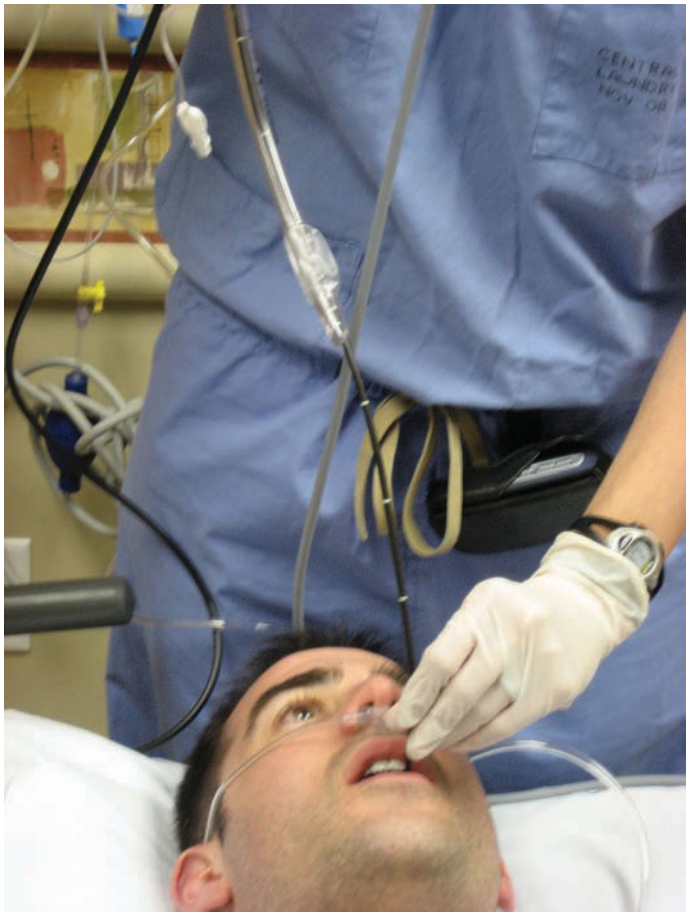

FIGURE 21-6. The technique of placing the fiberoptic bronchoscope insertion cord into the nares. Note the position of the ET tube over the proximal portion of the insertion cord.

The distance from the nares to the epiglottis is usually about 15 to 17 cm. At this position, the epiglottis should be visible. **If the 15 cm mark has been passed, it is very likely that the insertion cord has entered the esophagus.** If that is the case, withdraw it to 12 cm and redirect the tip upward with a slight downward movement of the angulation lever.[21] This will usually bring the glottic opening into view (**Figure 21-8**). Occasionally, the epiglottis will obscure the glottic opening. Position the tip of the insertion cord just above the tip of the epiglottis, then advance it a few millimeters posterior to the epiglottis while angulating the tip of the insertion cord slightly anterior by pressing down on the angulation lever. This will bring the glottic opening into view. Simultaneously rotate, angulate, and advance the insertion cord tip toward and past the vocal cords.

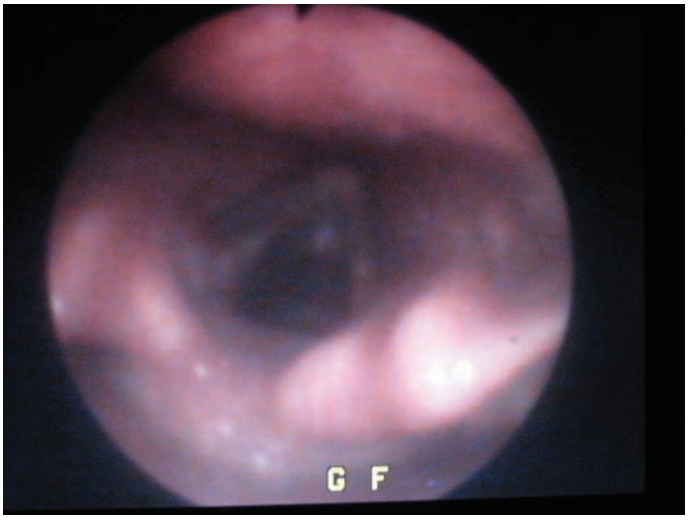

FIGURE 21-8. Visualization of the glottis through the flexible fiberoptic bronchoscope just prior to its insertion cord passing through the vocal cords.

An alternative technique would be to advance the ET tube through the nares until the tip is just past the soft palate. This is usually at a depth of 10 to 12 cm. The insertion cord is then passed through the ET tube and through the vocal cords (**Figure 21-9**). The ET tube is then advanced over the insertion cord into the trachea. This approach has the advantage of bringing the tip of the insertion cord directly midline and toward the epiglottis. However, this can cause some patient discomfort early on in the procedure and may decrease patient cooperation before the insertion cord has entered the trachea.

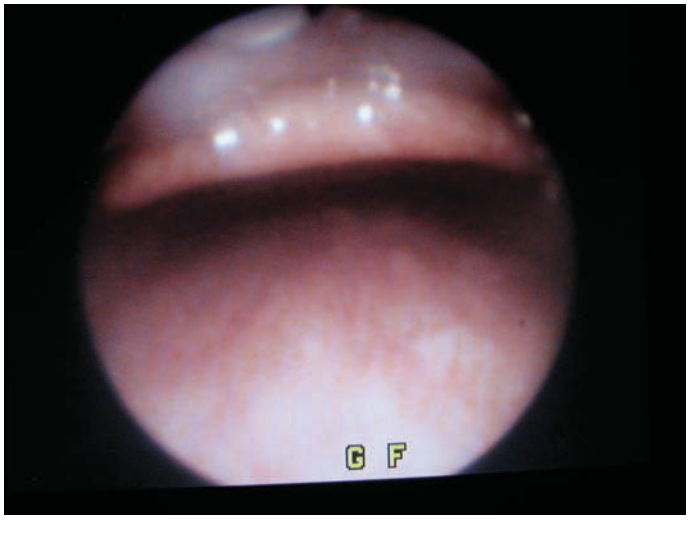

FIGURE 21-7. Visualization of the epiglottis (at the top of the photo) through the flexible fiberoptic bronchoscope.

FIGURE 21-9. The ET tube has been inserted into the nares and advanced into the oropharynx. The insertion cord is advanced through the ET tube.

There is the potential for epistaxis, making visualization of laryngeal structures difficult if not impossible. Despite the application of topical anesthesia to the nasal passages, they are difficult to anesthetize completely. For the awake patient, passage of the ET tube is often the most uncomfortable part of the fiberoptic intubation procedure.

Occasionally, some operators have difficulty passing the insertion cord through the vocal cords. There are several causes for this. The tip of the insertion cord may remain angulated and abut against the wall of the trachea. The vocal cords may not be properly anesthetized and may have closed reflexively. Finally, the insertion cord tip may be abutting the arytenoid cartilages or the pyriform sinus. If inadequate anesthesia is the cause, inject 2 mL of either 2% or 4% lidocaine through the working channel of the insertion cord and wait several minutes for it to take effect. Additionally, having the patient inspire deeply will bring the vocal cords into greater opposition. Once the insertion cord tip has passed the vocal cords, bring the tip into neutral position with a light downward motion of the angulation lever.

Once past the vocal cords, advance the insertion cord tip further to bring the bifurcation of the trachea at the carina into view. The trachea can easily be identified anteriorly by the cartilaginous rings and posteriorly by the smooth mucosa of the posterior wall. Advance the ET tube over the insertion cord and into the trachea. The arytenoids or the interarytenoid soft tissues can impede advancement of the ET tube past the vocal cords and into the trachea. If the ET tube advancement is inhibited, withdraw it slightly, rotate it 90° counterclockwise, and reattempt intubation.[22] If this maneuver fails, rotate the ET tube so that its bevel faces either posteriorly or to the left and laterally. The inability to advance the ET tube occurs with greater frequency when the diameter of the insertion cord is significantly smaller than that of the ET tube or with oral fiberoptic intubation, due to the greater curve that the ET tube must assume for it to enter the trachea.[21] If these maneuvers are unsuccessful, consider substituting a smaller ET tube, a spiral-bound ET tube, or an ET tube with a flexible tip.[23]

Occasionally, when the trachea is not anesthetized, the patient's subsequent coughing and the associated muscular contractions of the trachealis muscle will collapse the trachea almost completely. This makes it difficult to discern if the insertion cord tip is actually in the trachea or whether to advance the insertion cord or ET tube into the trachea. Wait until the trachealis muscle relaxes and then continue with the procedure.

To prevent endobronchial intubation in adults, which can occur with flexion of the head, confirm that the tip of the ET tube is 3 cm above the carina. This is accomplished by advancing the tip of the insertion cord to the carina with the thumb and forefinger of the nondominant hand. Mark the point on the insertion cord where it exits the ET tube. Withdraw the insertion cord until the distance on the insertion cord between the marked point and the tracheal tube connector is 4 cm. While looking through the eyepiece, advance the ET tube until its tip is visible. This places the tip of the ET tube at approximately 3 cm above the carina.

Occasionally, difficulty is encountered while attempting to pass the ET tube through the nares and nasal cavity. This might be caused by a deviated nasal septum, enlarged turbinates, a nasal spur (which can also tear the ET tube cuff), or nasal polyps. Selection of an ET tube that is too large, inadequate lubrication, or failure to presoften the ET tube can be the cause. Reattempt insertion with a well-lubricated, presoftened ET tube that is 0.5 to 1.0 mm smaller. Alternatively, try placing a 5.0 mm inner diameter (ID) ET tube in a 7.0 mm ID ET tube as discussed below.

ORAL INTUBATION

Begin by noting any loose or broken teeth. After ensuring an adequate sensory block by the absence of a gag reflex, insert an oral intubating airway into the patient's mouth. These devices are placed in the patient's mouth like any other oral airway. They allow for the midline passage of the insertion cord and protect the delicate glass fibers within it from the patient's teeth.

Technical problems exist in attempting oral fiberoptic intubation. As stated earlier, oral fiberoptic intubation requires that the insertion cord tip traverse a more acute angle to reach the vocal cords than it would by the nasal route. If one can safely do so, maximally extending the patient's head at the atlantooccipital joint will bring the oropharyngeal and laryngeal axes more closely in line. This maneuver will reduce the angle that the insertion cord tip must traverse.

In performing an oral fiberoptic intubation, the ET tube becomes hung up on the vocal cords more frequently than with the nasal route. A technique believed to significantly improve the first-time pass rate with oral fiberoptic bronchoscopic intubation is to pass a lubricated 5.0 mm ID ET tube through a 7.0 mm ID ET tube that has been cut to 24 cm. This should leave 2 cm of the 5.0 mm ID ET tube protruding from the distal end. It is believed that the close approximation of the diameters of the 5.0 mm ID ET tube and the fiberoptic bronchoscope allows easier passage of the scope. After the 5.0 mm ID/7.0 mm ID ET tube complex is in place, withdraw the 5.0 mm ID ET tube, leaving the 7.0 mm ID ET tube in the trachea.[24]

ALTERNATIVE TECHNIQUES

Alternative techniques that have been shown to be as effective as fiberoptic intubation for intubating patients with unstable cervical spines include the Bullard laryngoscope[25] and the lighted stylet.[26] Blind nasotracheal intubation is as successful as nasal fiberoptic intubation in anesthetized patients with unstable cervical spines.[27] The Glidescope, a video laryngoscope, causes less cervical spine movement than direct laryngoscopy.[28]

A combined technique using oral fiberoptic intubation through a LMA or alternative supraglottic airway can be extremely helpful in instances where there is severe oropharyngeal bleeding or when direct laryngoscopy is not possible.[7,29] After confirming successful placement of the LMA, place a self-sealing bronchoscopy elbow over the proximal end of a 6.0 mm ID ET tube. Advance the ET tube tip through the LMA until the LMA grille is encountered (resistance will be felt). Inflate just enough air into the ET tube cuff to provide a seal for positive-pressure ventilation via the ET tube. Advance the insertion cord through the ET tube and into the trachea under direct visualization. Deflate the ET tube cuff. Advance the ET tube over the insertion cord and into the trachea until the ET tube adapter meets the adapter of the LMA. Inflate the ET tube cuff and confirm ventilation through the ET tube.

Because standard ET tubes are not long enough to allow removal of the LMA, longer ET tubes have been developed. If you do not have access to a specially made ET tube, use a nasal Rae tube, which is 6 cm longer than a standard ET tube. If a longer ET tube is not available, another ET tube can be temporarily lengthened by removing the adapter of the 6.0 mm ID ET tube and placing the tip of a 5.0 mm ID ET tube into the lumen of the 6.0 mm ID ET tube. This maneuver lengthens the ET tube enough that the LMA cuff can be deflated and withdrawn, leaving the 6.0 mm ID ET tube correctly placed in the trachea. Additionally, ventilation can be maintained the entire time simply by using a bag-valve device connected to the 5.0 mm ID ET tube adapter. After removing the LMA, remove the 5.0 mm ID ET tube from the 6.0 mm ID ET tube, replace the adapter, and resume ventilation.[30] After removing the LMA and establishing ventilation, always confirm by fiberoptic bronchoscopy that the ET tube is correctly positioned.

An alternative to the traditional LMA is the intubating LMA or ILMA. The ILMA is a valuable resource in patients with an anticipated difficult airway.[31]

ASSESSMENT

The placement of an ET tube should be followed by an assessment to ensure its proper positioning. Please refer to Chapter 12 for a more complete discussion. This includes visual inspection of chest rise and lack of abdominal movement with ventilation, fogging in the ET tube for at least six breaths, auscultation, and end-tidal CO_2 monitoring. This should be followed by a chest X-ray to confirm proper positing of the ET tube within the trachea.

AFTERCARE

The steps of ensuring proper placement of the ET tube and securing the tube are the same as for any patient who has undergone orotracheal intubation (Chapter 11).

COMPLICATIONS

Many of the complications associated with fiberoptic intubation are the same as those seen with direct laryngoscopy (Chapter 11). The most severe complication is hypoxemia from a prolonged procedure or delays due to an inexperienced bronchoscopist. Use the suction channel on the bronchoscope to provide oxygenation to the patient during the procedure. Epistaxis can be minimal or significant enough to complicate the procedure. Bleeding can be minimized by using the correct ET tube size and pretreatment with a nasal vasoconstrictor and anesthetic. Failure to intubate can be due to narrow nasal or airway passages, blood or vomitus limiting the fiberoptic field of view, or an inexperienced bronchoscopist.

While the insertion cord is passed through the glottis and into the trachea under direct vision, the ET tube is passed blindly over the insertion cord tip. It is thus possible to cause injury to the arytenoids, resulting in permanent hoarseness, particularly if the ET tube bevel faces anteriorly. However, in a recent randomized control trial, there was no difference in the incidence of vocal cord injury for nasotracheal fiberoptic intubation versus orotracheal intubation.[32] The ET tube may also become blocked in the nasal cavity or larynx, resulting in epistaxis, nasal turbinate fracture, and tearing of the ET tube cuff[1,9] Sinusitis and otitis media are known complications from nasal intubation.[9]

SUMMARY

Awake intubation under direct visualization in spontaneously breathing patients by either the oral or nasal route is possible with the fiberoptic bronchoscope. Intubation by means of the fiberoptic bronchoscope is an option to consider when direct laryngoscopy is difficult, or impossible. In some instances, awake fiberoptic intubation may be preferable to other emergency intubation techniques that render the patient unconscious and apneic. Fiberoptic intubation is associated with a high success rate when performed by appropriately trained individuals. Training and practice are required to develop and master the necessary skills.[33] Appropriate patient selection, preparation, and physician patience are essential for a safe and successful fiberoptic intubation.

The benefits of performing regional anesthesia of the oropharynx, larynx, and trachea prior to fiberoptic intubation are a quiet visual field and improved patient acceptance. Oral fiberoptic intubation may be performed in conjunction with an LMA. It should be emphasized that while in most instances fiberoptic intubation is an extremely safe and effective means of securing the airway, one must be prepared to implement an alternate plan for securing the airway and for providing oxygen to the lungs in the case of failure or sudden deterioration of the patient's condition.

22 Nasotracheal Intubation

Ned F. Nasr, Raed Rahman, and Isam F. Nasr

INTRODUCTION

Nasotracheal intubation is a relatively simple procedure that is performed rapidly without the aid or risks of neuromuscular blockade.[1] This method of intubation is sometimes favored in difficult airway cases, especially when oral access is limited or impossible. Such conditions include trismus, oral injuries, and obstructive oral processes such as angioedema. Nasotracheal intubation is also the method of intubation preferred by some authors for acute epiglottitis.[2]

Nasotracheal intubation is well tolerated by most patients and produces less reflex salivation than orotracheal intubation, thus leading to fewer attempts at self-extubation. The nasotracheal tube is more easily stabilized and is generally easier to care for than an orotracheal tube. This method prevents biting of the tube by the patient and manipulation by the patient's tongue.[2,3]

INDICATIONS

Nasotracheal intubation is indicated in any patient with spontaneous respirations, especially those whose period of intubation is anticipated to be brief.[1–3] It is indicated in patients who are unable to lie supine due to respiratory distress from severe asthma, chronic obstructive pulmonary disease (COPD), or congestive heart failure. It is also indicated in patients who are unable to open their mouths due to facial trauma, mandibular trauma, or trismus. Nasotracheal intubation can be performed in patients with limited airway patency due to obstruction from neoplasm or tongue swelling. Nasotracheal intubation is an appropriate method of intubation in patients who require neck immobilization for suspected cervical spine injuries as well as patients who are unable to move their necks due to cervical kyphosis, severe arthritis, or postradiation fibrosis. Because they are often intubated for a short time, patients with severe alcohol intoxication or drug overdose whose level of consciousness is decreased are good candidates for nasotracheal intubation.[1–3] Nasotracheal intubation may be performed in patients who have contraindications to the use of succinylcholine (**Table 11-2**).

CONTRAINDICATIONS

Nasotracheal intubation is contraindicated in patients with apnea, severe facial or maxillofacial fractures, basilar skull fractures, head injury with an elevated intracranial pressure, recent nasal surgery, nasal or nasopharyngeal obstruction (nasal polyps), patients receiving thrombolytics or parenteral anticoagulants, and in the presence of a coagulopathy.[1–3]

Nasotracheal intubation should not be performed in neonates, infants, or very young children. The more anterior and cephalic position of the airway in these age groups makes blind passage of an endotracheal (ET) tube almost impossible. A patient must provide a degree of cooperation during the procedure. A crying, kicking, and struggling child who must be restrained is not a candidate for nasotracheal intubation.

EQUIPMENT

- Nasal mucosa vasoconstrictor (4% cocaine, 0.05% oxymetazoline, or 0.25% phenylephrine)
- Nasal mucosa anesthetic (viscous lidocaine, cocaine, benzocaine spray, or xylocaine spray)
- Nasopharyngeal airways, multiple sizes

- Laryngoscope handle
- Laryngoscope blades, various sizes and types
- ET tubes, various sizes (avg female 7.0–7.5 and avg male 7.5–8.0)
- Endotrol tubes, various sizes (Mallinckrodt Medical, St. Louis, MO)
- Magill forceps
- Suction apparatus
- Topical anesthetic (4% cocaine or 2% lidocaine with epinephrine)
- Gauze strips
- Water-soluble lubricant or anesthetic jelly
- Bag-valve device
- Face mask
- Oxygen source and tubing

PATIENT PREPARATION

Explain the risks, benefits, and potential complications of the procedure to the patient and/or their representative if time permits. All procedural steps should be clearly outlined, with the understanding that an orotracheal intubation may be necessary should the Emergency Physician fail to secure the airway nasotracheally. Since this is a lifesaving procedure, a signed consent may not be necessary, but a procedure note should be included in the medical record.

Prepare the patient with preoxygenation, hemodynamic monitoring, pulse oximetry, and intravenous access. Place the patient supine and in the "sniffing" position if there is no suspicion of a cervical spine injury. If the patient needs to remain sitting due to respiratory distress, also place them in the sniffing position.

Examine the patient's nostrils. Choose the larger and more patent nostril for the intubation. The choice of the nostril to use is not an exact science.[11] Look into each nostril and determine which one is more patent. Estimate the airflow through each nostril. Occlude one nostril and instruct the patient to exhale with their mouth closed. Repeat the process with the other nostril. Ask the patient which nostril they feel is more patent. This test can be repeated after the application of a vasoconstrictor agent. There is no evidence suggesting one nostril is better than the other (i.e., left vs. right) for intubation in a patient with normal anatomy.

Prepare the mucous membranes. Apply a topical vasoconstrictor to shrink the nasal mucosa followed by a topical anesthetic to the nasal mucosa. Cocaine is preferred if not contraindicated, because it is a single agent that acts as both a vasoconstrictor and an anesthetic. Dilate the nasal passage by serial dilation. Liberally lubricate a series of increasingly larger-size nasopharyngeal airways. Insert and then remove the smallest nasopharyngeal airway. Continue to insert and remove each successively larger nasopharyngeal airway until the nasal passage is dilated. This procedure can take 2 to 3 minutes. If time is an issue, insert a gloved and lubricated pinky finger into the nostril to dilate it. For routine nasotracheal intubations of healthy adults, serial dilation of the nasal passages can be bypassed in patients with large nostrils.[6] Next, apply a topical anesthetic spray to the palate and oropharynx.

Choose an ET tube. The proper size tube should be at least 0.5 to 1.0 mm smaller than the size chosen for orotracheal intubation of the same patient. If possible, soften the ET tube by placing it in warm saline or warm water before use to reduce epistaxis and nasal damage.[7] Apply a 10 mL syringe to the inflation port and inflate the cuff. Check the integrity of the cuff. Deflate the cuff and leave the syringe attached. Lubricate the ET tube.

TECHNIQUES

BLIND PLACEMENT OF AN ET TUBE

The technique of blind nasotracheal intubation was first described by Magill in 1930. The technique essentially remains the same with some modifications to increase the success rate and limit complications. This technique is technically more difficult than the placement under direct vision described below. **Its major advantages are that the patient's mouth does not have to be opened and minimal to no cervical spine movement is required.** This procedure may be performed while the patient is sitting or supine. Prepare the patient as mentioned previously.

Stand to the right side of the patient's bed and facing them. Insert the ET tube into the nostril with the bevel facing the septum (**Figures 22-1 and 22-2A**). If the patient's right nostril is being used, insert the ET tube concave side down (**Figure 22-1A**). If the patient's left nostril is being used, insert the ET tube concave side up

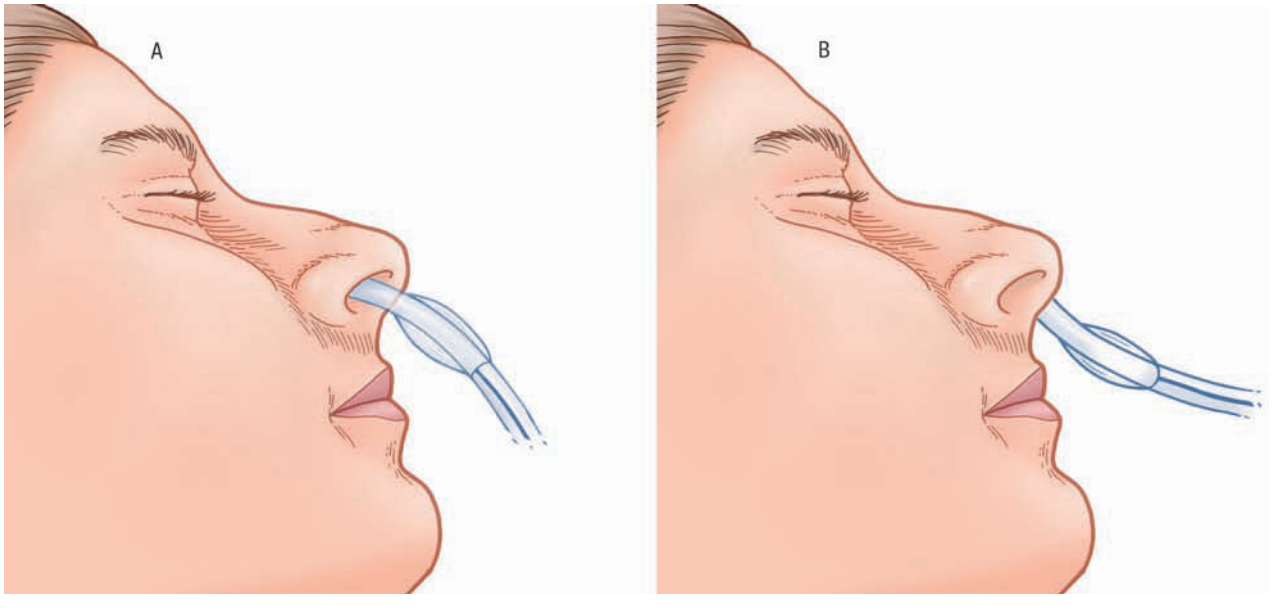

FIGURE 22-1. Insertion of the nasotracheal tube. The bevel of the ET tube should face the septum. **A.** Placement in the right nostril with the concave side of the tube downward. **B.** Placement in the left nostril with the concave side upward. When the tip of the tube enters the nasopharynx, rotate it 180°.

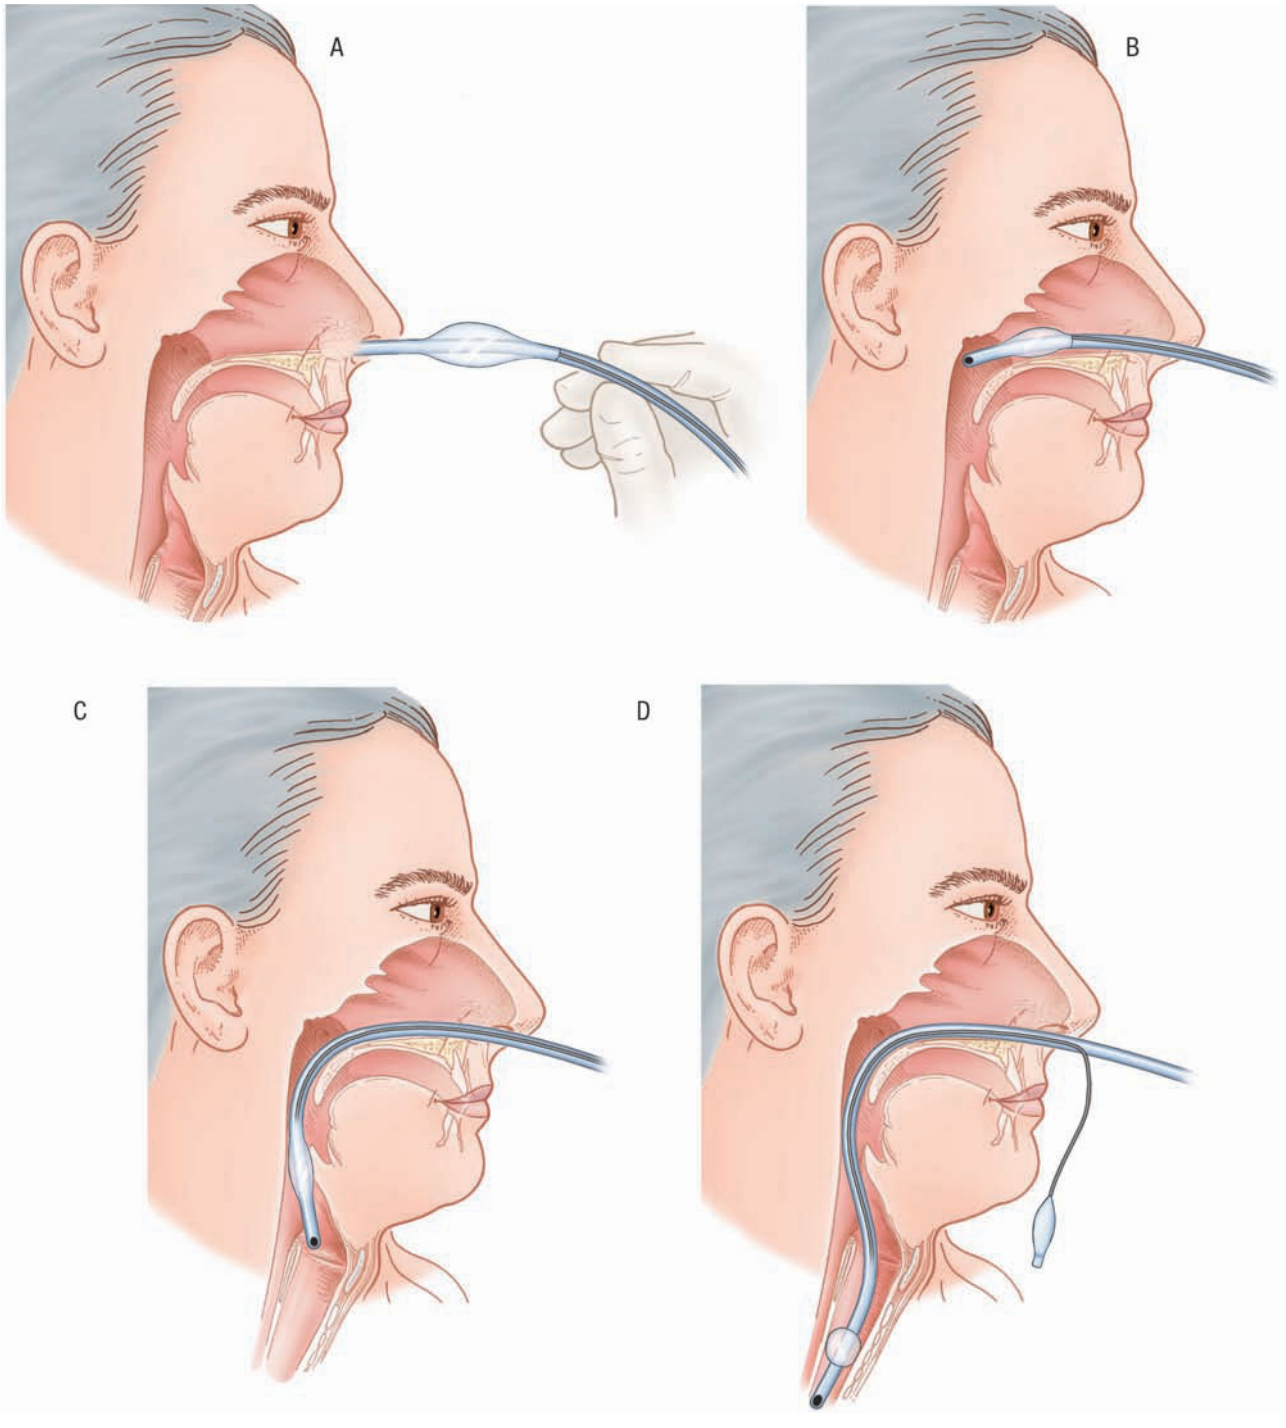

FIGURE 22-2. Blind nasotracheal placement. **A.** The nasotracheal tube is placed within the nasal cavity. **B.** The tube is advanced along the floor of the nasal cavity and into the nasopharynx. **C.** The tube is advanced into the laryngopharynx. **D.** At the start of inspiration, the tube is advanced through the vocal cords and into the trachea.

(**Figure 22-1B**). Advance the ET tube with gentle pressure along the nasal floor to pass it through the nasal cavity (**Figure 22-2B**). If any resistance is felt, slightly withdraw the ET tube. Readvance the tube with a slight twisting motion to bypass the obstruction. If resistance is still met, withdraw the ET tube, prepare the other nostril, and insert the tube into the other nostril.

When the ET tube is inserted approximately 5 to 7 cm, the tip will be past the choana and in the nasopharynx (**Figure 22-2B**). Continue advancing the ET tube as resistance is met while the tube makes a 90° change of direction into the oropharynx. A slight twisting motion may be required to advance the ET tube. A loss of resistance signifies that the ET tube has made the curve. Stop advancing the ET tube and rotate it so that the tube's natural curve is concave upward and in the same curvature of the airway. If the ET tube will not curve from the nasopharynx into the oropharynx, several options are available. These include trying the other nostril, using an ET tube 0.5 mm smaller and reattempting intubation through the original nostril, or using an Endotrol tube (described in the next section).

Advance the ET tube through the oropharynx and into the laryngopharynx (**Figure 22-2C**). Listen for breath sounds through the proximal end of the ET tube while advancing it. The breath sounds

and air movement will be maximal when the tip of the ET tube is just above the glottis. As soon as an exhalation is heard, the patient will take a breath and advance the ET tube. **The vocal cords are opened their widest during inspiration, and this will facilitate passage of the ET tube.**

The patient will often cough or gag as the ET tube traverses the vocal cords. At this point, breath sounds should be audible from the proximal end of the ET tube and it should fog with each breath. If the patient is able to groan or speak, the esophagus has been intubated. Withdraw the ET tube and reinsert it during inspiration. The application of posteriorly applied pressure on the trachea (Sellick's maneuver) will occlude the esophagus and may allow easier ET intubation.

If resistance to the advancement of the ET tube is felt, it may be caught in the hypopharynx. Common sites for the tip of the ET tube to get caught are the arytenoid cartilage, piriform sinus, vallecula, and the vocal cords. Withdraw the ET tube 3 to 4 cm, slightly rotate the ET tube, and readvance it.

Inflate the ET tube cuff. Confirmation of ET tube placement should be assessed by auscultating both lungs while ventilating the patient with a bag-valve device through the nasotracheal tube. Adjust the position of the tube until both lungs are being ventilated equally and secure the tube (**Figure 22-2D**). Continue to ventilate the patient.

BLIND PLACEMENT OF THE ENDOTROL TUBE

The indications, contraindications, and patient preparation are the same as described above. The Endotrol tube is an ET tube whose tip can be controlled. It looks like a cuffed ET tube but has a plastic ligature along the inner side that is connected to a ring on the proximal end of the ET tube (**Figure 22-3**). Pulling of the ring exerts tension on the plastic ligature, leading to an increase in the curvature of the tip of the ET tube. This will project the tip anteriorly and inferiorly (**Figure 22-4**). The procedure for inserting the Endotrol tube is the same as that for inserting an ET tube. Changing the curvature of the tip will aid in passage of the tube from the nasopharynx to the oropharynx and from the hypopharynx into the trachea. If the ring is sitting firmly against the nares after intubation, the tip of the tube may be exerting continuous pressure on the anterior tracheal mucosa. Cut the ligature and remove the ring.

PLACEMENT UNDER DIRECT VISION

The technique begins with nasotracheal intubation, followed by direct laryngoscopy. The placement of a nasotracheal tube using direct visualization must be performed with the patient supine. The indications and precautions are similar to those for orotracheal intubation (Chapter 11). This method should be considered in the event of an oral injury that renders an orotracheal tube a nuisance or if blind nasal intubation is unsuccessful.

FIGURE 22-3. The Endotrol endotracheal tube. The curvature can be changed by pulling on the ring to facilitate intubation.

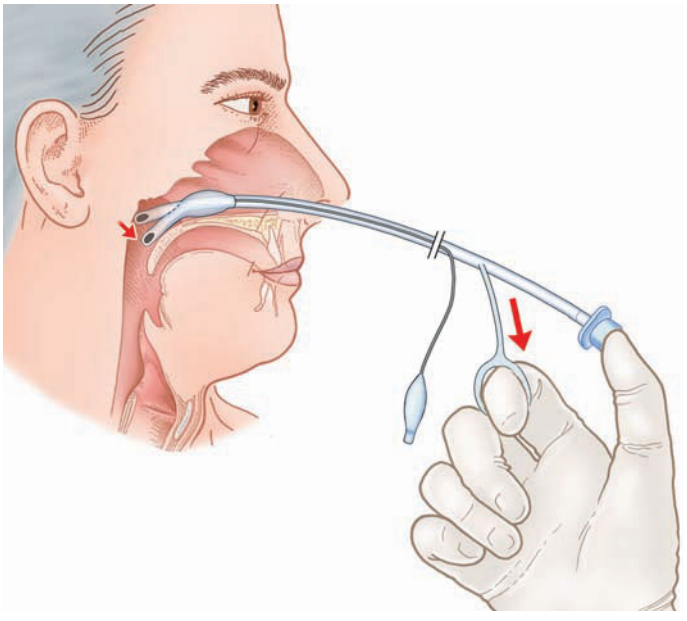

FIGURE 22-4. Blind nasotracheal placement of an Endotrol tube. Tension exerted on the ring of the tube causes the curvature of the tube to increase (*arrow*).

This procedure is initially performed as previously described. Once the tube is inserted into the hypopharynx, direct laryngoscopy is performed. Using the left hand, grasp the laryngoscope and insert the blade. Visualize the patient's epiglottis and vocal cords as well as the ET tube. Using a Magill forceps with the right hand, grasp the ET tube just above the cuff (**Figure 22-5**). **Never grasp the cuff, as it is delicate and can easily be damaged by the Magill forceps.** Have an assistant grasp the proximal end of the ET tube and gently advance it while the physician simultaneously guides the tip through the vocal cords (**Figure 22-5**). Remove the Magill forceps and the laryngoscope. Inflate the cuff, secure the tube, and ventilate the patient.

BLIND DIGITAL NASOTRACHEAL INTUBATION

A technique was developed that combines blind nasotracheal intubation and digital orotracheal intubation.[12] This technique starts with the procedure of blind nasotracheal intubation. If not successful, insert the index and middle fingers of the nondominant hand into the patient's mouth. Slide these fingers posteriorly over the tongue to palpate the epiglottis. Grasp the tip of the ET tube between the two fingers (**Figure 22-6A**). Pull the ET tube anteriorly and behind the epiglottis (**Figure 22-6A**). Use the nondominant hand to advance the ET tube further into the patient's nose, thus advancing the tip into the trachea (**Figure 22-6B**).

ASSESSMENT

The position of the ET tube should be confirmed by end-tidal CO_2 monitoring, fogging in the ET tube for at least six ventilations, loss of voice, auscultation over the chest and the epigastrium, and a chest X-ray. Please refer to Chapter 12 for a more detailed discussion regarding confirmation of endotracheal intubation.

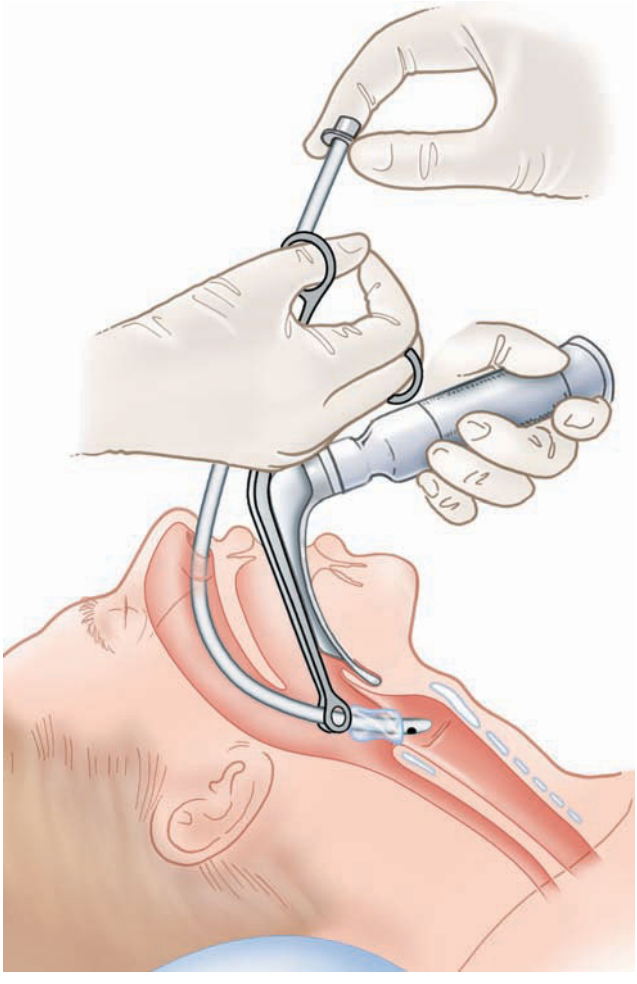

FIGURE 22-5. Nasotracheal intubation under direct visualization.

AFTERCARE

The ongoing care of the patient should proceed as with any other intubation technique.

COMPLICATIONS

The immediate complications of nasotracheal intubation include epistaxis, laryngeal and tracheal trauma, mucosal avulsion, retropharyngeal laceration, turbinate avulsion, intracranial placement, bacteremia, esophageal intubation, and prolonged attempts to place the tube.[4,5] Many of these can be prevented by choosing the appropriate size ET tube, ensuring adequate nasal mucosal vasoconstriction, and applying a liberal amount of lubricant to the ET tube. Risk factors for epistaxis should be assessed on every patient prior to nasotracheal intubation.[8] Long-term complications include maxillary sinusitis, retropharyngeal abscess, mediastinitis, nasal mucosal necrosis, and cellulitis.[4,5]

PEDIATRIC CONSIDERATIONS

Very little literature is available regarding nasotracheal intubation on children. In the past, this approach was an option for patients with epiglottitis and acute laryngotracheobronchitis.[9] The most recent data reserve nasotracheal intubation for children with congenital facial anomalies.[10] This technique cannot be recommended for children in the Emergency Department. Their small nostrils limit ET tube size. Large adenoids may make passage of the ET tube difficult and increases the risk of bleeding.

SUMMARY

Nasotracheal intubation is an alternative to orotracheal intubation to secure an airway in the spontaneously breathing patient. It allows awake intubations while the patient maintains protective airway

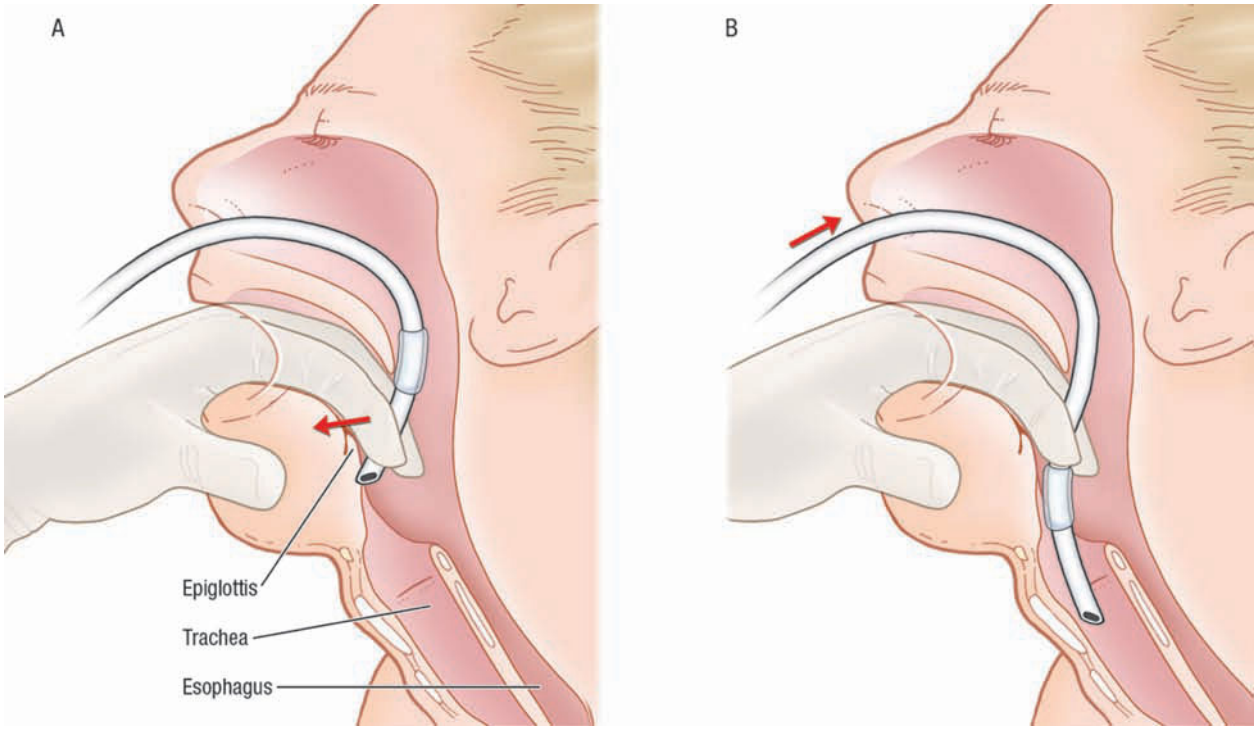

FIGURE 22-6. Blind digital nasotracheal intubation. **A.** The ET tube is grasped with the fingertips and pulled anteriorly (*arrow*) behind the epiglottis. **B.** The ET tube is advanced into the trachea.

reflexes, and it avoids the risks of paralytic agents. It is a fairly simple procedure that should be considered in patients in whom an oral airway is considered difficult and in those with an anticipated short intubation period.

23 Retrograde Guidewire Intubation

Roland Petri

INTRODUCTION

Failure to establish a definitive airway is a significant cause of death and disability among emergency patients. Oral endotracheal intubation via direct laryngoscopy, increasingly often video-assisted, remains the "gold standard" of airway management. Difficult situations arise in which oral endotracheal intubation is impossible, is contraindicated, or fails. Retrograde guidewire intubation is an alternative airway management technique that should be familiar to those involved with emergency airway management.[1]

Retrograde intubation was first described in 1960 by Butler and Cirillo.[2] In 1963, Waters described insertion of an epidural catheter through a cricothyroid puncture as an alternative means of establishing an airway.[3] Powell and Ozdil reported a series of 15 patients in whom retrograde intubation was employed without complications using a plastic catheter rather than an epidural catheter as a guide into the trachea.[4] The current technique of retrograde intubation varies little from these original descriptions.

Retrograde intubation represents one of several alternative maneuvers for securing the difficult airway. While mouth tumors, cervical arthritis, and jaw ankylosis represent rare cases of difficult-to-control airways, maxillofacial trauma continues to represent the most common indication for alternative airway management. Retrograde intubation has proven to be an effective method used by Emergency Physicians and prehospital personnel to establish an airway.

Completion times for retrograde intubation vary based on physician experience. Among healthcare professionals who had no prior experience with the technique but who had just completed a mannequin-aided training course, the mean length of time to intubation was 71 ± 4 seconds.[1] In a second study involving resident physicians after a brief instruction course, 36 of 40 residents (90%) completed retrograde intubation within 150 seconds, with a mean intubation time of 56 ± 6 seconds.[10]

INDICATIONS

The American Society of Anesthesiologists defines a difficult airway as the clinical situation in which a conventionally trained Anesthesiologist experiences difficulty with mask ventilation, difficulty with tracheal intubation, or both.[5] **Retrograde intubation, among other invasive back-up techniques such as cricothyroidotomy, should be considered in any patient in whom endotracheal intubation may be difficult, is contraindicated, or has failed.** It is potentially indicated when airway control is required and less invasive methods have failed. Maxillofacial trauma and cervical spine fractures represent the most common etiologies of a difficult airway.[6] In one report of 19 patients with either maxillofacial trauma or fractures of the cervical spine, six had prior, failed orotracheal intubation attempts. In all of these patients, retrograde intubation was successful on the first attempt.[6] Jaw ankylosis, cervical arthritis, mouth tumors, and muscular dystrophy represent less common but equally challenging airway situations.[4,7]

Another clinically important situation arises when a patient presents with impending ventilatory failure. While retrograde intubation is generally a longer procedure than orotracheal intubation, oxygenation and ventilation can be maintained with a bag-valve-mask device during the procedure. It is useful when bleeding obstructs visualization of the glottis.

A less common indication includes retrograde intubation of a difficult airway in a patient being ventilated with a laryngeal mask airway. This indication exists because withdrawal of the laryngeal mask airway over a blindly placed catheter can result in dislodgement of the catheter, necessitating replacement of the laryngeal mask airway.[8]

CONTRAINDICATIONS

The major contraindication to retrograde intubation is the ability to control the airway with less invasive techniques. Other contraindications include an anterior neck mass, infections, or cancerous process overlying the cricothyroid membrane. Trismus, or the inability to open the mouth, is a contraindication to this technique. Apneic patients who cannot be ventilated with a bag-valve-mask device should receive a cricothyroidotomy and not a retrograde guidewire intubation. Those unfamiliar with the equipment and/or technique should not attempt this procedure. While one case report presents the successful use of a mannequin to teach retrograde intubation to emergency caregivers, familiarity with the procedure is required for optimum patient management.[1]

EQUIPMENT

- 68 to 80 cm spring guidewire with a J tip
- 16 to 18 gauge catheter-over-the-needle (angiocatheter)
- Endotracheal tubes, various sizes
- Sterile saline
- 10 mL syringes
- 18 gauge needles
- Hemostats, 2
- Magill forceps
- Sterile drape
- 20 mL syringe
- Povidone iodine or chlorhexidine solution
- Face mask
- Bag-valve device
- Oxygen source and tubing
- Suction source and tubing
- Yankauer suction catheter
- 1% lidocaine
- 4% viscous lidocaine (optional)
- Spray anesthetic (lidocaine or benzocaine)
- Tape (or a commercially available endotracheal tube holder)

Retrograde guidewire intubation can be performed using a standard commercial retrograde intubation kit (Cook Retrograde Intubation Set, Cook Incorporated, Bloomington, IN). It consists of an 18 gauge needle set, 68 to 80 cm spring guidewire, and an 11 French introducer catheter (**Figure 23-1**). The remainder of the material must be supplied as listed above.

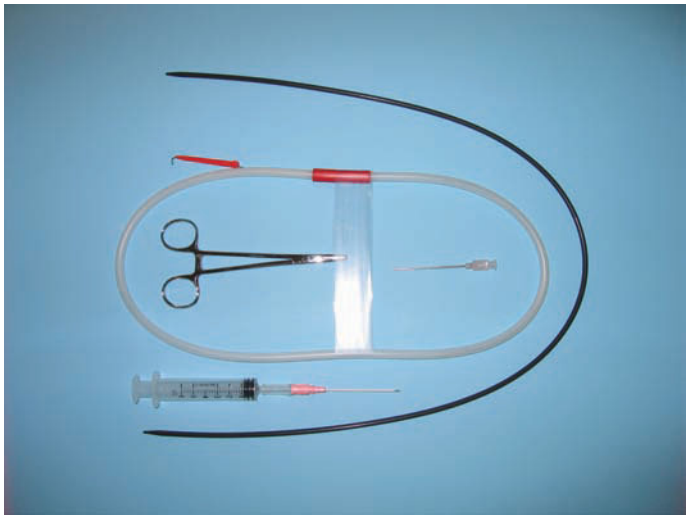

FIGURE 23-1. The retrograde guidewire intubation kit.

PATIENT PREPARATION

If time permits, and the patient is aware of pain, anesthetize the airway. Nebulized viscous lidocaine will anesthetize the airway in 15 to 20 minutes. Alternatively, inject 2 mL of 1% lidocaine percutaneously through the cricothyroid membrane and into the trachea.[6] This may cause the patient to cough and gag, with the subsequent possibility of aspiration. Lidocaine or benzocaine may be sprayed into the pharynx. An alternative anesthetic method includes a superior laryngeal nerve block.[9] Refer to Chapter 21 for details regarding this nerve block.

Clean the patient's neck of any dirt and debris. Identify, by palpation, the hyoid bone, thyroid cartilage, cricoid cartilage, and cricothyroid membrane. Apply povidone iodine to the patient's neck, followed by sterile drapes.

TECHNIQUE

The procedure is relatively simple in theory but difficult to perform "in the heat of battle."[1,10–13] Prepare the equipment. Place the 16 to 18 gauge catheter-over-the-needle onto a 10 mL syringe containing 3 to 5 mL of sterile saline. Select an appropriate size endotracheal tube for the patient. Check the integrity of the cuff. Lubricate the inside and outside of the distal tip of the endotracheal tube liberally. Open the retrograde guidewire kit and/or assemble all equipment. The equipment should be preassembled, prepackaged, sterilized, and stored in an easily accessible site.

Stabilize the patient's larynx with the thumb and middle finger of the nondominant hand (**Figure 25-2**). Identify the cricothyroid membrane with the index finger of the nondominant hand. Leave the index finger on the cricothyroid membrane. Infiltrate lidocaine subcutaneously over the cricothyroid membrane if the patient is awake to minimize discomfort from the percutaneous catheter insertion. Insert the 16 to 18 gauge catheter-over-the-needle guided along the index finger, at a 20° to 30° angle upward and through the cricothyroid membrane (**Figure 23-2A**). Although not recommended, some physicians prefer to use the needle without the catheter. The sharp needle within the trachea can cause significant injury when compared to the soft catheter. **Care should be taken to puncture the cricothyroid membrane just above the cricoid cartilage to avoid injury to the cricothyroid arteries.** The loss of resistance signifies that the needle is in the larynx. **Aspirate air through the saline-filled syringe to confirm correct needle placement** (**Figure 23-2A**). Advance the catheter until the hub is against the skin. Remove the needle and syringe, leaving the catheter pointed upward and through the cricothyroid membrane. If this has not already been done and the patient is awake, inject 2 mL of 1% lidocaine through the catheter to anesthetize the airway.

Advance the guidewire through the catheter and into the oropharynx (**Figures 23-2B & 23-3**). The guidewire may exit the mouth or nose. The preferred site of exit is the mouth, but the nose is acceptable. If it is not visualized, insert a laryngoscope and look for the guidewire. It is often in the oropharynx or hypopharynx. Retrieve it with a Magill forceps. Continue to advance the guidewire through the mouth (or nose) until only 4 to 5 cm of the wire is protruding from the patient's neck. **Carefully remove the catheter while firmly holding the guidewire in place.** Place a hemostat on the guidewire where it enters the skin of the neck (**Figure 23-2C**). This will ensure that the tip does not pull through the skin and into the trachea.

If the kit is being used, select the introducer catheter contained in it. Pass the introducer catheter over the guidewire that is exiting the mouth (or nose). Advance the catheter until resistance is met. This signifies that the tip of the introducer catheter is at the inside of the cricothyroid membrane (**Figure 23-2C**). Advance the well-lubricated endotracheal tube over the introducer and guidewire (**Figure 23-2D**). Continue to advance the endotracheal tube until resistance is met. The tip of the endotracheal tube should be at the inside of the cricothyroid membrane (**Figure 23-2D**). While securely holding the endotracheal tube at the patient's mouth, remove the hemostat from the guidewire. Pull on the proximal end of the guidewire until the distal tip is through the skin and just into the endotracheal tube. **Simultaneously withdraw the guidewire and introducer catheter while advancing the endotracheal tube into the trachea** (**Figure 23-2E**). Inflate the endotracheal tube cuff and confirm proper placement (i.e., auscultation, detection of end-tidal CO_2, fogging in the endotracheal tube, etc.).

A second method can also be used to insert the endotracheal tube. This follows the same technique described above to the point of the guidewire exiting the mouth (or nose), being secured with a hemostat at the neck, and passing the introducer catheter over the guidewire. Remove the hemostat from the guidewire. **While securely holding the introducer catheter at the patient's mouth (or nose), remove the guidewire through the mouth (or nose).** Advance the introducer catheter an additional 2 to 3 cm into the trachea. Lubricate the endotracheal tube liberally. Place the endotracheal tube over the introducer catheter. While holding the introducer catheter securely, advance the endotracheal tube into the patient's trachea. Remove the introducer catheter. Inflate the endotracheal tube cuff and confirm proper placement (i.e., auscultation, detection of end-tidal CO_2, fogging in the endotracheal tube, etc.).

ALTERNATIVE TECHNIQUES

This technique may be performed without a formal retrograde intubation kit as the introducer catheter is not required.[7,12,13] This follows the same technique described above to the point of the guidewire exiting the mouth (or nose) and being secured with a hemostat at the neck (**Figure 23-2C**). Lubricate the endotracheal tube liberally. Insert the guidewire through the Murphy eye and into the endotracheal tube. This allows the distal tip of the endotracheal tube to project approximately 1 cm distal to the site at which the guidewire enters the larynx. As an alternative, some physicians prefer to load the guidewire through the tip of the endotracheal tube (**Figure 23-4**). **Always hold the proximal end of the guidewire to maintain control during the procedure.** Advance the endotracheal

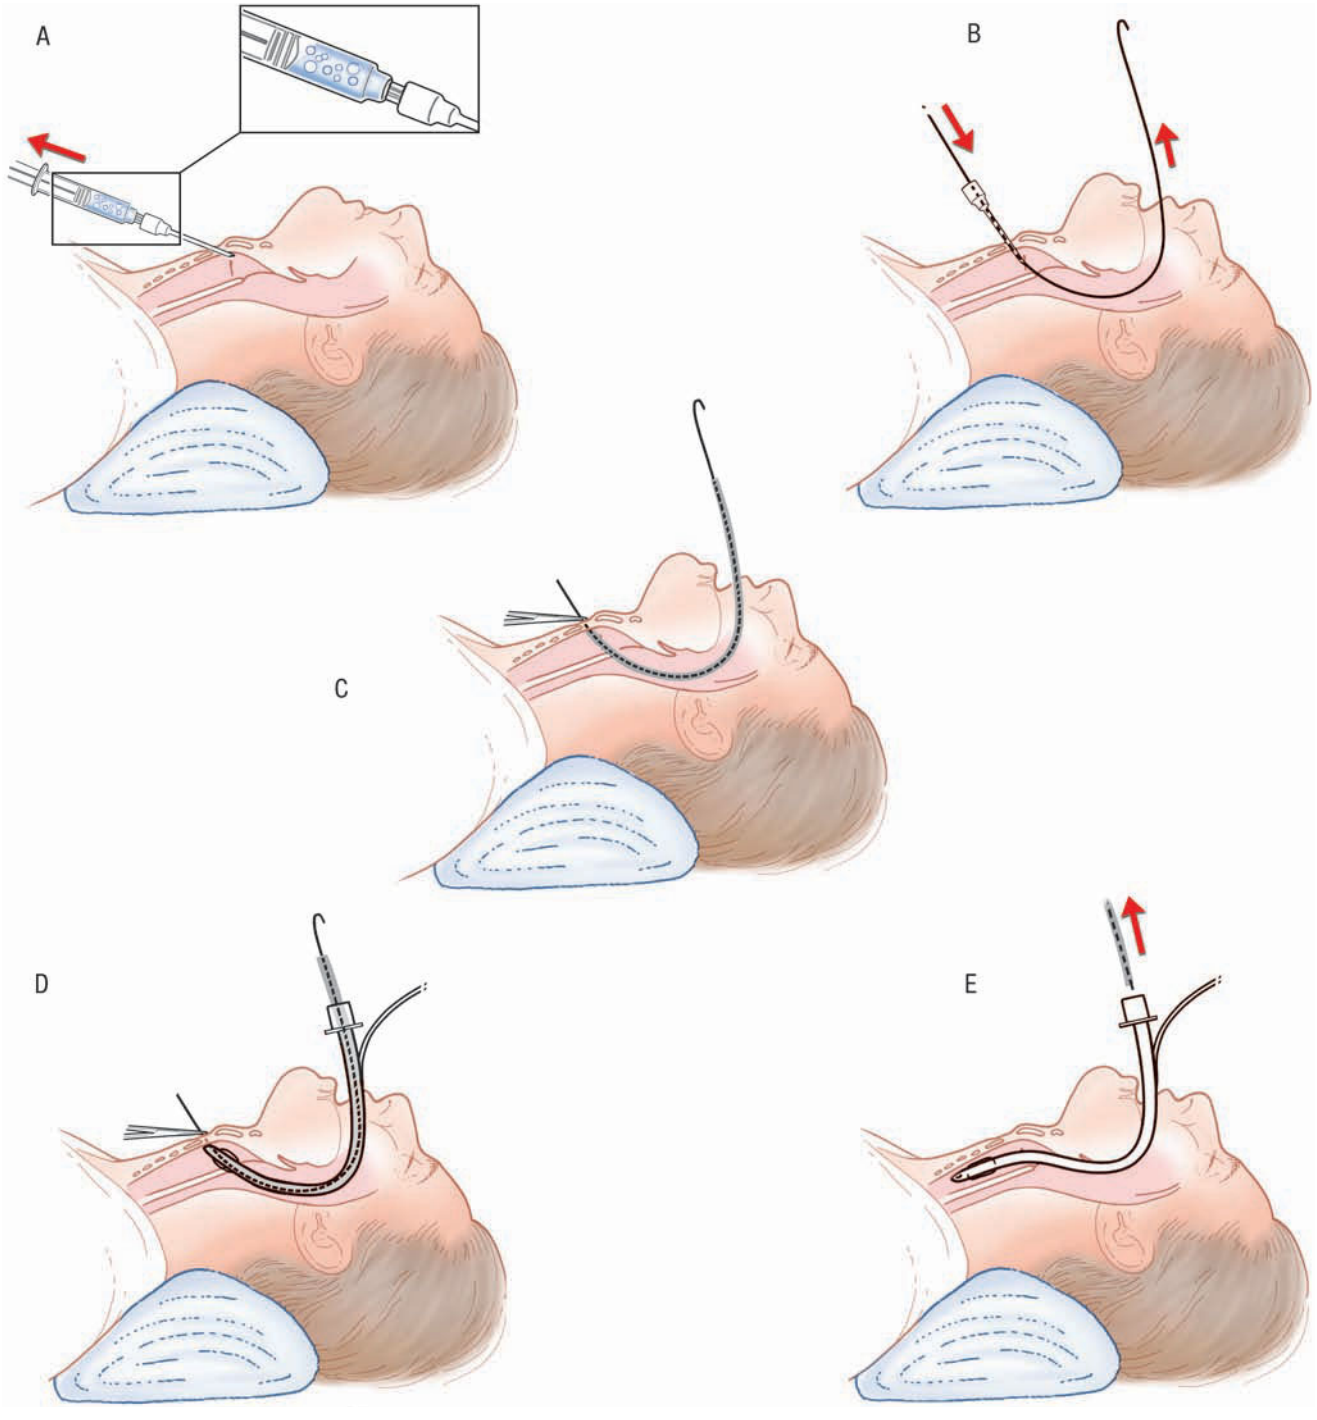

FIGURE 23-2. Retrograde guidewire intubation. **A.** A syringe containing saline is attached to the catheter-over-the-needle. The catheter-over-the-needle is inserted through the cricothyroid membrane. The air bubbles in the syringe indicate air aspirated from the trachea. For clarity, the physician's hand and fingers stabilizing the airway and identifying the cricothyroid membrane are not seen in this illustration. **B.** The needle and syringe have been removed and the catheter remains. The guidewire is fed through the catheter and out the patient's mouth. **C.** The distal guidewire is clamped with a hemostat as it exits the skin of the neck. The introducer catheter is fed over the guidewire and advanced to the cricothyroid membrane. **D.** An endotracheal tube is advanced over the guidewire and introducer catheter until its tip is at the cricothyroid membrane. **E.** The hemostat has been removed. The endotracheal tube is advanced as the guidewire and introducer catheter is removed.

tube over the guidewire until resistance is felt. The tip of the endotracheal tube should be at the inside of the cricothyroid membrane. **Hold the proximal end of the guidewire firmly.** Release the hemostat over the neck. Pull the guidewire through the skin and just into the endotracheal tube. Advance the endotracheal tube until it is at 20 to 21 cm at the teeth for an adult female or 22 to 23 cm at the teeth for an adult male. Hold the endotracheal tube securely at the patient's lips. Withdraw the guidewire through the patient's mouth. Inflate the endotracheal tube cuff and confirm proper placement (i.e., auscultation, detection of end-tidal CO_2, fogging in the endotracheal tube, etc.).

When the endotracheal tube is advanced over the guidewire until resistance is met, the tip should be situated against the inside of the cricothyroid membrane. It is imperative to determine if the tip of

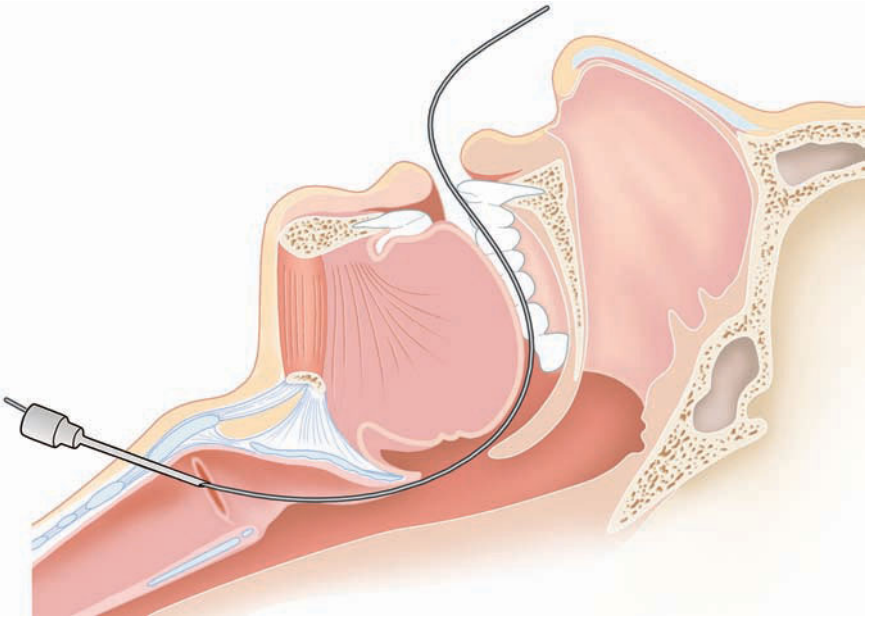

FIGURE 23-3. The guidewire is inserted through the needle (or catheter depending on physician preference) until it exits the mouth.

the tube is in the trachea or caught on the epiglottis, arytenoid cartilage, pyriform recess, vallecula, or vocal cords. If concern exists as to the position of the tip, withdraw the endotracheal tube 2 cm, rotate it 90°, and readvance it into the trachea. As an alternative, a laryngoscope or fiberoptic broncho/nasopharyngoscope can be inserted to help visualize the placement of the endotracheal tube.

Another variation involves the use of the guidewire sheath as an introducer catheter.[12,13] Shorten the sheath by 3 to 5 cm using sterile scissors. The remainder of the technique is the same as described above. The only drawback to this technique is that the curvature of the sheath must be straightened before use to allow easy threading over the guidewire.

In another description, a central venous catheter is used rather than a guidewire.[6] It allows the physician to inject air through the catheter in retrograde fashion to help locate the catheter in the mouth of the severely injured patient with significant intraoral blood or secretions. This technique requires a relatively long central venous catheter. It does allow retrograde intubation without the use of a formal retrograde intubation kit.

Finally, another version uses a lighted stylet attached to the endotracheal tube.[14] The lighted stylet acts as a guide to indicate the tube's location. When the tip of the endotracheal tube enters the glottic opening, a bright, circumscribed glow is readily seen in the anterior neck, below the thyroid prominence. This glow acts as an indicator of correct endotracheal tube placement.

When continuous oxygenation is required throughout the procedure, two possibilities exist.[12] A T-adapter (1260, Deseret, Sandy, UT) can be connected to the needle hub with its side arm for oxygen insufflation. Alternatively, a swivel adapter with a fiberoptic bronchoscopic cap (1/25/09, Portex, Wilmington, MA) can be

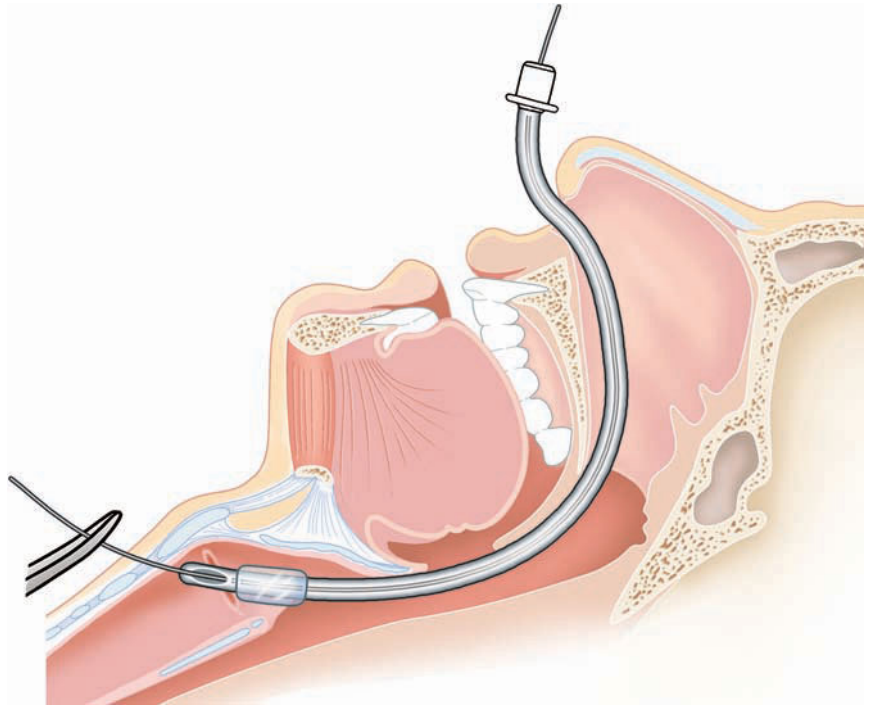

FIGURE 23-4. The endotracheal tube is advanced over the guidewire until the tip is against the cricothyroid membrane.

interposed between the endotracheal tube and the bag-valve-mask device or anesthesia breathing circuit.

ASSESSMENT

Auscultation of both lungs will confirm proper placement of the endotracheal tube and minimize the risk of intubation into the right mainstem bronchus. End-tidal CO_2 has also become part of the postintubation routine. After the procedure is completed, a chest radiograph will confirm the placement of the endotracheal tube tip in relation to the clavicles and carina. Please refer to Chapter 12 for a more complete discussion of the methods to confirm endotracheal intubation.

AFTERCARE

The patient should receive standard wound care and dressing of the skin at the neck entrance site. Wound checks and infection monitoring should continue as with any other surgical procedure. The risk of skin, tracheal, or pharyngeal infection is minimal if sterile technique was followed. If infection develops, wound evaluation and treatment with appropriate antibiotics is warranted.

COMPLICATIONS

Complications of retrograde guidewire intubation include those of standard endotracheal intubation. Complications can occur when the needle traverses the cricothyroid membrane.[10] Hypoxia due to prolonged intubation time or incorrect endotracheal tube placement remains an important complication. Drug reactions or side effects secondary to administered medications must always be considered.

Retrograde intubation is associated with additional complications due to use of the guidewire. One case report discusses a patient with a history of retrograde intubation for coronary bypass surgery who experienced a foreign-body sensation and bloody sputum 2 years after the procedure.[15] Upon radiographic examination, the patient was found to have a 10 cm segment of guidewire fixed in the soft tissue of the puncture site and extending cephalad 2 cm past the true vocal cords.

In one cadaveric study, numerous complications were noted during 40 cricothyroid punctures. Two punctures (5%) occurred below the cricothyroid membrane. One was between the cricoid cartilage and the first tracheal ring. The other was between the first and second tracheal rings. Four cases (10%) showed minor injuries to the thyroid or cricoid cartilage. Three cases (7.5%) showed injuries to the posterior wall of the larynx, epiglottis, or soft palate. No posterior tracheal perforations were found in this study. The clinical importance of these injuries is unclear given the nature of this postmortem study.

Three technical complications from retrograde guidewire intubation have been identified.[10,12] Difficulties inserting the guidewire can be prevented by first aspirating air into a saline-filled syringe to confirm the proper intratracheal needle tip position. Endotracheal intubation over a flexible guidewire necessitates keeping the guidewire taut to minimize the risk of kinking. Unfortunately, this moves the guidewire anteriorly toward the narrowest portion of the glottis and may prevent passage of the endotracheal tube, as the tip can become caught on the epiglottis or the vocal cords. This problem is obviated by the use of the introducer catheter in the retrograde guidewire intubation kit. It lies in the posterior pharynx and glottis and allows for easier passage of the endotracheal tube into the trachea. The tip of the endotracheal tube may flip out of the larynx when the introducer is being removed, because the distance between the vocal cords and the point where the introducer enters and anchors the larynx averages only 1.0 to 1.3 cm in adults.

While complications may occur in association with retrograde intubation, the rate of complications is relatively low. In one study, 20 resident physicians performed retrograde intubation twice each on 40 cadavers.[10] In two cases (5%), the wire was fed caudad into the trachea due to improper angling of the needle. The remaining intubations were performed without complications.

SUMMARY

Retrograde guidewire intubation requires little operator experience or equipment. Multiple reports suggest that this technique is safe, relatively easy to learn, and routinely successful. All physicians involved in the airway management of critically ill and injured patients should be aware of this technique as a potential method to overcome the challenge of a difficult airway. Within the armamentarium of management techniques for the difficult airway, retrograde guidewire intubation should be given due consideration in any situation in which orotracheal intubation is impossible or contraindicated.

Numerous difficult airway management devices and adjuncts have been invented and marketed. Arguably, the various video-assisted laryngoscopy devices have come to dominate the realm of alternative airway management techniques. The role of retrograde guidewire intubation as a difficult airway management approach has further diminished as a consequence. However, retrograde guidewire intubation remains an easy-to-learn and potentially life-saving tool in the Emergency Physician's growing airway management armamentarium.

24 Percutaneous Transtracheal Jet Ventilation

Eric F. Reichman and Aaron Brown

INTRODUCTION

Percutaneous transtracheal jet ventilation (PTTJV) provides emergency ventilatory support in patients who cannot be adequately ventilated with a bag-valve-mask device (with oral or nasal airways), a laryngeal mask airway (LMA), or endotracheally intubated.[1,2,10] This includes patients with upper airway foreign bodies or neoplasms, maxillofacial trauma, laryngeal edema, or infection.[2,3] It is also used electively with general anesthesia for surgery involving the larynx and subglottic areas.[4] PTTJV involves placement of a percutaneous catheter into the trachea and ventilation via a cyclic delivery of tidal volume to the lungs.[5]

ANATOMY AND PATHOPHYSIOLOGY

Early studies of transtracheal ventilation used transtracheal catheters connected to 4 to 5 L/min of oxygen.[6] Oxygenation with this apparatus was adequate, but patients quickly developed hypercarbia due to lack of ventilation.[5] This "apneic oxygenation" also occurs in ventilation through a catheter attached to a bag-valve device.[7] The low pressure and flow of oxygen generated by the bag-valve device result in increases in $PaCO_2$ of 4 mmHg/min and the rapid development of respiratory acidosis.[1,8] Numerous studies have since demonstrated that intermittent jets of pressurized 100% oxygen at 50 pounds per square inch (psi) allows for both oxygenation and adequate ventilation.[8,9]

The anterior neck provides direct access to the airway via the trachea as it extends from the larynx into the lungs (**Figure 24-1**). At

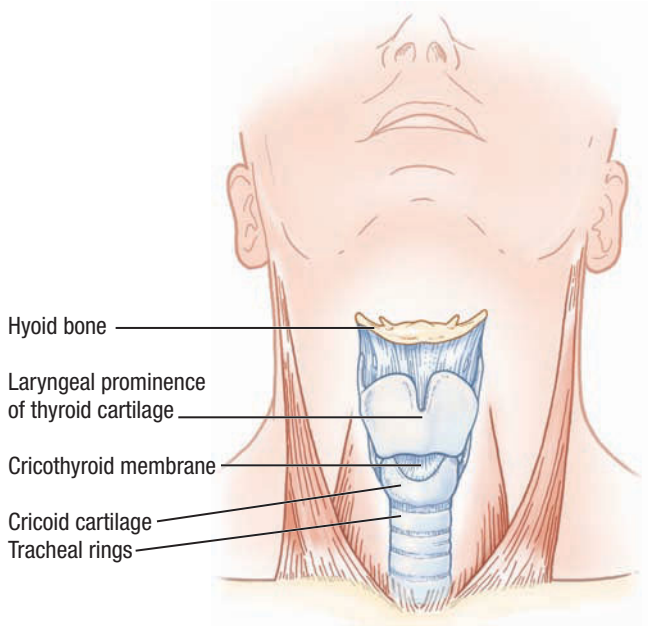

FIGURE 24-1. Airway structures of the neck.

the top of the laryngeal skeleton is the thyroid cartilage, which lies at the level of the fourth and fifth cervical vertebrae. The laryngeal prominence of the thyroid cartilage (more prominent in men) is easily palpated with the thumb and index finger. The cricoid cartilage lies just inferior to the thyroid cartilage at the level of the sixth cervical vertebra. It serves as the junction of the larynx and trachea. Multiple cartilaginous rings support the trachea. Between the cricoid and thyroid cartilages lies the cricothyroid membrane. **The cricothyroid membrane is a palpable membranous depression just inferior to the laryngeal prominence and is the access site for PTTJV.**[11] The cricothyroid artery is a branch of the superior thyroid artery. It travels transversely across the cricothyroid membrane just below the thyroid cartilage. Placement of the catheter through the lower half of the cricothyroid membrane will prevent injury to this small artery.[22]

Once the catheter is placed and appropriately connected to an oxygen source, oxygen is delivered via bulk flow through the cannula into the trachea and lungs. Entrainment of room air translaryngeally via the Venturi principle is negligible, even with minimal upper airway obstruction.[1] Therefore, near 100% O_2 is delivered with each insufflation.

Inhalation occurs through the catheter via a pressurized flow of oxygen. Exhalation occurs passively through the elastic recoil of the lungs and chest wall.[10] The minute ventilation delivered during PTTJV is proportional to the volume of air injected, the driving air pressure, and the degree of upper airway obstruction.[2,12] Animal studies demonstrate that PTTJV delivers more tidal volume than positive-pressure mask ventilation with the same tracheal and transpulmonary pressures despite delivery of oxygen from a pressurized source.[2]

INDICATIONS

PTTJV is indicated as a backup emergent airway in any patient who cannot be endotracheally intubated or ventilated with a bag-valve-mask device despite the use of a jaw-thrust maneuver, oropharyngeal airway, or nasopharyngeal airway or LMA.[1,2,5] It serves as a simple, relatively safe, and effective alternative to cricothyroidotomy.[1,6] This is especially true in pediatric patients below 5 years of age, in whom a cricothyroidotomy is contraindicated. PTTJV is the procedure of choice in the pediatric age group for establishing an emergent airway when endotracheal intubation fails.[7] PTTJV can serve as a quick alternative to a difficult intubation. It is especially valuable in cases of maxillofacial trauma, suspected cervical spine injury, or when nasal intubation is contraindicated or unsuccessful.[5,6,13] PTTJV is also used routinely by Anesthesiologists in the operating room. Electively, transtracheal catheters are placed in patients undergoing surgery of the upper airway, including the larynx and subglottic structures.[7]

This procedure is also indicated in cases of partial upper airway obstruction due to foreign bodies, laryngeal edema, neoplasm, or infection.[2,3] In cases of upper airway foreign bodies, PTTJV not only serves as an emergent airway but can also assist in dislodging the foreign body.[6,7] Animal studies have demonstrated that the expulsion of foreign bodies from the hypopharynx and upper trachea is possible with high-frequency jet ventilation, in effect similar to the Heimlich maneuver.[13] Approximately 30% of the air flow from transtracheal jet ventilation is directed cephalad and can therefore assist in the expulsion of airway foreign bodies.[14]

PTTJV has a large number of advantages when compared to an emergent cricothyroidotomy.[1–21] It is easier and faster to perform. The technique is simpler to learn. The need for a large number of instruments, surgical preparation and technique, and an assistant is eliminated. The complications of bleeding, glottic stenosis, subglottic stenosis, and tracheal erosion are significantly lessened. If the patient survives, PTTJV causes less cosmetic disfigurement. Finally, PTTJV can direct secretions and foreign bodies out of the proximal trachea.

CONTRAINDICATIONS

PTTJV is contraindicated in patients who can be orally or nasally intubated. Anterior neck trauma may be a contraindication to PTTJV. Damage to the larynx or cricoid cartilage is a contraindication to PTTJV. If laryngeal trauma is suspected, catheter placement may result in laryngeal disruption.[5,12] It should not be performed in patients with partial or complete transection of the trachea. Lower tracheal or proximal bronchial tree disruption can result in an increased risk of pneumothorax and pneumomediastinum with high-pressure ventilation.[5,7,12]

Complete airway obstruction is also an absolute contraindication to PTTJV.[5,8,12] Exhalation requires passive recoil of the lungs and chest wall, and a patent airway for outflow of gas. A patient with a complete upper airway obstruction is at an increased risk for barotrauma (i.e., pneumothorax and pneumomediastinum). Numerous studies have been performed to evaluate PTTJV with varying degrees of upper airway obstruction. Ward *et al.* found that progressively increasing airway obstruction up to 80% did not cause barotrauma.[20] **With upper airway obstruction, less air is allowed to escape and more volume is forced into the lungs.** Therefore, tidal volume increases with increasing airway obstruction. Once a patient develops complete upper airway obstruction, auto-PEEP (end-expiratory alveolar pressure above the set level of positive end-expiratory pressure) will develop as air is trapped within the thoracic cavity with no outlet and insufflation of air under pressure continues. This will ultimately result in barotrauma and decreased mean arterial pressure.[19]

EQUIPMENT

- Pressurized oxygen source, wall source or tank at 50 psi
- Povidone iodine solution or Chlorhexidine prep
- Commercially available PTTJV kit or a self-assembled kit from available components
- 12 to 16 gauge, 2 to 3 in catheter-over-the-needle (angiocatheter)

FIGURE 24-2. The manual jet ventilation system (Instrumentation Industries, Bethel Park, PA).

FIGURE 24-4. The Norgren jet ventilation system (Norgren Inc., Littleton, CO).

- Noncompressible high-pressure oxygen tubing
- Valve device (manual push valve, Y connector, T piece)
- 10 mL syringe
- Sterile saline
- Sterile drapes
- Local anesthetic solution (1% lidocaine)
- 3-0 nylon suture
- Needle driver
- Bag-valve device
- 3 mL syringe
- Adult endotracheal tube connector

A PTTJV system can be purchased from a commercial company. It may also be assembled with individual parts.[1] Examples of PTTJV systems are shown in **Figures 24-2, 24-3, & 24-4**. The components of a PTTJV system are quite simple (**Figure 24-5**). The oxygen source may be a wall supply or tank. It should have a pressure regulator that can provide 100% O_2 at 50 psi through noncompressible and high-pressure tubing. Along the tubing there must be a valve (Y connector or manual push valve) to allow intermittent flow of oxygen.[5] The flow into the trachea is regulated by manual control of this valve. Ventilations should be delivered at a rate of 12 to 20 breaths per minute. Oxygen flow rates will vary with catheter size. Flow rates for 20, 16, and 14 gauge catheters at 50 psi are 400, 500, and 1600 mL/s, respectively.[9] The inspiratory time is brief compared to the expiratory time by a ratio of 1:2 to 1:9 seconds.[2,10,15]

FIGURE 24-3. The Manujet jet ventilation system (VBM Medizintechnik, W. Germany).

If a high-pressure system is unavailable, the patient may still be temporarily oxygenated through a transtracheally placed catheter.[23] Attach a 3 mL syringe without the plunger to the catheter. Insert a standard endotracheal tube connector, from a size 5 to 9 mm i.d. endotracheal tube, into the barrel of the syringe. Connect the bag-valve device to the connector and begin ventilation while preparing for more definitive airway control.[6,7,24,25]

The commercially available PTTJV kits are designed to provide 100% oxygen at 50 psi which has been shown to provide both adequate oxygenation and ventilation.[8,9] Several recent studies have compared the effectiveness of a self-made apparatus with the commercial kits. They have shown that flow rates of >15 L/min (regulator wide open) are needed to produce equivalent flow rates.[26] Using flow rates less than 15 L/min will result in failure of ventilation within 60 seconds. Therefore, if a high pressure system is unavailable and a more definitive airway cannot be obtained, a surgical cricothyroidotomy should be performed.[27]

PATIENT PREPARATION

The establishment of PTTJV requires not only proper insertion of the transtracheal catheter, but also a proper setup of the ventilatory equipment. The required equipment should be prepackaged and placed where it is readily accessible. Ensure that the fittings are secure and the tubing is not damaged. Place the patient supine and in the "sniffing" position if no contraindications exist. The patient is most likely already in the proper position, as this technique is most often performed on apneic patients in whom other intubation techniques have failed. Place a rolled towel behind the middle of the neck to hyperextend the neck and allow for better access. Identify by palpation the hyoid bone, thyroid cartilage, cricoid cartilage, and cricothyroid membrane. Clean the anterior neck of any dirt and debris. Apply povidone iodine solution or chlorhexidine

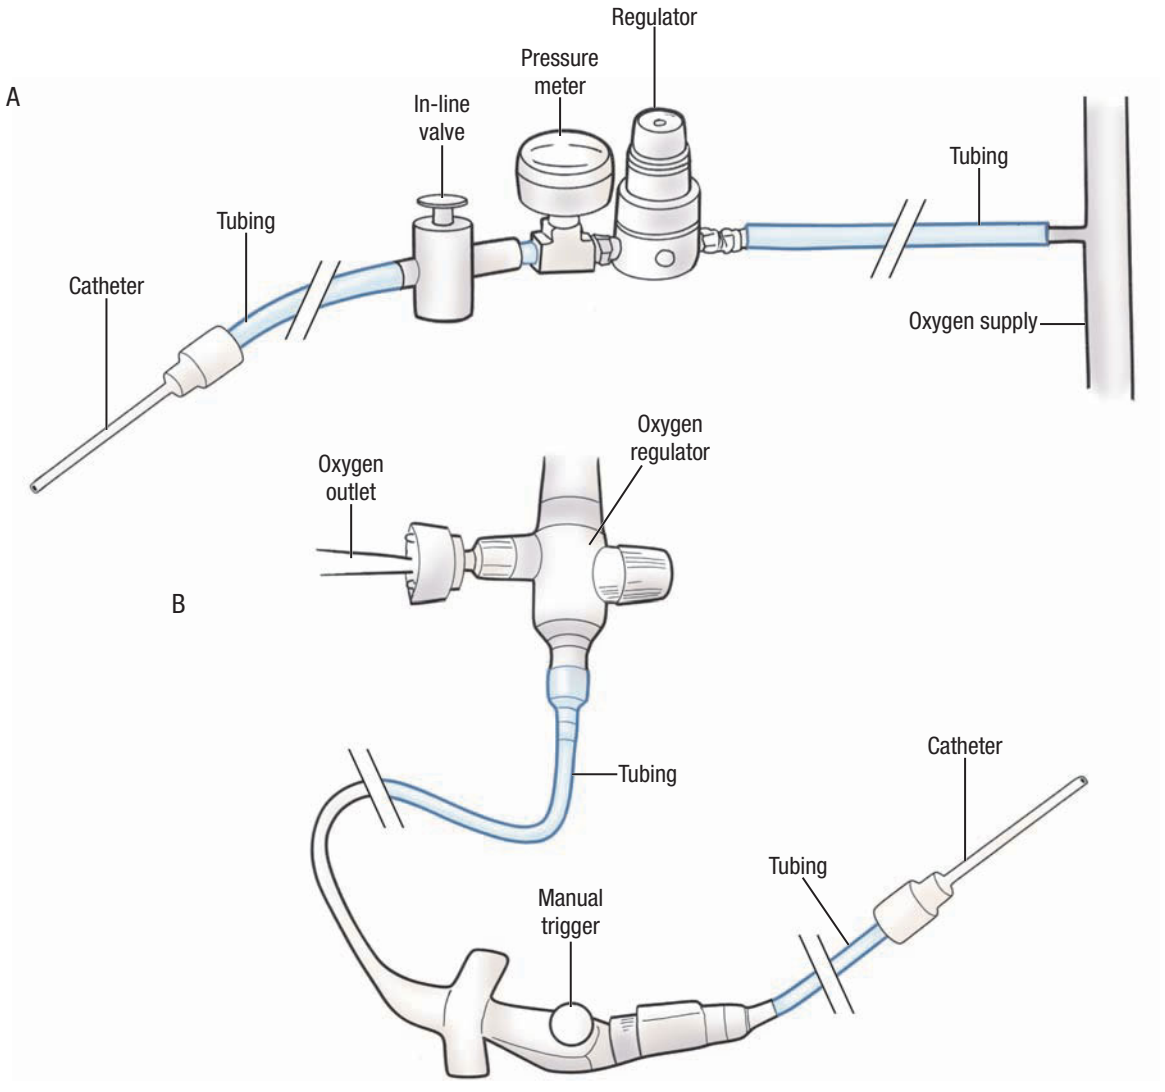

FIGURE 24-5. The components of high-pressure jet ventilation systems. **A.** Modified from Greenfield.[21] **B.** Modified from Patel.[10]

prep to the anterior neck. Prepare the needed equipment. Attach a 12 to 16 gauge catheter-over-the-needle (angiocatheter) to a 10 mL syringe containing 5 mL of sterile saline.

TECHNIQUE

Stand at the side of the bed and adjacent to the patient's head and neck. **Reidentify the anatomic landmarks. This is crucial to perform this procedure.** Using the nondominant hand, place the thumb on one side of the thyroid cartilage and the middle finger on the other side. Use these fingers to stabilize the larynx. Use the index finger to identify the anatomic landmarks.[5,10] Start at the laryngeal prominence (Adam's apple) and work inferiorly. The soft membranous defect inferior to the laryngeal prominence is the cricothyroid membrane. Below this is the firm cartilaginous ring of the cricoid cartilage.

Insert the catheter-over-the-needle (angiocatheter) through the skin, subcutaneous tissue, and inferior aspect of the cricothyroid membrane. **The inferior aspect of the cricothyroid membrane is the preferred site as it avoids injury to the cricothyroid arteries.**[7] Direct the catheter-over-the-needle inferiorly and at a 30° to 45° angle (**Figure 24-6A**). Maintain constant negative pressure within the syringe as it is advanced (**Figure 24-6B**). **Continue to advance the catheter-over-the-needle while maintaining negative pressure until air bubbles are visible in the syringe and a loss of resistance is felt.[5,10] These both signify that the angiocatheter is within the trachea.**

Once placement within the trachea is confirmed, securely hold the needle and advance the catheter until the hub is against the skin (**Figure 24-6C**). Remove the needle and syringe (**Figure 24-6C**). Reattach the syringe without the needle to the catheter. **Aspirate once again to reconfirm placement of the catheter within the trachea.** The 2 to 3 cm catheter should be long enough to pass into the tracheal lumen without sitting against the posterior wall. If the catheter tip directly touches or faces the posterior tracheal wall, there is the risk of forcing air submucosally.[12] Firmly grasp and hold the catheter hub at the skin of the neck. Remove the syringe. Attach the oxygen tubing to the catheter (**Figure 24-6D**). Begin ventilation and continue until a more permanent and secure airway is established.[5] **Watch for adequate chest rise with ventilation and allow for complete elastic recoil of the chest wall before giving the next breath to avoid air trapping and barotrauma.**

ASSESSMENT

PTTJV requires continuous cardiac and pulse oximetry monitoring to evaluate oxygenation. Continuous capnography can be used to assure adequate ventilation. Arterial blood gas samples should be

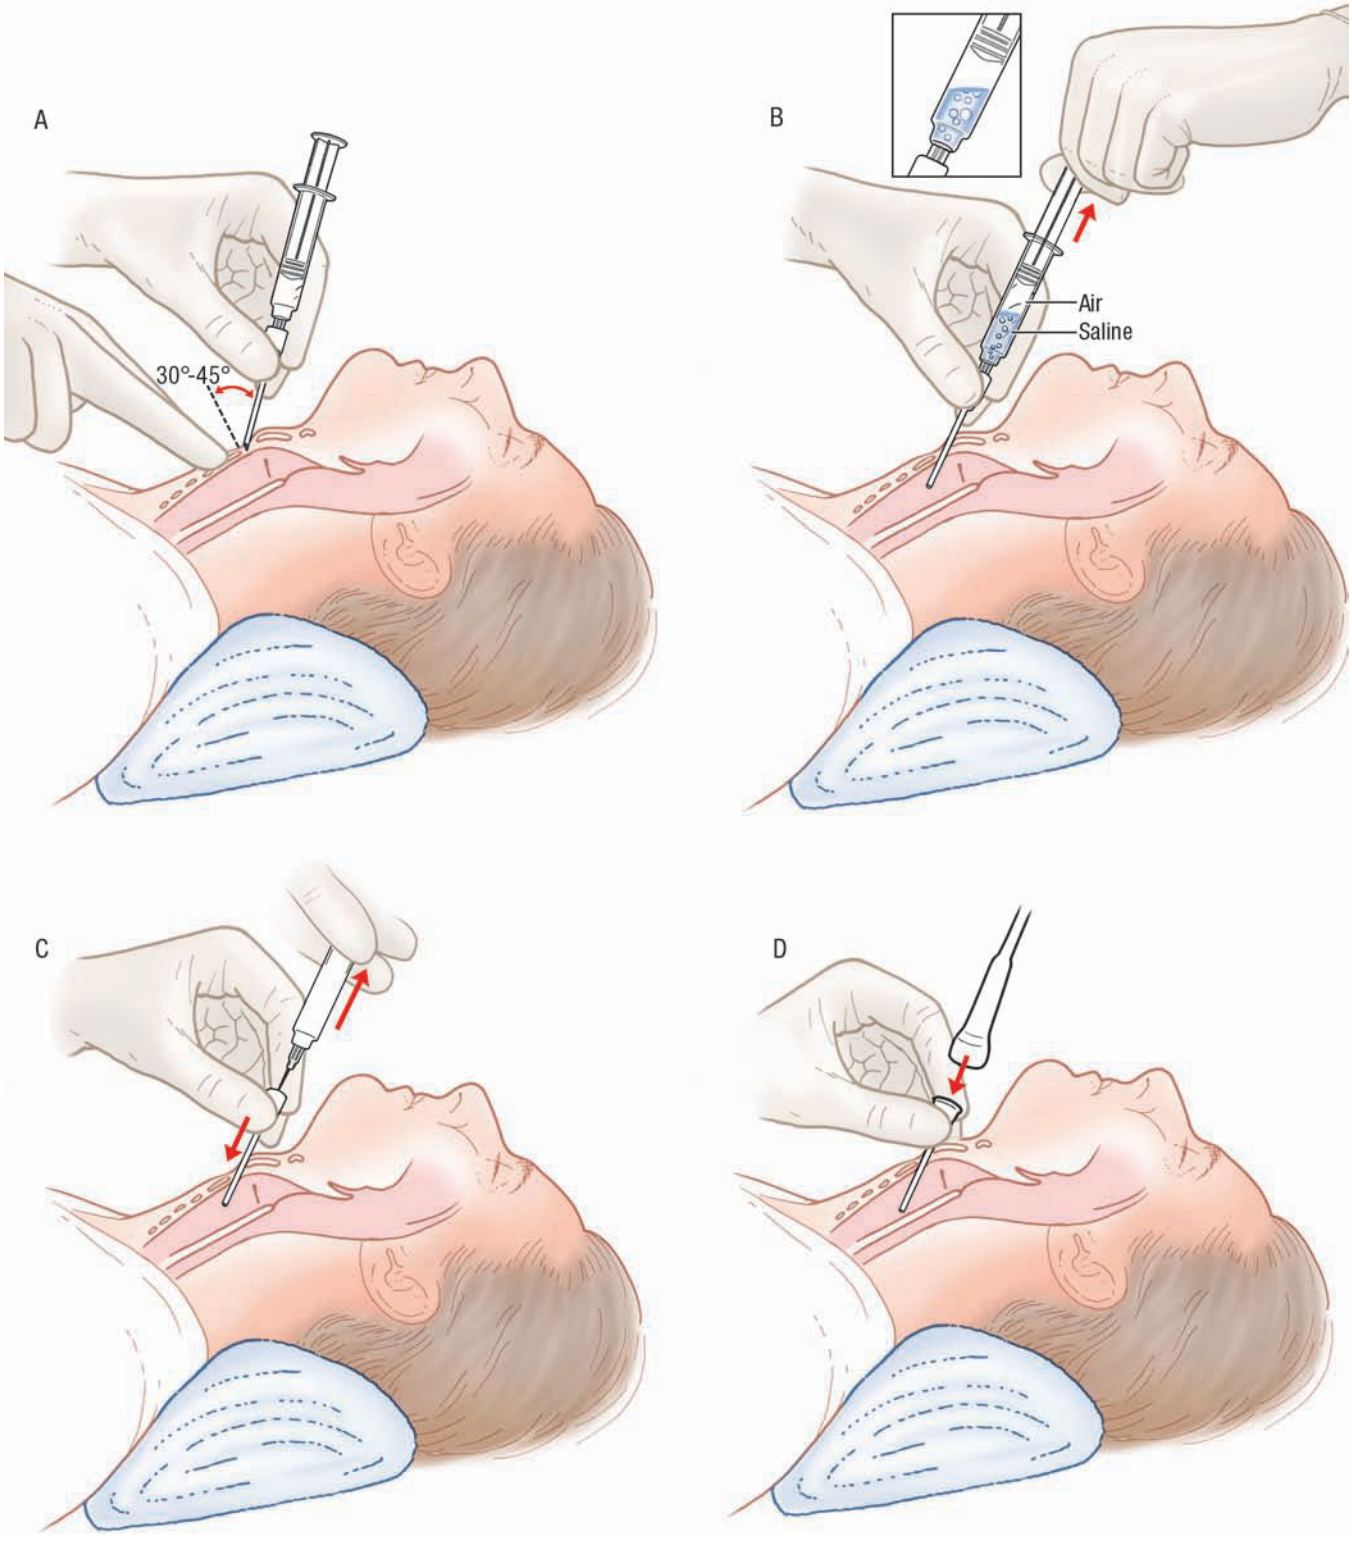

FIGURE 24-6. Insertion of the transtracheal catheter. **A.** The catheter-over-the-needle is inserted 30° to 45° to the perpendicular (*dotted line*) and aimed inferiorly. **B.** Application of negative pressure to a saline-containing syringe during catheter insertion (*arrow*). Air bubbles in the saline confirm intratracheal placement of the catheter. **C.** The catheter is advanced until the hub is against the skin. The needle and syringe are then removed. **D.** High-pressure oxygen tubing is attached to the catheter and ventilation is begun.

obtained periodically to look for hypoxia and hypercarbia. Careful attention must be paid to maintaining a patent upper airway to allow for passive expiration and avoid barotrauma. Oropharyngeal and/or nasopharyngeal airways, or a jaw-thrust maneuver, are often adequate.

The catheter, oxygen tubing, and patient must be continually assessed during PTTJV. Check the catheter tubing at regular intervals for signs of dislodgement or kinking. Examine the patient for crepitus in the neck and torso. If crepitus is present, the catheter tip is most likely directly against or directed toward the mucosa of the

posterior tracheal wall. Oxygen is being forced into the submucosal tissues and tracking subcutaneously. Remove the catheter and reinsert a new one. Obtain a chest radiograph to assess the patient for a pneumomediastinum, pneumopericardium, or pneumothorax that may require decompression. Pulse oximetry and cardiac monitoring and capnography should also be continuously monitored.

AFTERCARE

The catheter and tubing must be secured to prevent accidental dislodgement.[10] One person must continuously hold the hub of the catheter against the patient's skin during PTTJV while a second person secures it. There are three ways to secure the equipment. The first and preferred method is to suture it in place. Place a skin wheal of local anesthetic solution (1% lidocaine) next to the catheter hub. Using 3-0 nylon suture, place a stitch through the skin wheal and tie it securely. Do not cut the suture. Wrap the long end of the suture around the catheter hub two or three times and tie it securely to the tail of the suture. Wrap the long end of the suture around the oxygen tubing, just above the attachment to the catheter hub, two or three times and tie it securely to the tail of the suture. Alternatively, wrap a piece of umbilical or plain tape around the patient's neck, the catheter hub, and the oxygen tubing. A second alternative is to attach a commercially available endotracheal tube holder around the patient's neck and connect it to the oxygen tubing. The catheter will still have to be secured with suture or by being taped to the oxygen tubing and skin.

The patient should be reevaluated for possible endotracheal intubation. Studies have shown that subsequent attempts have been successful. It is possible that the positive pressure used in PTTJV increases the success rate.[10]

COMPLICATIONS

PTTJV is a relatively safe and effective means of establishing an emergent airway in a patient who cannot be intubated or ventilated by another mechanism. Complications are fewer than with a cricothyroidotomy, but they do occur and must be anticipated.

Subcutaneous emphysema occurs most commonly when the transtracheal catheter is misplaced, becomes dislodged into the soft tissues of the neck during ventilation, or is placed against the mucosa of the posterior tracheal wall.[1,5,6] It may also occur if catheter placement is unsuccessful on the first attempt, creating a port for leakage of pressurized air into the subcutaneous tissues of the neck.[5] Frequent examination of the catheter site for evidence of subcutaneous emphysema may provide the earliest clue to catheter malfunction.

Barotrauma may present as a pneumothorax, pneumomediastinum, or pneumopericardium. It may be a result of upper airway obstruction. The exhalation of air is passive and depends on a patent upper airway. **It is therefore important to monitor chest rise and fall as evidence of continued air exchange.**[1] An oropharyngeal airway, nasopharyngeal airway, or jaw-thrust maneuver will often provide adequate upper airway patency.[5] **Assume, until proven otherwise, that any sudden change in the patient's heart rate or blood pressure during PTTJV is secondary to a tension pneumothorax.** There has been a case report of laryngospasm with PTTJV use during an elective surgical procedure.[16] It resulted in sudden desaturation and hypotension that were easily resolved with the administration of a paralytic agent.

Catheter obstruction is another potential complication. Most commonly, the catheter will kink as it traverses the soft tissues of the neck.[1,5] This may occur if the catheter is dislodged or as a result of high-pressure ventilation. The use of a commercially available kink-resistant catheter greatly reduces this risk.

The catheter may be inappropriately placed. Misplacement of the catheter into the submucosa of the larynx can lead to a laryngeal pneumatocele. If this is suspected or identified, remove the catheter and reinsert a new one. The pneumatocele can be aspirated with a needle and syringe after placement of a new transtracheal catheter.[5] Misplacement of the catheter posteriorly through the back of the trachea and perforation of the esophagus is a theoretical concern that has never been reported.[1,5,6]

Pulmonary aspiration is another potential complication of PTTJV. The epiglottis provides no airway protection, and the small transtracheal catheter does not prevent aspiration of secretions or gastric contents into the lungs. Animal studies have demonstrated that pulmonary aspiration in fact did not occur despite variable frequencies of ventilation, variable oxygen flow pressure, and cardiac compressions during cardiopulmonary resuscitation (CPR).[17,18] Studies have shown that the pressurized flow of air through the catheter provides an adequate forceful gas outflow from the lungs which may prevent pulmonary aspiration. [17,18] Secretions and foreign bodies have been shown to stay above the jetting catheter while PTTJV is in progress. **If PTTJV is to be discontinued, great care must be taken to assure complete suctioning and cleansing of the upper airway above the catheter.**[18]

Less serious complications include local hematoma formation at the catheter insertion site, hemoptysis, and cough.[1,5,6] The use of nonhumidified oxygen in the catheter has been reported to cause irritation and erosion to the tracheal mucosa.[1]

SUMMARY

PTTJV is an effective and easy method for establishing an emergent airway in patients who cannot be ventilated with a bag-valve-mask device or intubated. The indications for PTTJV are the same as those for a cricothyroidotomy. Placement of a catheter through the cricothyroid membrane and attached to a high-pressure oxygen source will provide adequate oxygenation and ventilation until a more definitive airway can be established. This is an airway management technique that is rapidly performed and should be considered as a reliable backup rescue technique for the "can't intubate, can't ventilate" patient.

25 Cricothyroidotomy

Eric F. Reichman

INTRODUCTION

Establishment of an airway is of prime importance to survival. The most predictive factor of survival from cardiac arrest is establishment of an airway.[1] Unfortunately, the Emergency Physician is occasionally confronted with an airway that is extremely difficult or even impossible to obtain by endotracheal intubation. Between 1% and 4% of all emergent airways require a cricothyroidotomy.[2–5] Up to 7% of trauma patients who present in cardiopulmonary arrest will require a cricothyroidotomy.[3]

The technique of cricothyroidotomy has been documented in use since the early 1900s. In 1921, Chevalier Jackson condemned its use because of fears of subglottic stenosis.[6,7] Jackson's technique involved incising the cricoid cartilage, which led to the subglottic stenosis. The technique was popularized again in 1966 by Brantigan and Grow, but it was considered primarily an elective procedure.[6,7] **Cricothyroidotomy has since evolved into the**

surgical airway of choice for emergent situations in which other intubation methods have failed or are contraindicated.[2,8] The Emergency Physician using rapid sequence induction to intubate patients should be knowledgeable and skilled in performing a cricothyroidotomy.[3] The success rate of a cricothyroidotomy ranges from 96% to 100%.[4,9]

A cricothyroidotomy has numerous advantages over a tracheostomy.[6,10,11] A cricothyroidotomy is easier, faster, and safer to perform. It can be performed in less than 2 minutes. It can be performed by those with little or no surgical training. It does not require the support of an operating room and a large amount of equipment. The anatomic landmarks are superficial, easily seen, and easily palpated. The procedure does not require a deep dissection, as the structures are located subcutaneously. The cricothyroid membrane is not covered by any structures that would interfere with the procedure. Because the cricothyroid membrane is in the upper part of the neck, there is less chance of injuring the esophagus. A cricothyroidotomy can be performed with the patient's neck in a neutral position. This is especially important in those with potential cervical spine injuries. The procedure has fewer associated complications than a tracheostomy. Although not a concern when securing an airway, the skin incision will heal with a smaller and less noticeable scar.

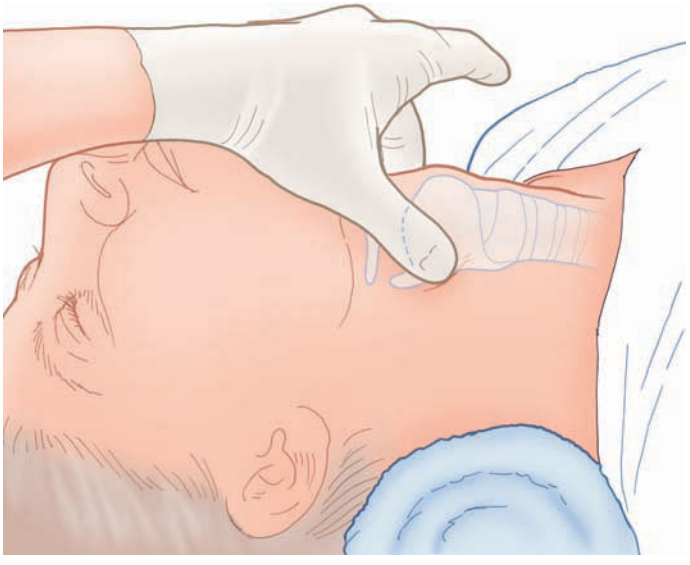

FIGURE 25-2. Proper hand positioning to identify the airway structures of the neck.

ANATOMY AND PATHOPHYSIOLOGY

The cricothyroid membrane is located between the thyroid cartilage superiorly and the cricoid cartilage inferiorly (**Figure 25-1**). **The cricothyroid membrane must be identified by palpation of the surrounding cartilaginous structures.** Using the nondominant hand, place the thumb on one side of the thyroid cartilage and the middle finger on the other side (**Figure 25-2**). Palpate the laryngeal prominence (Adam's apple) with the index finger. **It is important to locate the hyoid bone superiorly to ensure that the incision is not superior to the vocal cords.** Moving inferiorly, the index finger will fall into a hollow, which is the location of the cricothyroid membrane. The next structure palpated is the firm cartilaginous ring of the cricoid cartilage, followed by the tracheal rings.

The cricothyroid membrane itself is a thin membrane measuring 2 to 3 cm in width and only 9 to 10 mm in height.[8,11] It is located approximately 1 cm below the true vocal cords.[11] There is relatively little subcutaneous tissue overlying the cricothyroid membrane. There are few to no vascular structures overlying the cricothyroid membrane. The anterior cricothyroid arteries travel from lateral to medial over the superior border of the cricothyroid membrane. The anterior jugular veins may lie immediately superior and lateral to the cricothyroid membrane. Farther lateral and posterior are the great vessels of the neck. Posterior to the larynx and trachea is the esophagus. It is therefore important not to make the incision too deep, thus risking an esophageal intubation or injury.

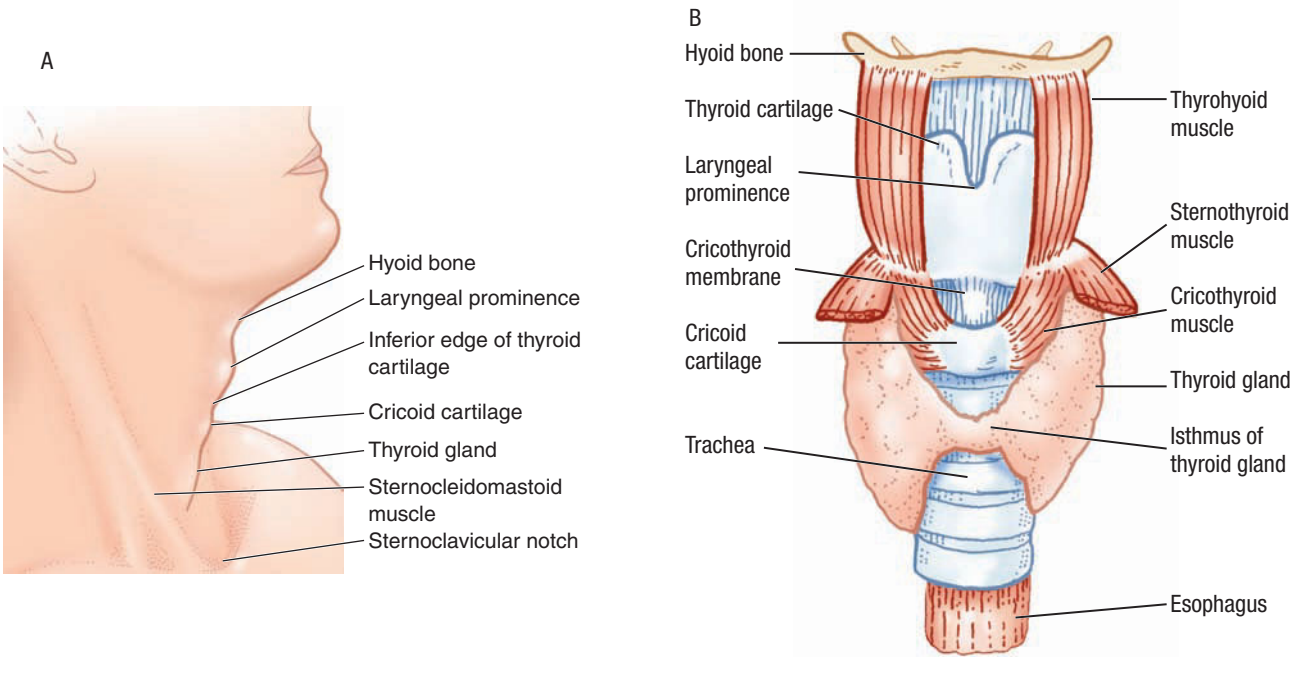

FIGURE 25-1. Anatomy of the airway in the neck region. **A.** Topographic anatomy. **B.** The framework of the airway.

INDICATIONS

The most frequent indication for an emergent or urgent surgical airway is the inability to intubate endotracheally with less invasive techniques. These less invasive techniques may have failed or been contraindicated.[10] **Attempts at orotracheal or nasotracheal intubation should be made prior to attempts at creating a surgical airway.**[4,8] A common reason for the failure of orotracheal intubation is not using rapid sequence induction and the patient's clenched teeth precluding intubation.[9] Other common reasons for failure to establish endotracheal intubation include severe neck or facial injury resulting in distortion of the normal anatomy, edema, masseter spasm, laryngospasm, cervical spine injury, deformities of the mouth and/or pharynx, upper airway hemorrhage, large amounts of vomitus in the oropharynx, and upper airway obstruction.[8,9,11] **Although endotracheal intubation should be attempted first, it is prudent to have the surgical airway supplies nearby if it is suspected that the patient may have a difficult airway.** The old saying among Anesthesiologists "A surgical airway is better than a deceased patient with a good-looking neck" holds quite true.

Needle cricothyroidotomy is the emergent "surgical" airway of choice in a patient younger than 8 to 10 years of age.[11,12] In young children, the cricothyroid membrane as well as the surrounding structures are much smaller and more difficult to access. It is easier to injure one of the cervical vessels or the esophagus when a standard cricothyroidotomy is performed in a child. Subglottic stenosis is a common late complication following cricothyroidotomy in children.[12] A needle cricothyroidotomy is a safer alternative and allows for adequate oxygenation and ventilation until a formal tracheostomy or other method of endotracheal intubation can be performed. Unfortunately, the small caliber of the catheter may not provide adequate oxygenation and ventilation in an adult.

CONTRAINDICATIONS

There are a few absolute contraindications to performing a cricothyroidotomy. The most important is if the patient can be endotracheally intubated by less invasive methods. Partial or complete transection of the airway is a contraindication to a cricothyroidotomy. In these cases, a tracheostomy is the preferred method to secure the airway. Finally, this procedure should not be performed in cases of significant injury or fracture of the cricoid cartilage, larynx, and/or thyroid cartilage.

There are some situations where the performance of a cricothyroidotomy may be less desirable. The presence of laryngeal pathology (e.g., tumor, fracture) may preclude the performance of a cricothyroidotomy and necessitate a high tracheostomy.[11,13] If a patient has been previously intubated endotracheally for a prolonged period, there is a higher incidence of long-term complications following a cricothyroidotomy.[13] While this does not prevent the performance of a cricothyroidotomy, one should consider an early revision to a tracheostomy to minimize these complications. Other relative contraindications to performing a cricothyroidotomy are the presence of a coagulopathy, massive neck swelling, or a hematoma in the neck; all of which increase the risk of bleeding and distortion of the anatomy. Finally, unfamiliarity with the technique may lead to increased complications.[11]

EQUIPMENT

General Supplies

- Sterile gloves, gowns, and drapes
- Face mask and eye protection
- 1% lidocaine local anesthetic solution
- Syringes, 5 and 10 mL
- Needles, 18 to 27 gauge
- Bag-valve-mask device
- Oxygen source and tubing
- Suction source, tubing, and catheter
- Pulse oximeter
- Noninvasive blood pressure cuff
- Cardiac monitor
- End-tidal CO_2 monitor

Surgical Cricothyroidotomy

- Povidone iodine or chlorhexidine solution
- #11 scalpel blade on a handle
- Trousseau tracheal dilator or curved 6 in hemostat
- Tracheal hook
- Hemostats, 4 small
- Needle driver
- Suture scissors
- Tracheostomy tubes, sizes #4 and #6
- Endotracheal tubes, various sizes
- Tracheostomy tape (twill tape)
- 3-0 sutures for hemostasis (e.g., Dexon, Vicryl, or chromic)
- 3-0 nylon sutures for skin closure
- 1 in tape (or a commercially available endotracheal tube holder)
- Gauze 4 × 4 squares
- Iodoform gauze ribbon
- Percutaneous cricothyroidotomy kit, adult and pediatric sizes

Needle Cricothyroidotomy

- Povidone iodine or chlorhexidine solution
- 14 gauge catheter-over-the-needle (angiocatheter), 2 in long
- 5 mL syringe
- Tape
- Percutaneous transtracheal jet ventilator (Chapter 24)

The equipment should be prepackaged in a sterile tray that is readily accessible. Some institutions maintain separate cricothyroidotomy and tracheostomy trays. Others have one tray that contains the equipment necessary to perform both procedures. If a cricothyroidotomy tray is not immediately available, a thoracotomy tray usually contains all the required equipment to perform this procedure.

Should the Emergency Department stock surgical cricothyroidotomy kits, percutaneous cricothyroidotomy kits, or both? The answer to this will depend on Emergency Physician preference, hospital stores, and available budget. The Melker Universal Emergency Cricothyroidotomy Catheter Set (Cook Inc., Bloomington, IN) may resolve this issue for some Emergency Departments. This single-use, disposable kit contains all the equipment required to perform both types of cricothyroidotomies. The convenience of having all the required equipment readily available in one kit can clearly justify the cost. Unfortunately, this kit is only available in one adult size.

PATIENT PREPARATION

A cricothyroidotomy is most commonly an emergent procedure. There is little if any time to explain this to the patient and obtain their consent. If there is sufficient probability that an awake and

FIGURE 25-3. Patient positioning with a rolled towel under their neck and upper shoulders.

stable patient will require a surgical airway, informed consent may be obtained.

The patient should be appropriately monitored with electrocardiography (ECG), end-tidal CO_2 monitoring, noninvasive blood pressure cuff, and pulse oximetry. The patient preparation is exactly the same as that for orotracheal intubation. As for any situation where airway manipulation is to occur and the patient's protective airway reflexes are blunted or ablated, a fully functioning suction apparatus with a variety of catheters must be immediately available.

Place the patient supine with their head in a neutral position. Place a rolled towel under the patient's upper shoulders and neck if no contraindications exist (**Figure 25-3**). This position offers excellent exposure, stabilizes and prevents the airway structures from moving, and lengthens the cricothyroid membrane. While it is not impossible to perform a cricothyroidotomy with a cervical collar on the patient, it is very difficult. If the patient is at risk for a cervical spine injury, it is preferable to remove the collar while an assistant maintains in-line stabilization of the head and neck in a neutral position. An additional assistant should maintain the airway and provide ventilatory support with a bag-valve-mask device.

In the ideal situation, the skin of the anterior neck should be prepped with povidone iodine or chlorhexidine solution and sterile drapes placed to isolate a surgical field. The Emergency Physician performing the procedure should be clad in a mask, a sterile gown, and gloves. The circumstances in which the procedure is usually performed often require that the airway be obtained rapidly. In these cases, a quick spray of povidone iodine or chlorhexidine and sterile gloves will suffice.

TECHNIQUES

During the performance of this procedure, one or two assistants should be maintaining the airway by providing ventilation and oxygenation with a bag-valve-mask device or a supraglottic airway device. The right-handed Emergency Physician should be standing at the patient's right side. The position is reversed for the left-handed Emergency Physician.

Stabilize the large thyroid cartilage in place with the thumb and middle finger of the nondominant hand (**Figure 25-2**).[8,14] **The immobilization of the larynx cannot be overemphasized. If the larynx is not secure and thus the landmarks are lost, the procedure will fail. Identify the anatomic landmarks necessary to perform this procedure. This is critical to the performance of a cricothyroidotomy.** Place the index finger over the laryngeal prominence (Adam's apple). Move the index finger inferiorly to identify the cricothyroid membrane, cricoid cartilage, and tracheal rings (in this order). Move the index finger superiorly until it falls back into the cricothyroid membrane. Leave the index finger over the cricothyroid membrane. Using the index finger of the dominant hand, confirm that the nondominant index finger is situated over the cricothyroid membrane. If the patient is awake and stable, infiltrate the area of the incision with local anesthetic solution after the landmarks are identified.

TRADITIONAL TECHNIQUE

Make a 2 to 3 cm transverse incision, centered in the midline, through the skin and subcutaneous tissue (**Figures 25-4 & 25-5A**). Continue the incision through the cricothyroid membrane. As one gains skill with this procedure, all layers may be incised simultaneously with one incision. The beginner should proceed with some caution because there is a small risk of incising through the posterior wall of the airway.[8,11] **The incision should be no longer than 3 cm or 1.5 cm on either side of the midline, as this represents the width**

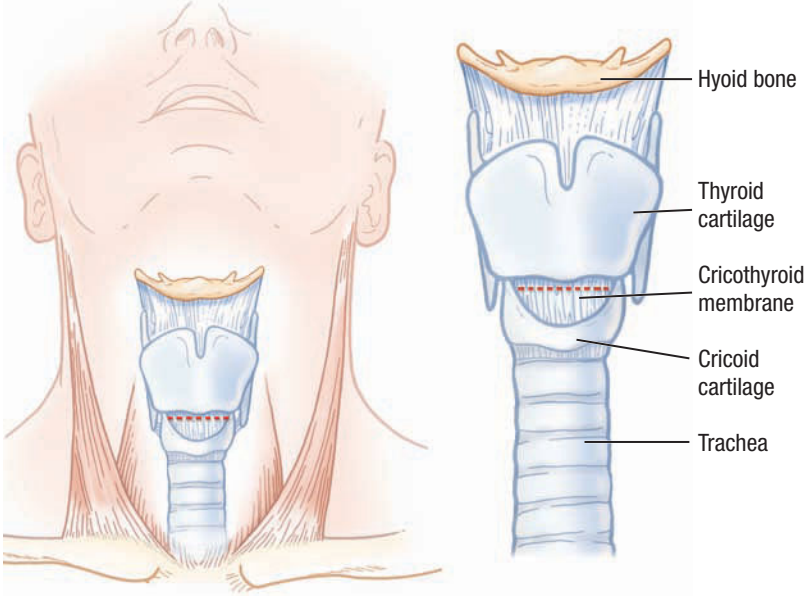

FIGURE 25-4. The cricothyroidotomy site. The dotted line represents the incision over the cricothyroid membrane.

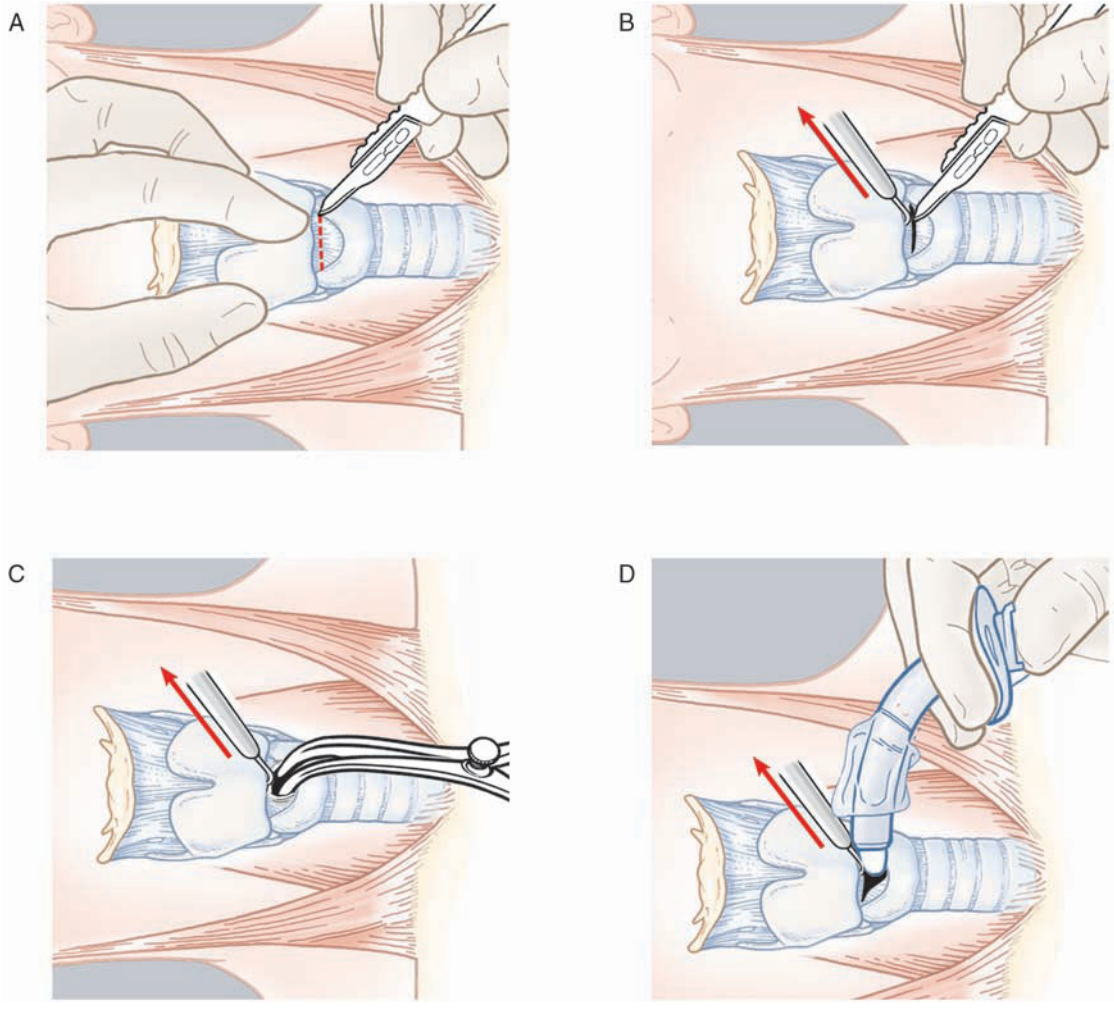

FIGURE 25-5. A surgical cricothyroidotomy. **A.** The nondominant hand stabilizes the cricothyroid membrane. A transverse incision is made through the skin, subcutaneous tissue, and cricothyroid membrane. **B.** A tracheal hook has been inserted over the scalpel blade to grasp the inferior border of the thyroid cartilage. The hook is lifted anteriorly and superiorly to control the airway (*arrow*). **C.** A Trousseau dilator is inserted into the incision and opened to dilate the incision site. **D.** A tracheostomy tube is inserted through the cricothyroid membrane.

of the cricothyroid membrane.[7,14] Longer incisions risk injury to the anterior jugular veins that lie just lateral to the thyroid cartilage.[11]

Longitudinal incisions in the midline are not recommended. They take longer to perform and require repositioning after the skin incision. The primary indication for a longitudinal skin incision is in the patient with a suspected laryngeal injury and distortion of the anatomic landmarks.[11] In these cases, the longitudinal incision permits the extension of the incision inferiorly in order to perform a high tracheostomy.

Once the cricothyroid membrane has been incised and the airway entered, a hiss of air with ventilations and bubbling should be noted through the wound. This is true if the patient is ventilating spontaneously or with the assistance of a bag-valve-mask device. **Do not remove the scalpel.** Insert the tracheal hook along the scalpel and grasp the inferior border of the thyroid cartilage (**Figure 25-5B**). Elevate the tracheal hook to retract the thyroid cartilage anteriorly and superiorly.[4,5] The scalpel may now be removed. The incision site must be expanded to accommodate the passage of an endotracheal tube or a tracheostomy tube. While controlling the airway with the tracheal hook, insert the jaws of a Trousseau dilator (or 6 in hemostat) through the cricothyroid membrane in the midsagittal plane (**Figure 25-5C**). Open the jaws of the instrument to dilate the opening in the sagittal plane.[4,5,7,8] Rotate the dilator 90° within the incision. Open the jaws of the dilator to dilate the incision in the transverse plane. Remove the dilator while continuing to maintain control of the airway with the tracheal hook.

Select a tracheostomy tube that is of an appropriate size for the patient. Instruct an assistant to lubricate the obturator and outer cannula, then insert the obturator into the outer cannula. While maintaining control of the airway with the tracheal hook, insert the tracheostomy tube perpendicularly (90°) to the skin (**Figure 25-5D**). Continue to advance the tracheostomy tube with a semicircular motion and inferiorly until the flange is against the skin. The tracheostomy tube should pass with minimal difficulty. Remove the tracheal hook. Securely hold the outer cannula. Remove the obturator, insert the inner cannula, inflate the cuff of the tracheostomy tube, connect the bag-valve device, and ventilate the patient.[4] Confirm the intratracheal position of the tube by auscultating bilateral breath sounds, noting the absence of breath sounds over the stomach, and a colorimetric or quantitative end-tidal CO_2 assessment.

ALTERNATIVE SURGICAL TECHNIQUE

An alternative surgical approach to a cricothyroidotomy was first developed by Oppenheimer.[17] It is simpler, more rapid, and easier to perform than the traditional technique described above

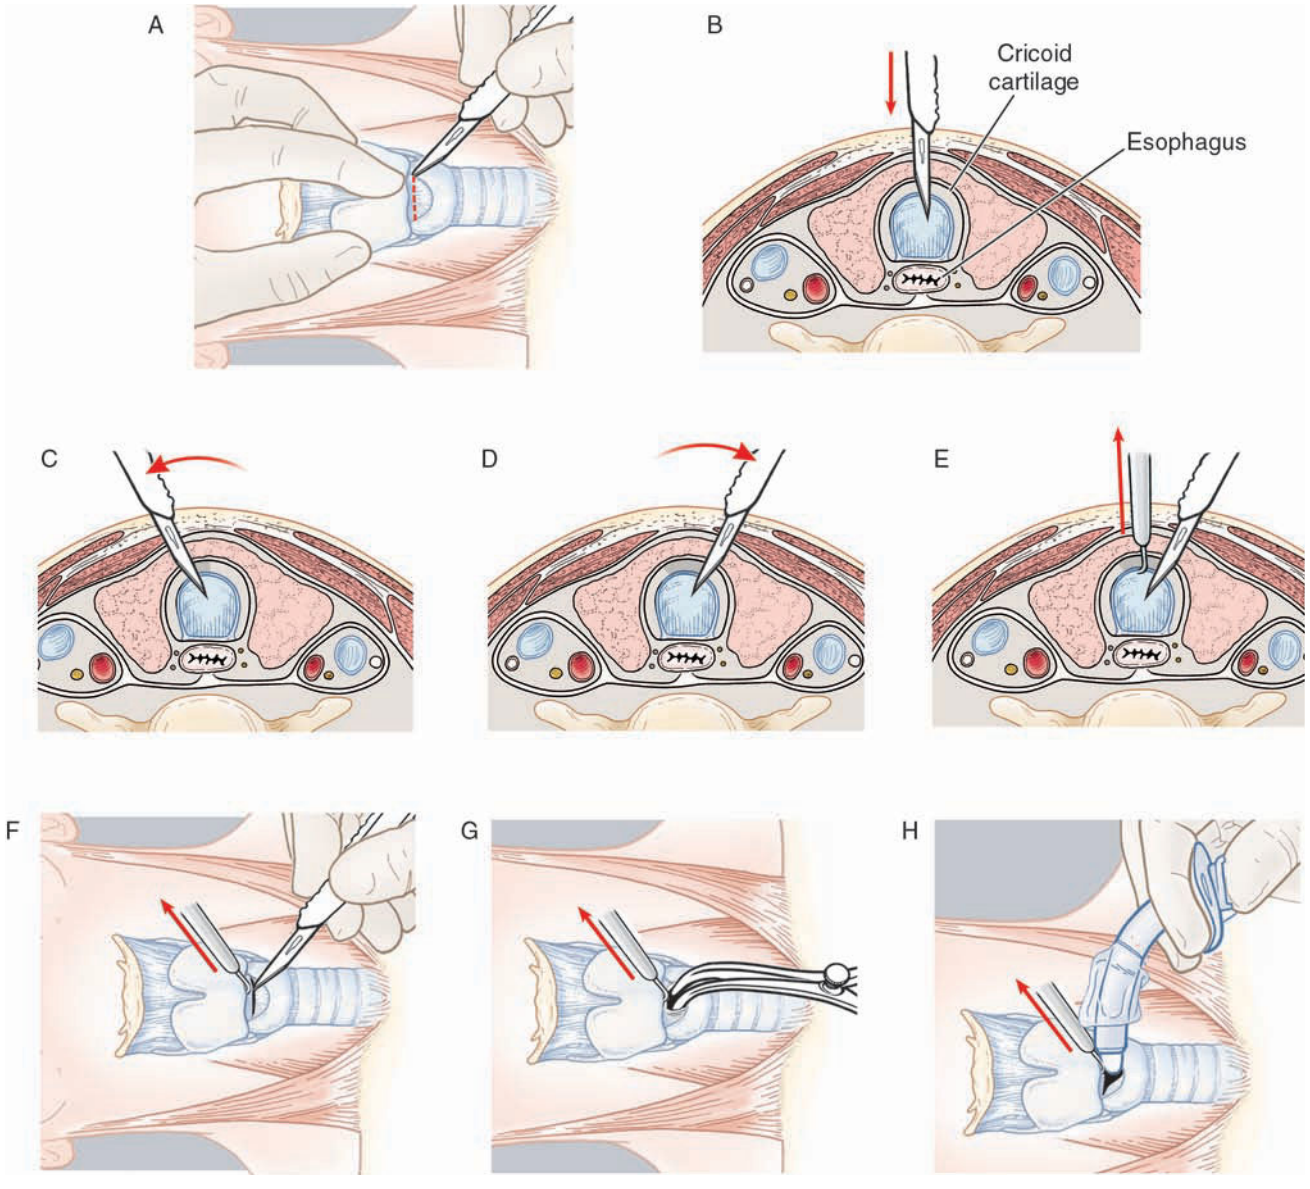

FIGURE 25-6. An alternative method to perform a surgical cricothyroidotomy. **A.** The thyroid cartilage is secured while a stab incision is made in the cricothyroid membrane. **B.** The scalpel blade penetrates the midline and enters the airway. **C.** The incision is extended laterally from the midline. **D.** The scalpel is rotated 180° and extends the incision to the other side. **E.** A tracheal hook is inserted in the midline and grasps the inferior border of the thyroid cartilage. **F.** The thyroid cartilage is lifted anteriorly and superiorly to control the airway (*arrow*). After the airway is controlled, the scalpel is removed. **G.** A Trousseau dilator is inserted into the incision, and the jaws are opened to dilate the incision. **H.** A tracheostomy tube is inserted into the trachea using a semicircular motion.

(**Figures 25-6 & 25-7**). The technique has been modified from the original description.[18]

Clean, prepare, and drape the neck as mentioned previously. Position the nondominant hand with the thumb on one side of the thyroid cartilage and the middle finger on the other side (**Figures 25-6A & 25-7A**). Identify the anatomic landmarks as described previously. Leave the nondominant index finger over the cricothyroid membrane. If the patient is awake, infiltrate local anesthetic solution subcutaneously over the cricothyroid membrane.

Guide a #11 surgical blade along the nondominant index finger and into the cricothyroid membrane using a stab incision (**Figures 25-6A, B, & 25-7B**). **Do not insert the scalpel blade more than 1.5 to 2.0 cm to prevent it from injuring the esophagus.** It is recommended to hold the scalpel just above the blade with the thumb and index finger to prevent it from plunging too deep.[18] Air or bubbles from the incision signify that the tip of the scalpel blade is inside the trachea. **Do not remove the scalpel blade.** Move it laterally 0.75 cm to extend the incision (**Figures 25-6C & 25-7C**). Rotate the scalpel blade 180° and extend the incision 0.75 cm in the opposite direction (**Figures 25-6D & 25-7D**). **Do not remove the scalpel blade. Removing the scalpel from the incision will result in losing the landmarks and the location of the incision through the cricothyroid membrane.**

With the scalpel blade in place, insert a tracheal hook into the midline of the incision (**Figures 25-6E & 25-7E**). Grasp the inferior border of the thyroid cartilage with the tracheal hook. Lift the tracheal hook upward and superiorly to elevate and control the airway (**Figures 25-6F & 25-7F**). **Remove the scalpel from the incision only after the airway is controlled with the tracheal hook.**

The incision site must be expanded to accommodate the passage of an endotracheal tube or a tracheostomy tube. While controlling the airway with the tracheal hook, insert the jaws of a Trousseau dilator (or 6 in hemostat) through the cricothyroid membrane in the midsagittal plane (**Figures 25-6G & 25-7G**). Open the jaws of the

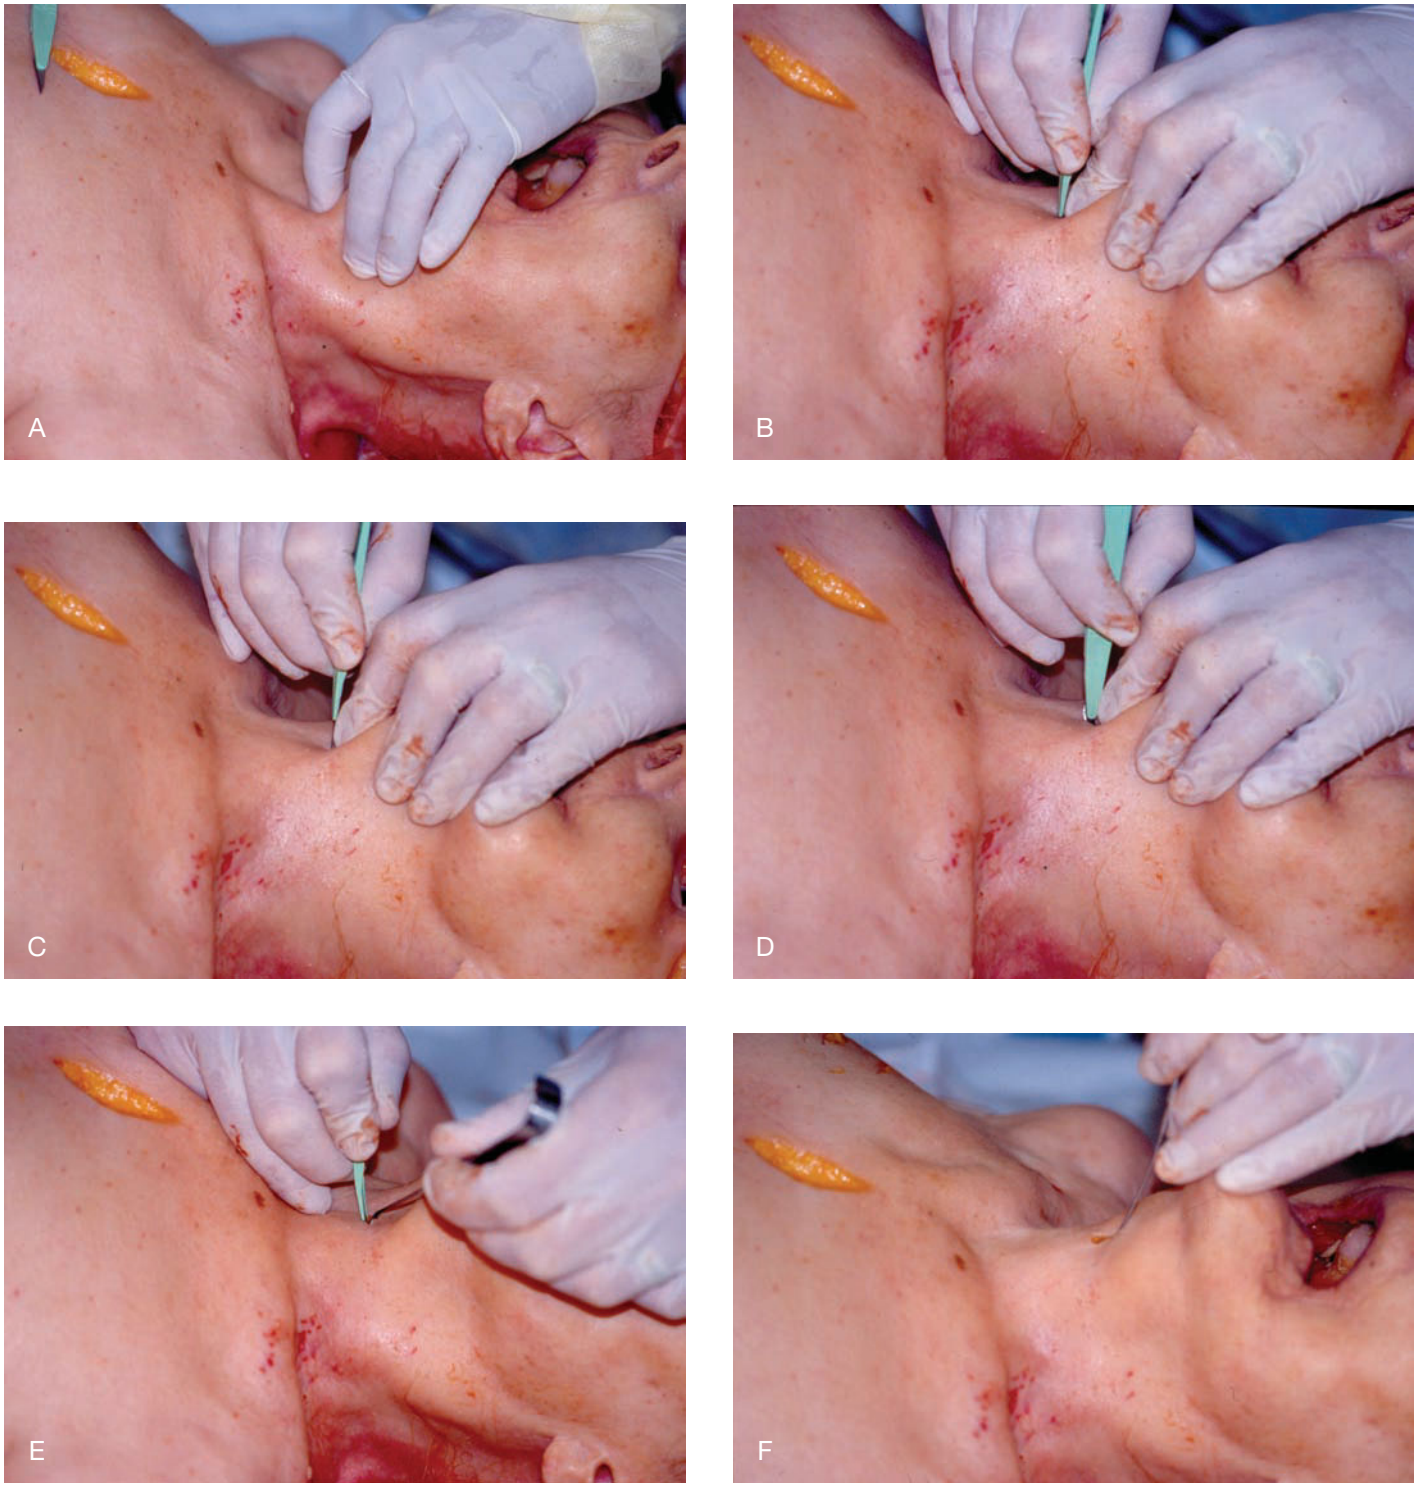

FIGURE 25-7. The alternative method performed on a cadaver. **A.** The larynx is stabilized and the Emergency Physician's index finger overlies the cricothyroid membrane. **B.** A stab incision is made into the cricothyroid membrane using the finger as a guide. **C.** The incision is extended toward the Emergency Physician. **D.** The scalpel is rotated 180° and the incision is extended away from the Emergency Physician. **E.** A tracheal hook is inserted over the scalpel blade to grasp the inferior border of the thyroid cartilage. **F.** The tracheal hook is lifted upward and superiorly to control the airway. The scalpel has then been removed.

instrument to dilate the opening in the sagittal plane (**Figure 25-7H**). Rotate the dilator 90° within the incision (**Figure 25-7I**). Open the jaws of the dilator to dilate the incision in the transverse plane (**Figure 25-7J**). Insert an endotracheal tube or a tracheostomy tube through the incision and into the trachea (**Figures 25-6H & 25-7K**). Hold the tube securely against the skin and remove the tracheal hook. The remainder of the procedure is as described previously.

PATIENTS WITH MASSIVE NECK SWELLING

Patients may present with massive neck swelling secondary to hemorrhage, hematoma, edema, or subcutaneous emphysema after trauma.[19] These patients often have no palpable anatomic landmarks in the neck, making it difficult to create a surgical airway. The traditional surgical methods used to perform a cricothyroidotomy

FIGURE 25-7. (*Continued*) **G.** The Trousseau dilator is inserted into the cricothyroid membrane. **H.** The jaws of the dilator are opened in the sagittal plane to widen the incision. **I.** The dilator is rotated 90°. **J.** The jaws of the dilator are opened to open the incision transversely. **K.** An endotracheal tube is inserted through the incision and into the trachea.

are not usable due to hemorrhage and difficulty in identifying the anatomic landmarks. However, a technique has been developed to perform a cricothyroidotomy in these patients.[20–22]

To use this technique, the location of the hyoid bone must be determined (**Figure 25-8A**). A piece of suture, string, or tracheal tie is required. Place one end of the suture at the angle of the patient's mandible. Stretch the suture along the mandible and note where it contacts the tip of the chin (**Figure 25-8A, line 1**). Cut the suture at the point where it contacts the tip of the chin. Fold the suture in half. Place one end of the folded suture on the tip of the chin. Pull the other end of the folded suture tight to make a 90° angle to line 1 (**Figure 25-8A, line 2**). An imaginary line should be drawn from the free end of the folded suture to the angle of the patient's mandible (**Figure 25-8A, line 3**). This third line is the line used to identify the hyoid bone.

Insert a #11 scalpel blade through the midline of the neck in an upward and posterior direction along line 3 (**Figure 25-8B**). Advance the scalpel blade until it meets resistance as it contacts the hyoid bone. Alternatively, a spinal needle can be inserted along line 3 until it contacts the hyoid bone (**Figure 25-8C**). Then, insert the #11 scalpel along the track of the spinal needle until the hyoid bone is also contacted. **Do not remove the scalpel.** Insert a

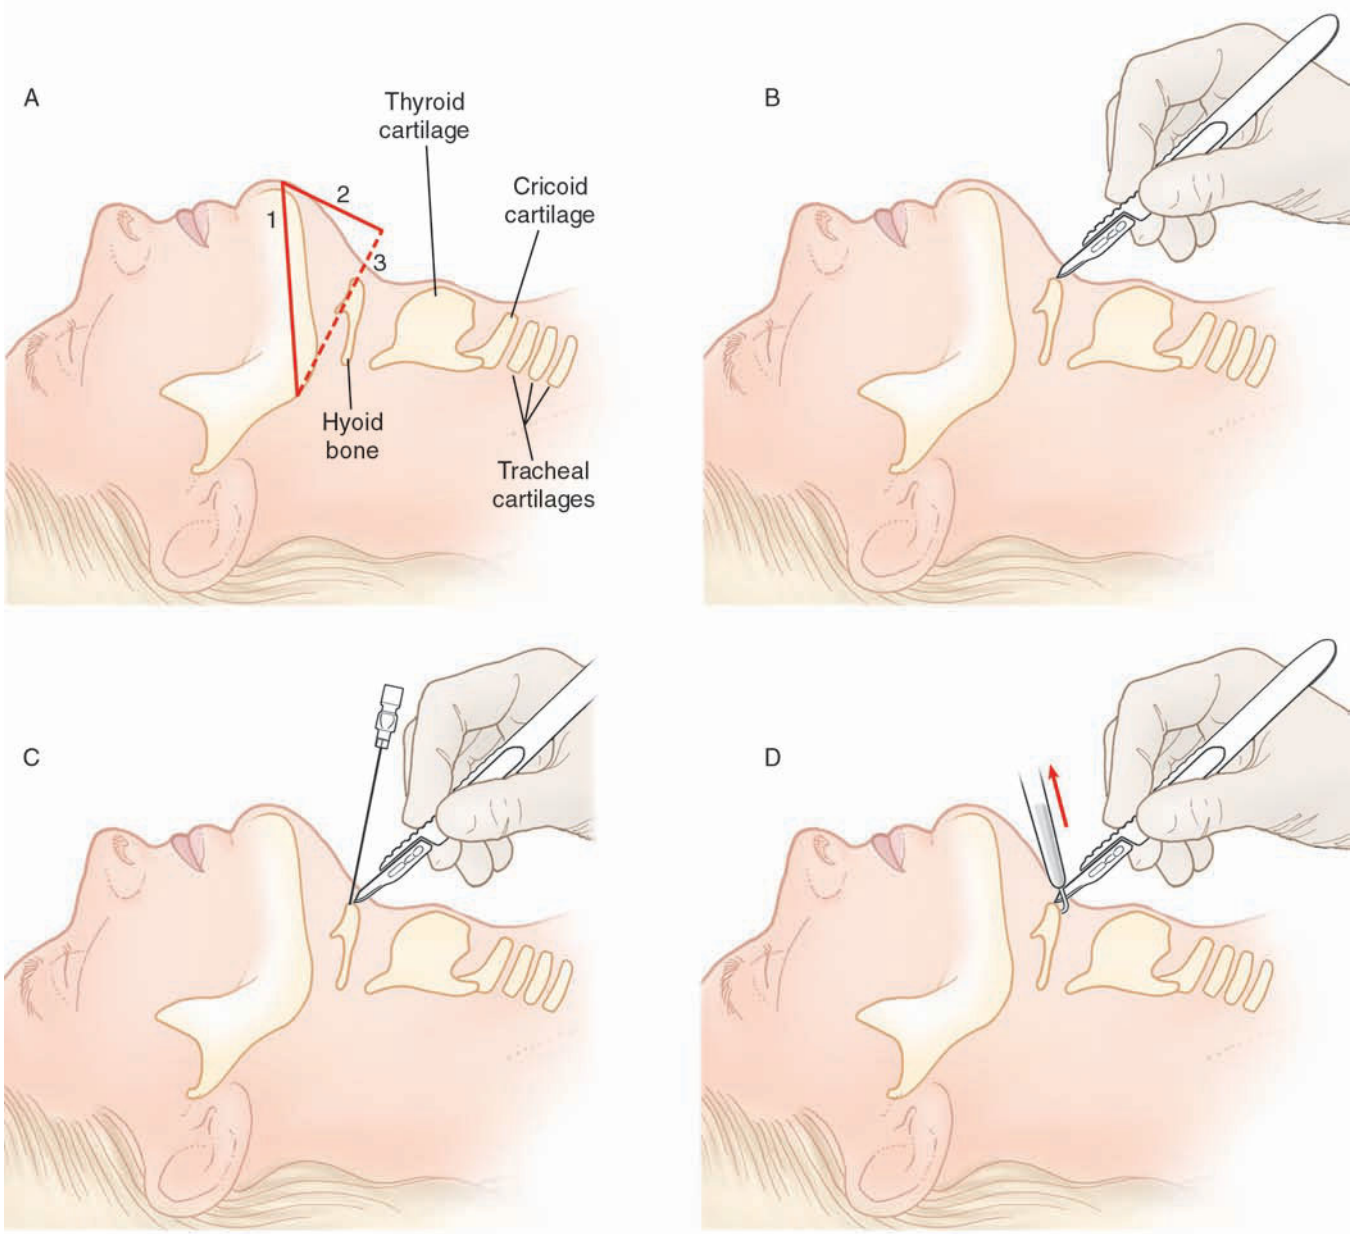

FIGURE 25-8. Cricothyroidotomy in a patient with neck swelling. **A.** Locate the hyoid bone. Line 1 is from the angle of the mandible to the tip of the chin. Line 2 is half the length of line 1 and perpendicular to it. Line 3 is from the end of line 2 to the angle of the patient's mandible. **B.** A #11 scalpel blade is inserted in the midline and aimed along line 3 until it contacts the hyoid bone. **C.** An alternative method. A spinal needle is used to locate the hyoid bone. A #11 scalpel blade is inserted along the tract of the spinal needle until the hyoid bone is contacted. **D.** A tracheal hook is inserted along the scalpel blade and used to grasp the hyoid bone. The tracheal hook is lifted (*arrow*) anteriorly and superiorly to elevate and control the airway.

tracheal hook along the scalpel blade until the hyoid bone is contacted. Move the tip of the tracheal hook under the hyoid bone (**Figure 25-8D**). Lift the tracheal hook anteriorly and superiorly to elevate and control the airway (**Figure 25-8D**). **Do not release the hold of the tracheal hook on the hyoid bone.** Remove the scalpel from the incision.

Make an incision inferiorly and in the midline starting at the site the tracheal hook exits the skin. **The incision should extend directly inferiorly without regard to the anatomy of the neck. Do not release the tension on the tracheal hook.** Identify the cricothyroid membrane. Make a transverse incision through the cricothyroid membrane. Dilate the opening and insert a tracheostomy tube or an endotracheal tube into the trachea as described previously.

SELDINGER TECHNIQUE

A percutaneous cricothyroidotomy kit is available from several manufacturers. One of the more commonly used kits is the Melker Percutaneous Cricothyrotomy Set (Cook Inc., Bloomington, IN). It is a self-contained kit that may be used in the prehospital setting, Emergency Department, or Operating Room. It contains percutaneous needles, a catheter-over-the-needle, a syringe, a #15 scalpel blade, adult and pediatric airway catheters, dilators that fit inside the airway catheters, a 30 cm flexible guidewire, and a tracheal tie (**Figure 25-9**). The dilator was developed to fit inside the airway catheter (**Figure 25-10**). The dilator and airway catheter are inserted as a unit during the procedure.

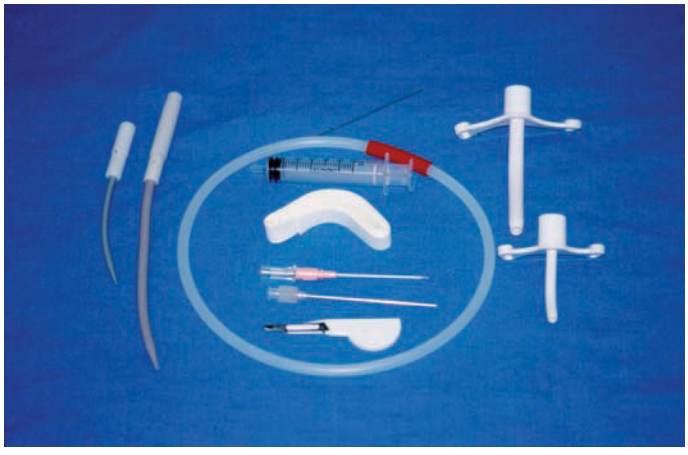

FIGURE 25-9. The percutaneous cricothyroidotomy kit (Cook Critical Care, Bloomington, IN).

The percutaneous cricothyroidotomy kit can be used to establish an airway using a modification of the Seldinger technique.[23–25] This technique can be used to establish an airway in about the time it takes to create a surgical cricothyroidotomy.[23,24] For those with little surgical experience, a percutaneous cricothyroidotomy is a simpler and quicker technique with which to establish an airway than traditional surgical methods. The technique is quite similar to inserting a central venous line.[28]

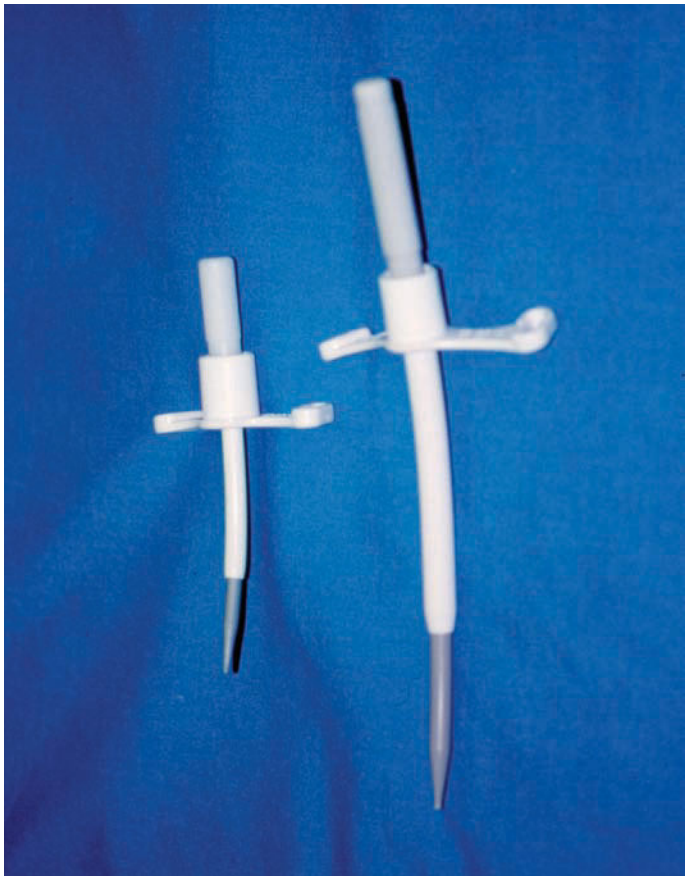

FIGURE 25-10. The dilator is placed inside the airway catheter to form a unit. The pediatric unit (*left*) and the adult unit (*right*) are both contained within each percutaneous cricothyroidotomy kit.

Clean, prep, drape, and anesthetize the patient's neck as mentioned previously. Lubricate the dilator liberally and insert it through the airway catheter (**Figure 25-10**). Lubricate the airway catheter and dilator after it has been assembled into a unit. Stabilize the trachea with the nondominant hand and identify the landmarks as previously described. Leave the nondominant index finger over the center of the cricothyroid membrane.

Make a stab incision just through the skin over the center of the cricothyroid membrane with the #11 scalpel blade (**Figure 25-11A**). Insert the catheter-over-the-needle attached to a 5 mL syringe containing saline through the skin incision and aimed inferiorly (**Figure 25-11B**). Insert and advance the catheter-over-the-needle at a 30° to 45° angle to the skin (**Figure 25-11B**). Advance the catheter-over-the-needle while applying negative pressure to the syringe. Stop advancing the catheter-over-the-needle when the airway has been entered. This will be signified by a loss of resistance and air bubbles in the syringe (**Figure 25-11B**).

Hold the syringe securely and advance the catheter over the needle until the hub is at the skin of the neck. Hold the catheter hub securely against the skin of the neck and remove the needle and syringe. Insert and advance the guidewire through the catheter and into the trachea (**Figure 25-11C**). Grasp the guidewire securely and remove the catheter over the guidewire (**Figure 25-11D**). **Do not release your grasp on the guidewire in order to prevent it from completely entering the patient's airway.**

Insert the dilator/airway catheter unit over the guidewire and into the trachea in a semicircular motion (**Figure 25-11E**). The tip of the dilator is rigid. **Insert it gently to prevent injury to or perforation of the posterior tracheal wall.** Continue to advance the unit until the flange is against the skin of the neck. Hold the airway catheter securely. Remove the guidewire and dilator as a unit, leaving the airway catheter in place (**Figure 25-11F**). Begin ventilation of the patient and secure the airway catheter as previously described.

NEEDLE CRICOTHYROIDOTOMY

A needle cricothyroidotomy, rather than a surgical cricothyroidotomy, should be performed in children less than 8 years of age. The latter is technically more difficult. The child has a laryngeal prominence that is difficult to palpate as it is not well developed. The cricothyroid membrane is small and often will not allow the passage of an airway tube. The larynx is anatomically positioned relatively higher than in an adult and is more difficult to access. A commercially available kit (ENK Oxygen Flow Modulator Set, Cook Inc., Bloomington, IN) or commonly available equipment in the Emergency Department may be used to perform this procedure.

Stand at the side of the bed and adjacent to the patient's head and neck.[11] **Reidentify the anatomic landmarks. This is crucial to performing this procedure.** Using the nondominant hand, place the thumb on one side of the thyroid cartilage and the middle finger on the other side. Use these fingers to stabilize the larynx.[8,14] Use the index finger to identify the anatomic landmarks.[4,5,11] Start at the laryngeal prominence (Adam's apple) and work inferiorly. The soft membranous defect inferior to the laryngeal prominence is the cricothyroid membrane. Below this is the cartilaginous ring of the cricoid cartilage.

Attach a 12 to 16 gauge catheter-over-the-needle (angiocatheter) onto a 10 mL syringe containing 5 mL of sterile saline. Insert the catheter-over-the-needle through the skin, subcutaneous tissue, and inferior aspect of the cricothyroid membrane. The inferior aspect of the cricothyroid membrane is the preferred site, as use of it avoids injury to the cricothyroid arteries. Direct the catheter-over-the-needle inferiorly and at a 30° to 45° angle (**Figure 25-12A**). Maintain constant negative pressure within the syringe as it is advanced

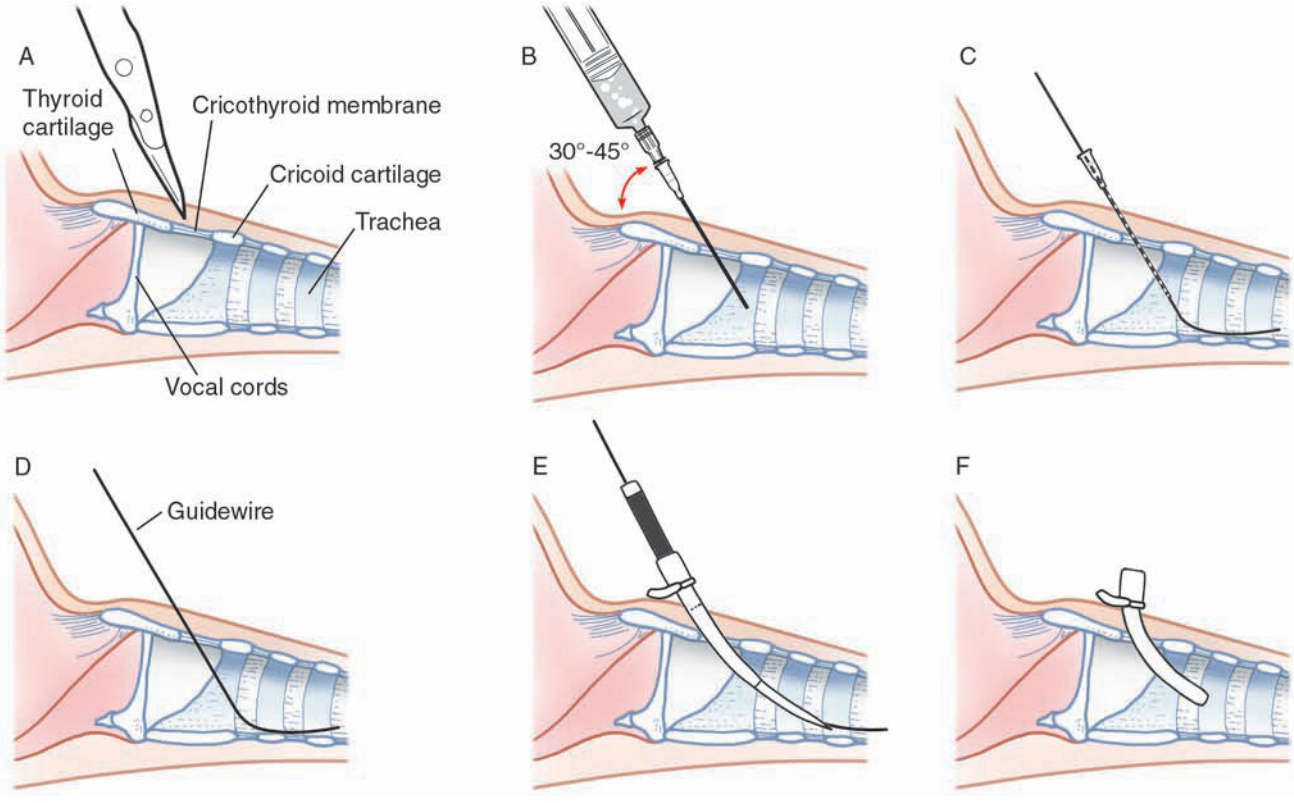

FIGURE 25-11. The percutaneous cricothyroidotomy. **A.** A stab incision is made in the midline over the cricothyroid membrane. **B.** A catheter-over-the-needle is inserted at a 30° to 45° angle to the skin and advanced in a caudal direction. Negative pressure is applied to a saline-containing syringe during catheter insertion. Air bubbles in the saline confirm intratracheal placement of the catheter. **C.** The catheter has been advanced until the hub is against the skin. The needle and syringe have been removed. A guidewire is inserted through the catheter. **D.** The catheter has been removed, leaving the guidewire in place. **E.** The dilator/airway catheter unit are advanced over the guidewire. **F.** The guidewire and dilator have been removed, leaving the airway catheter in place.

(**Figure 25-12B**). Continue to advance the catheter-over-the-needle while maintaining negative pressure until air bubbles are visible in the syringe and a loss of resistance is felt. These both signify that the catheter-over-the-needle is within the trachea.

Once placement within the trachea is confirmed, securely hold the needle and advance the catheter until the hub is against the skin (**Figure 25-12C**). Remove the needle and syringe (**Figure 25-12C**). Reattach the syringe without the needle to the catheter. Aspirate once again to reconfirm placement of the catheter within the trachea. The 2 to 3 cm catheter should be long enough to pass into the trachea without sitting against the posterior wall. If the catheter tip directly touches or faces the posterior tracheal wall, there is the risk of forcing air submucosally. Grasp and hold the catheter hub firmly at the skin of the neck. Remove the syringe. Attach the oxygen tubing to the catheter (**Figure 25-12D**). Begin ventilation and continue until a more permanent and secure airway is established.

At this point, the patient may be oxygenated and ventilated by two methods. The first involves inserting the adapter piece from a #3.0 endotracheal tube to the catheter hub and then connecting it directly to the bag-valve device or a ventilator. This method allows for the confirmation of breath sounds and provides better ventilation of the patient.

The second method of oxygenation involves direct connection of the high-flow oxygen tubing to the hub of the catheter. This method requires cyclic ventilation for 1 to 2 seconds followed by exhalation for 4 to 5 seconds.[12] This method provides adequate oxygenation but less adequate ventilation and is more labor-intensive. The complete details of percutaneous transtracheal jet ventilation can be found in Chapter 24.

Once breath sounds are confirmed, the catheter can be secured to the skin. This may be done with nylon sutures or strips of adhesive tape. The patient should undergo orotracheal intubation or a formal tracheostomy as soon as possible because of the risk of dislodging the catheter and the suboptimal ventilation associated with this technique.

ALTERNATIVE TECHNIQUES

If a tracheostomy tube is not available, an endotracheal tube can be used. The endotracheal tube is much longer than is needed. Remove the 15 mm connector from the proximal end of the endotracheal tube. Cut the endotracheal tube with scissors just above where the tubing to inflate the cuff enters the tube. Place the 15 mm connector on the shortened endotracheal tube. The procedure to insert an endotracheal tube is the same as that for a tracheostomy tube.

A cricothyroidotomy is a seldom performed procedure. A tracheal hook may not be immediately available or found when one is required. A simple alternative is to make one using a 16 or 18 gauge needle, a 10 mL syringe, and a hemostat or needle driver (**Figure 25-13**). Securely apply the needle onto the syringe. Use the hemostat or needle driver to place two 90° bends in the distal needle (**Figure 25-13**). The syringe acts as a handle and the bent needle as a tracheal hook.

Numerous other percutaneous cricothyroidotomy kits are available. The QuickTrach (Rusch Inc. of Teleflex Medical, Research Triangle Park, NC) is a preassembled, one-piece device (**Figure 25-14**). The Bivona Nu-Trake (Smiths Medical, Inc., Gary, IN) is also preassembled, but requires the use of an obturator

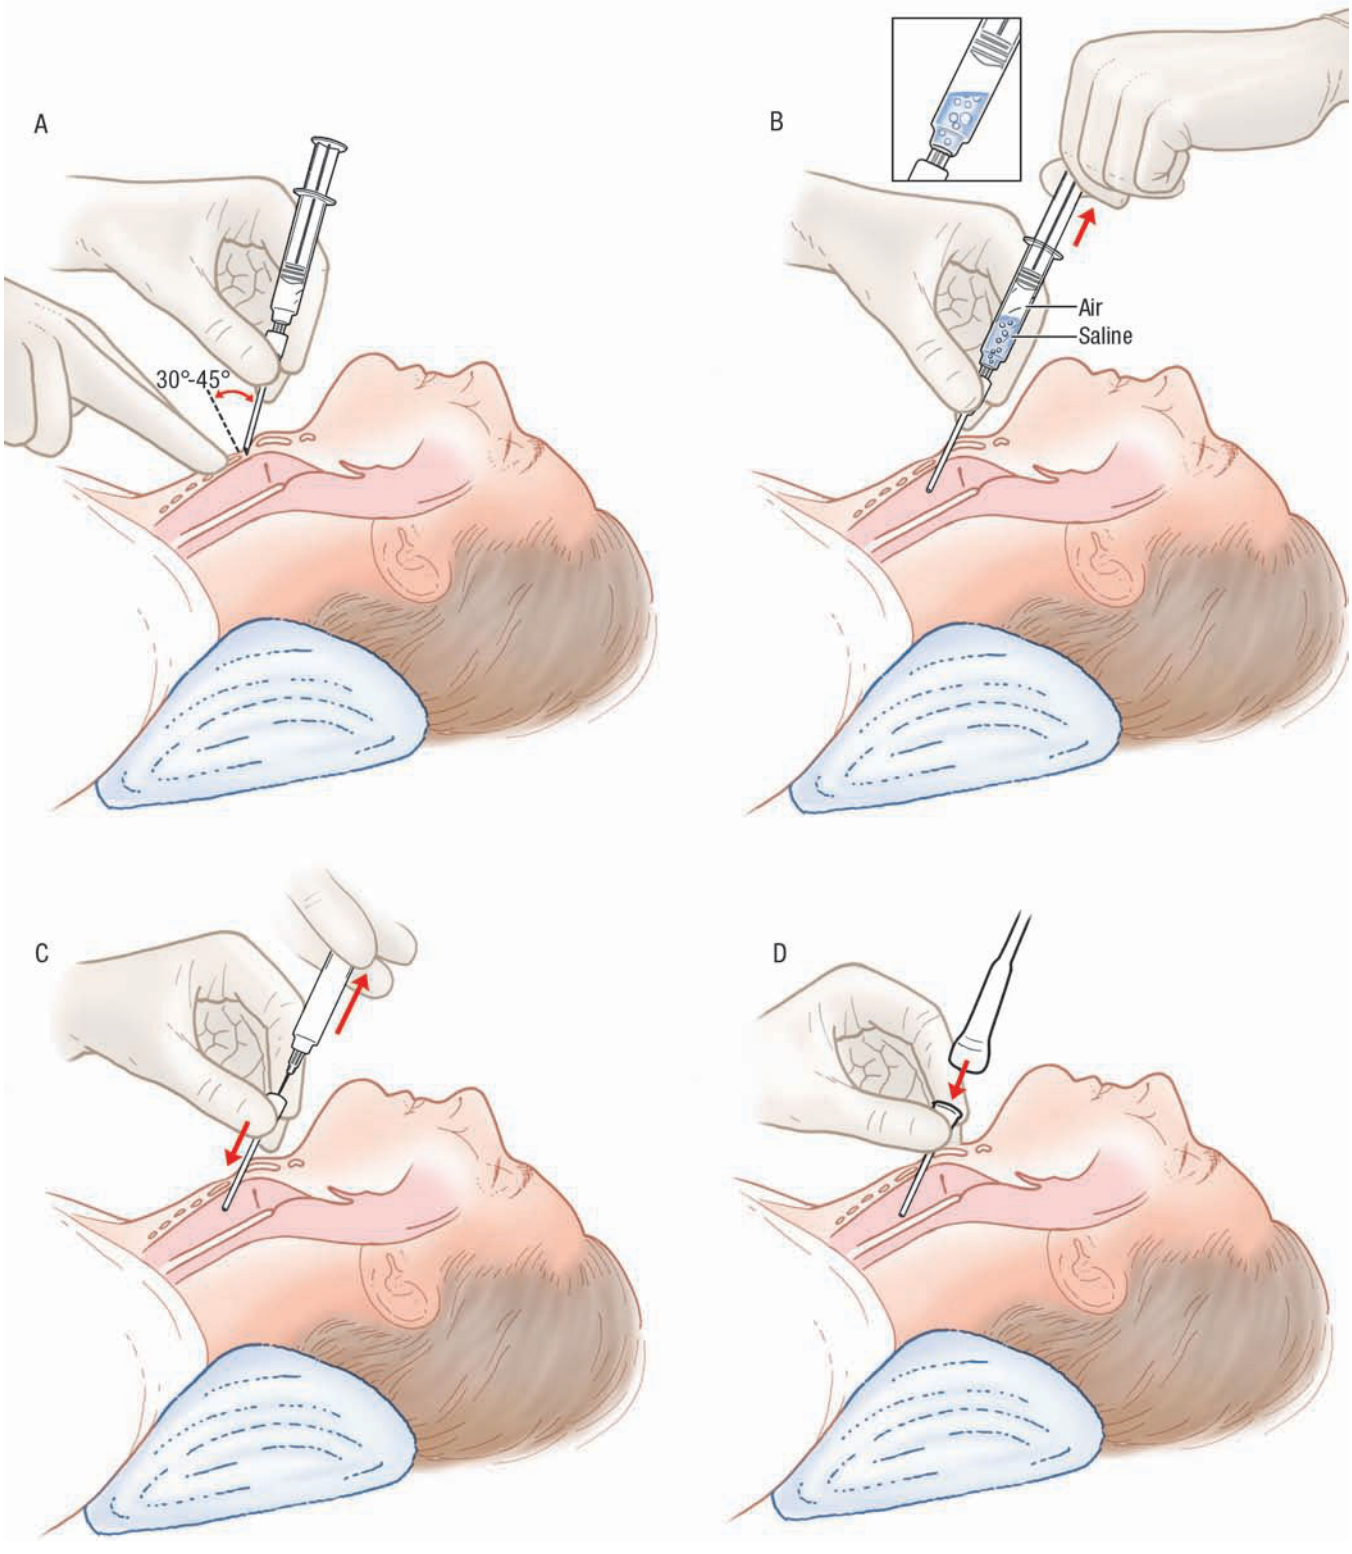

FIGURE 25-12. Needle cricothyroidotomy. **A.** The catheter-over-the-needle is inserted 30° to 45° to the perpendicular (*dotted line*) and aimed inferiorly. **B.** Application of negative pressure (*arrow*) to a saline-containing syringe during catheter-over-the-needle insertion. Air bubbles in the saline confirm intratracheal placement of the catheter. **C.** The catheter is advanced until the hub is against the skin. The needle and syringe are then removed. **D.** High-pressure oxygen tubing is attached to the catheter and ventilation is begun.

(**Figure 25-15**). These devices are quick, simple to use, and do not require the use of a guidewire or the Seldinger technique. These are more likely to be used in the prehospital setting than in the Emergency Department.

The use of a bougie or endotracheal tube introducer may aid the performance of a surgical cricothyroidotomy.[26] Begin the procedure as described previously. Once the airway is controlled with the tracheal hook, insert a bougie or endotracheal tube introducer through

FIGURE 25-13. A "homemade" tracheal hook.

the incision, directed inferiorly, and into the trachea. The bougie or endotracheal tube introducer will provide tactile feedback as it crosses the tracheal rings. Advance the tracheostomy tube or endotracheal tube over the bougie or endotracheal tube introducer and into the trachea. The major advantages of these devices are their lengths. It will not pull out and it will ensure that the tract is not lost.

Several quick assembly and low cost needle cricothyroidotomy setups can be put together quickly with commonly available equipment in the Emergency Department.[27] Insert a catheter-over-the-needle as previously described. Remove the needle, leaving the angiocatheter through the skin and into the airway. Attach and connect the following components in the listed order to the hub of the angiocatheter. The first consists of a 3.5 mm endotracheal tube respiratory adapter and a bag-valve device. The second consists of a 10 mL syringe without the plunger, a 7.0 mm endotracheal tube inserted into the syringe, and a bag-valve device. The third consists of a 3 mL syringe without the plunger, a 7.0 mm endotracheal tube respiratory adapter, and a bag-valve device. The fourth consists of the cut distal 10 cm of an intravenous infusion tubing, a 2.5 mm endotracheal tube respiratory adapter, and a bag-valve device.

ASSESSMENT

Immediately after securing the tracheostomy tube, confirm its proper positioning by auscultation of bilateral breath sounds, chest rise, and end-tidal CO_2 monitoring. Obtain a chest radiograph to confirm the position of the tube and rule out the presence of a pneumothorax.[12]

FIGURE 25-14. The Rusch QuickTrach.

FIGURE 25-15. The Bivona Nu-Trake.

AFTERCARE

The tracheostomy tube should be held in place firmly while the patient is ventilated with a bag-valve device or a ventilator.[11] **Do not release the hold on the tracheostomy tube until it is secured.** Obtain hemostasis of the wound edges by grasping any bleeding vessels with a hemostat and place an absorbable 3-0 suture over the vessel. If the skin incision is significantly larger than the tracheostomy tube, pack the wound with iodoform gauze. Secure the tracheostomy tube by placing twill tape (tracheostomy tape) through one end of the flange, around the patient's neck, and through the other end of the flange.[11,12] An alternative is to suture the four corners of the tracheostomy flange to the patient's skin using 3-0 nylon suture.

If an endotracheal tube was inserted, it should also be secured. Wrap tape around the endotracheal tube as it exits the incision site. Wrap the tape around the patient's neck and back onto the endotracheal tube. Alternatively, a commercially available endotracheal tube holder can be used to secure the tube.

The tracheostomy or endotracheal tube can be removed easily when the indication for airway control no longer exists. This usually occurs after the patient is orotracheally intubated, nasotracheally intubated, or has a formal tracheostomy performed. After removal of the tube, place an occlusive dressing, such as petroleum gauze, over the incision until it heals. If the patient is predicted to require ventilatory management for more than 7 days, it is advised that the cricothyroidotomy be converted to a formal tracheostomy to minimize the risk of long-term complications.

COMPLICATIONS

Complications following a cricothyroidotomy can be classified as early or late based on when they occur. Early complications will be recognized either immediately after insertion of the tracheostomy tube or within a few hours. Late complications may not be apparent for weeks to months following the procedure.

The most serious early complication is malposition of the tracheostomy tube within the soft tissues of the neck. If the tube is not within the trachea, the patient cannot be ventilated or oxygenated. This, fortunately, is easily recognized on auscultating the chest. It can be remedied by removing the tracheostomy tube and replacing it in its proper location. The tube may also be misplaced above or below the cricothyroid membrane. Placement above the cricothyroid membrane often results from inadequate palpation of landmarks and is associated with an incision into the larynx. The airway

should be converted to a tracheostomy once this malposition is recognized.[6] Placement below the cricoid cartilage has been estimated to occur in 10% of cricothyroidotomies.[2] There is no specific treatment required for this other than the recognition that the patient actually has a high tracheostomy.

Laryngeal injury may occur if the tracheostomy tube that is inserted is larger than the cricothyroid membrane. The cricothyroid membrane is only 9 to 10 mm in height in the average adult.[8,11] Placement of a tracheostomy tube with a larger outer diameter may cause a fracture of the thyroid cartilage. It is important that the tracheostomy tube placed is no larger than a #6.0 or a #7.0.[8,11] Placement of a larger tube is also associated with an increased incidence of subglottic granulation and stenosis.[2,4]

Incisional bleeding occurs in 4% to 8% of patients following a cricothyroidotomy.[2,4,6,8,15] This may result from transection of the anterior jugular veins if the incision extends too far laterally. Bleeding is usually easily treated by point ligation of the bleeding vessels and packing around the tracheostomy tube with iodoform gauze. A small amount of bleeding or oozing from the cricothyroid arteries can be tamponaded by packing iodoform gauze around the tracheostomy tube.

An emergent cricothyroidotomy is usually performed in less than sterile circumstances. There is thus a risk of developing a wound infection.[15] This is usually the result of skin flora. It can often be treated with wet-to-dry saline dressing changes. Occasionally, the infection will not resolve until the cricothyroidotomy tube has been removed, either by decannulation or conversion to a formal tracheostomy. Antibiotics are usually not required.

Late complications take two general forms: progressive airway obstruction and chronic voice changes. Patients with progressive airway obstruction present with slowly increasing stridor and dyspnea weeks to months after the procedure. This usually results from subglottic stenosis and granulation tissue formation at the site of the stoma.[2,6,13] It is unclear whether this complication results from the cricothyroidotomy or the tracheostomy tube. The majority of these patients have had prolonged endotracheal intubations before the cricothyroidotomy or prolonged tracheostomy placement after the cricothyroidotomy.[2,13,14,16] In one series, patients with a cricothyroidotomy for a prolonged period (average 72 days) had a 52% incidence of chronic obstruction compared to no obstruction in patients with cricothyroidotomy for a shorter period (average 27 days).[16] Another study recommended that the tracheostomy tube be removed by the fourth day to minimize these long-term complications.[9]

A final late complication is that of voice changes. This has been described in up to 25% of patients that received a cricothyroidotomy.[6,13–15] Again, many of these patients had other methods of airway management either before or after the cricothyroidotomy. Voice changes tend to be somewhat nonspecific. Patients will complain of hoarseness, decreased volume, and fatigue. These changes may be due to small amounts of granulation tissue at the stoma site and generally resolve over time.[4]

SUMMARY

A cricothyroidotomy is a potentially lifesaving airway management technique. It is an important procedure for the Emergency Physician to be skilled in, as it may represent the only access to the patient's airway. It can be used to provide oxygenation and ventilation to a patient when other less invasive airway control methods have failed or are contraindicated. It is a relatively safe, simple, and reliable procedure that can be performed within a few minutes. A self-contained percutaneous cricothyroidotomy kit is commercially available and simple to use. Knowledge of the anatomy of the anterior neck is essential in order to minimize complications.

26 Tracheostomy

Teresa M. Romano and Christopher J. Haines

INTRODUCTION

Control of the airway is the first priority in the resuscitation of a critically ill patient and must be accomplished before any other intervention can proceed. Emergency Physicians are equipped with multiple nonsurgical techniques and devices to secure an airway including orotracheal intubation, nasotracheal intubation, and laryngeal mask airways. Unfortunately, there are cases in which these methods become impossible or are contraindicated. In these instances, a surgical airway must be obtained and can be accomplished by performing a cricothyroidotomy or tracheostomy. Cricothyroidotomy is described in Chapter 25. This chapter will focus on the indications, technique, and complications for a tracheostomy.

A tracheotomy is the surgical creation of an opening into the trachea, while tracheostomy refers to the more permanent procedure of bringing the tracheal mucosa into contact with the skin of the neck.[1,2] The most traditional role for a tracheostomy is as an elective procedure done in patients with the need for a prolonged artificial airway. The role of a tracheostomy for emergent airway access has diminished as newer, safer, and equally effective techniques have evolved.

Familiarity with the methods to perform a tracheostomy is still valuable. Knowledge of proper techniques, possible indications, limitations, and likely complications will guide one's judgment in critical moments, when it most counts. Understanding the procedure for a tracheostomy will allow Emergency Physicians to properly care for a problem or complication when a patient with a tracheostomy tube presents to the Emergency Department.

ANATOMY AND PATHOPHYSIOLOGY

A surgical approach to the airway relies upon a sound knowledge of the anatomy of the neck and a safe approach to the trachea. **A careful review of this anatomy illustrates how critical it is to remain in the midline in order to avoid morbidity and mortality.** External landmarks are useful in identifying the significant structures of the airway (**Figure 26-1**).[3,4] The laryngeal prominence is a useful guide to the thyroid cartilage. The cricoid cartilage can be identified as a ring just inferior to the thyroid cartilage. In the absence of edema or

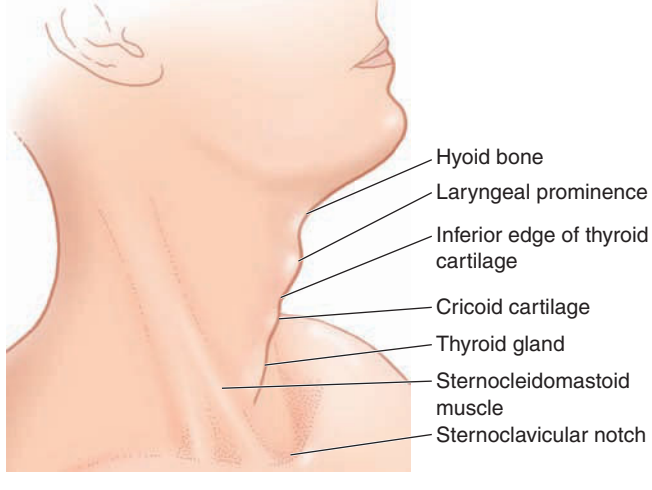

FIGURE 26-1. Lateral view of the topographic anatomy of the neck.

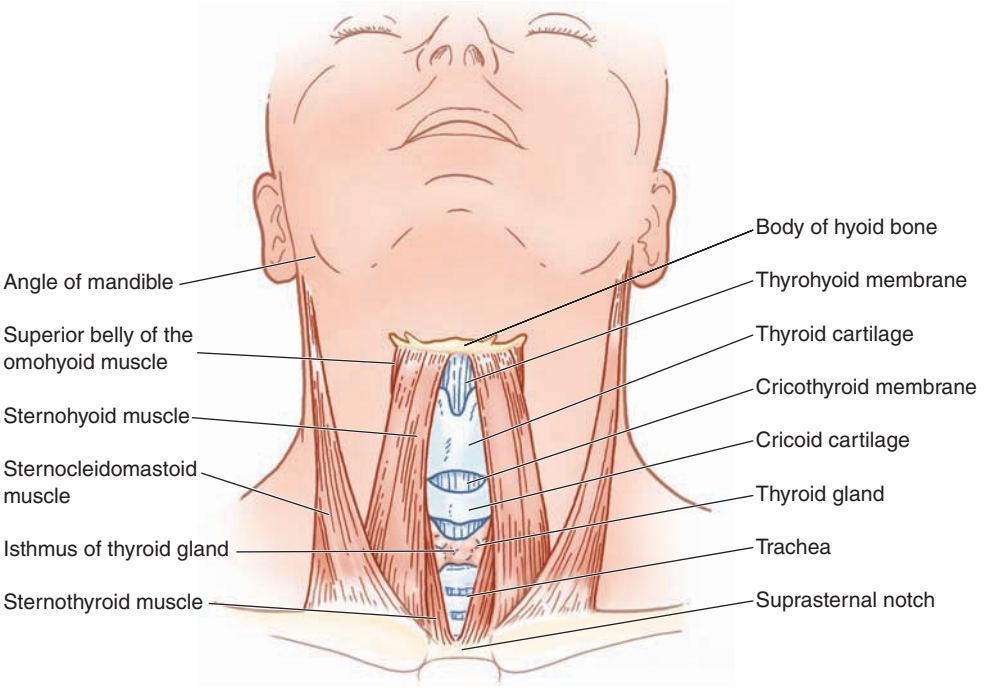

FIGURE 26-2. The superficial muscles and airway structures in the neck.

a hematoma, a finger marched down the midline from the cricoid cartilage can palpate and identify the cartilaginous rings of the trachea. In an emergent situation, these external landmarks may be all a physician has to guide the establishment of a surgical airway.

The neck is a complex three-dimensional structure with numerous vital structures coursing through a small space (**Figures 26-2** through **26-6**). The cervical portion of the airway is anterior, superficial, and midline. It is covered by skin, subcutaneous tissue, and numerous muscles (**Figure 26-2**). The basic cartilaginous framework of the airway begins superiorly at the hyoid bone and continues inferiorly with the larynx and trachea (**Figure 26-3**). The external skeleton of the larynx comprises the hyoid bone, thyroid cartilage, and cricoid cartilage.[5] The hyoid bone is a U-shaped structure attached to the mandible, tongue, and base of the skull by muscles. It is the most stable portion of the airway. Even in the presence of pathology, the hyoid bone is remarkably constant in position and can be considered a stable landmark.[6–8]

The larynx is easy to identify externally. The prominent thyroid cartilage forms the laryngeal prominence (Adam's apple) at its inferior pole (**Figure 26-3**). It is a freely mobile structure that is anchored by muscles and moves with deglutition. Airway manipulation done on an awake patient will need to fix the larynx to avoid involuntary movement of the larynx from reflex swallowing. The thyroid cartilage is attached to the cricoid cartilage via the cricothyroid membrane (**Figure 26-3**). This is the site for a cricothyroidotomy and can be identified by palpating a slight indentation inferior to the laryngeal prominence. The cricoid is signet ring-shaped and is the only complete cartilaginous ring in the airway. Procedures should avoid damage to the cricoid cartilage, fearing a loss of stability in the airway. The cricotracheal ligament attaches the cricoid cartilage to the trachea.

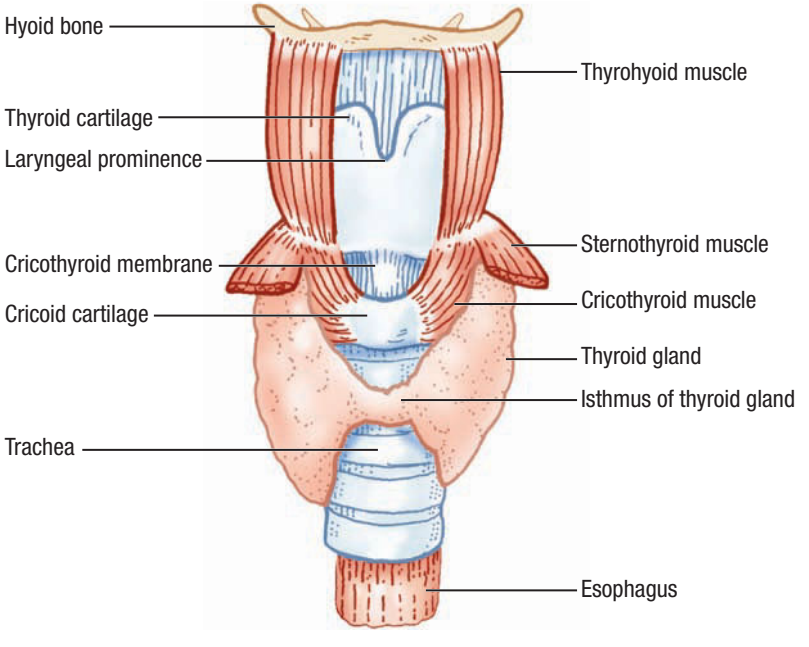

FIGURE 26-3. The framework of the airway in the neck.

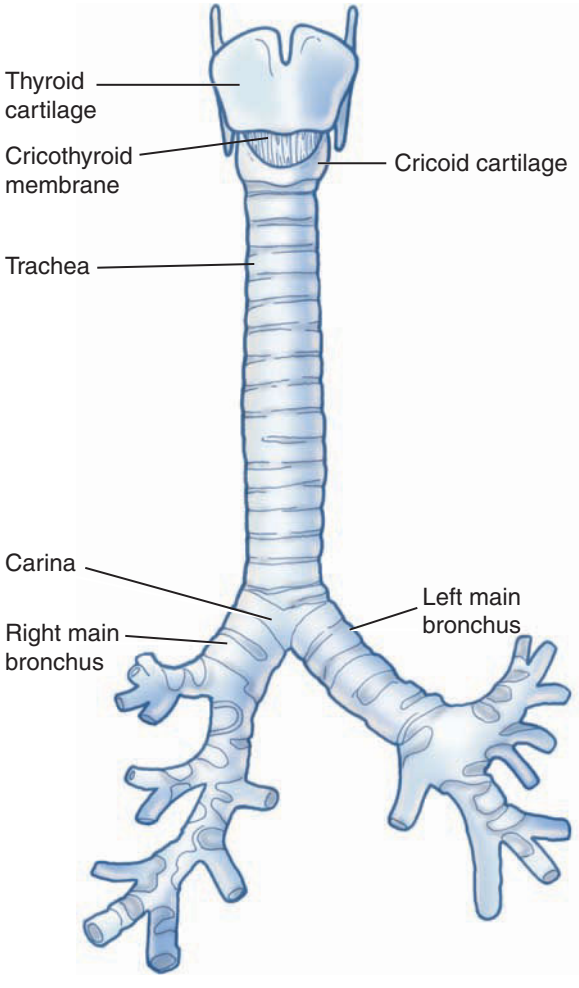

FIGURE 26-4. The cartilaginous framework of the airway.

The trachea is a cartilaginous and membranous tube that is approximately 10 to 11 cm long and 2 to 2.5 cm wide in the average adult. In the pediatric patient, the length and width of the trachea will vary depending on the size and age of the child.[9] It extends from the neck into the thorax, where it ends at the carina by dividing into the right and left mainstem bronchi (**Figure 26-4**). It is made up of 16 to 20 incomplete U-shaped cartilaginous rings anteriorly and laterally. The posterior portion is comprised of a fibromuscular membrane. This membrane attaches the cartilaginous rings to one another and imparts great elasticity in the trachea.[2] Full extension of the neck adds significant length to the supraclavicular trachea. This feature should be taken advantage of when performing a tracheostomy.[10]

The trachea is bordered anteriorly by skin, subcutaneous tissue, platysma muscle, pretracheal fascia, and the thyroid gland (**Figure 26-5**). The pretracheal fascia is the anterior portion of the deep cervical fascia. It descends from the thyroid and cricoid cartilages and splits to enclose the thyroid gland, trachea, and esophagus. The pretracheal fascia continues downward into the thorax and mediastinum. Anterior to the trachea, it is very thin and inconsequential. Laterally, it is extremely thick and blends with the carotid sheath.

The thyroid gland lies anterior to the second through fourth tracheal rings and is inevitably encountered during a tracheostomy. It is a richly vascular structure (**Figure 26-6**) that receives its blood supply from the superior thyroid artery (a branch of the external carotid artery) and the inferior thyroid artery (a branch of the thyrocervical trunk). These vessels anastomose into a rich plexus on the anterior surface of the thyroid gland. These major arteries do not usually cross the midline.

Unfortunately, the midline is not always free of blood vessels. An unpaired thyroid ima artery will occasionally be found in the midline to supply the isthmus of the thyroid gland. The anterior thyroid veins often form a vascular arch across the midline and just inferior to the thyroid gland. A hastily performed tracheostomy or one carried out under difficult conditions may encounter significant hemorrhage from transected vessels.

A number of vital structures surround the trachea and are at risk for injury during a tracheostomy. Their positions relative to one another are best appreciated in a cross-sectional view of the neck (**Figure 26-5**). The deep strap muscles, the sternohyoid and sternothyroid, run adjacent to the trachea and may have to be reflected away for adequate visualization (**Figure 26-2**). The right and left lobes of the thyroid gland encase the upper trachea (**Figures 26-5 & 26-6**) with the thyroid isthmus crossing anteriorly from the second to the third tracheal rings.[2] Close to the thyroid lobes, the recurrent laryngeal nerves run vertically on both sides of the trachea. These nerves are particularly vulnerable when dissection is extended laterally.[11] The common carotid artery, internal jugular vein, and vagus nerve are contained by the carotid sheath and lie adjacent to the thyroid gland. The carotid sheath lies extremely close to the trachea

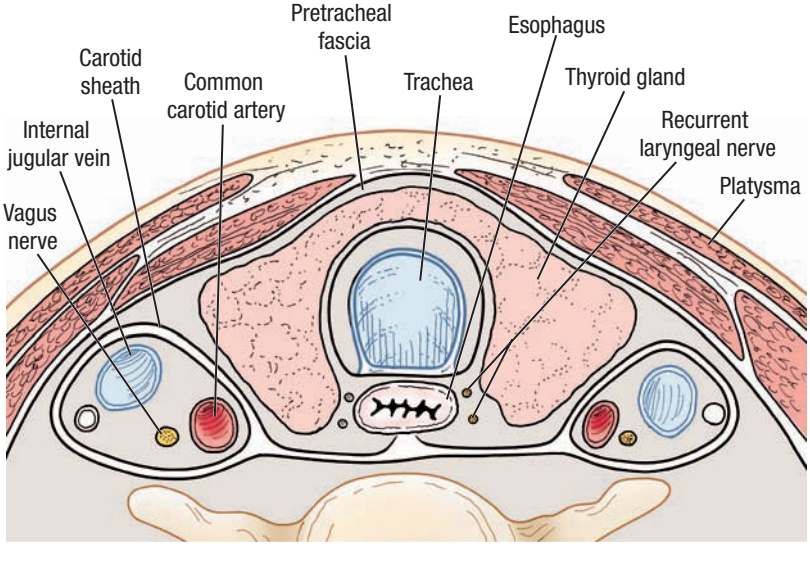

FIGURE 26-5. Cross-sectional anatomy of the neck at the level of the isthmus of the thyroid gland.

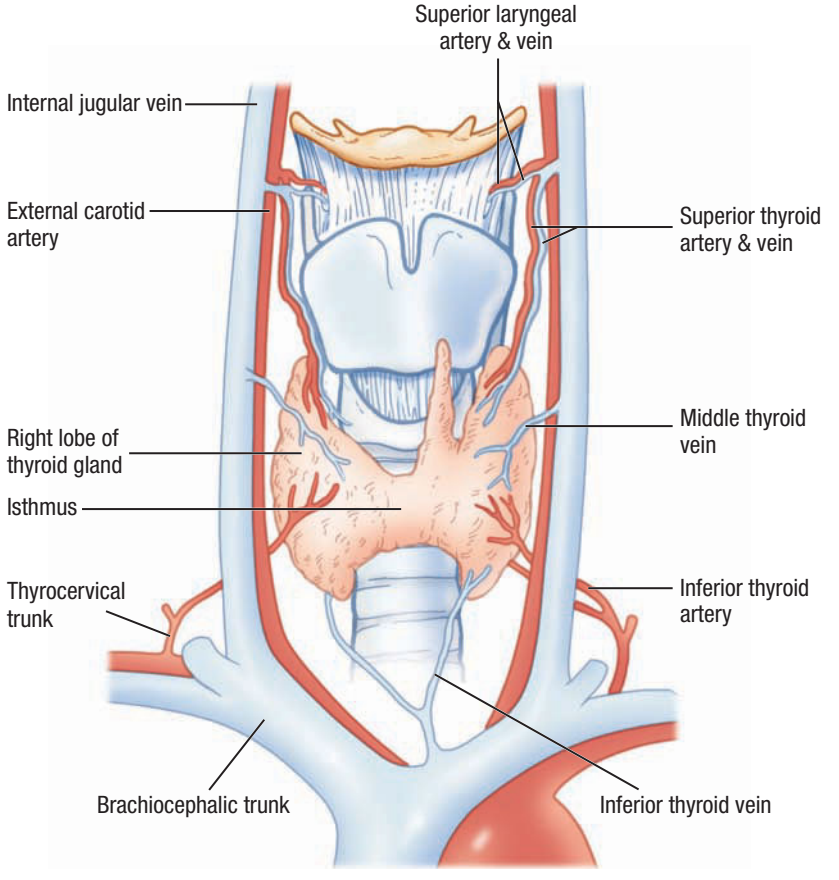

FIGURE 26-6. Vascular structures supplying and surrounding the thyroid gland.

in infants and have been mistaken for the trachea in emergent situations.[11] The innominate or brachiocephalic artery crosses left to right immediately anterior to the trachea, while the esophagus lies immediately posterior to the trachea. Erosion of the anterior tracheal wall can occur with prolonged tracheostomy tube placement leading to a tracheoinnominate artery fistula. The parietal pleura can be found on either side of the trachea at the sternal notch and is also at risk of injury during a tracheostomy.

INDICATIONS

The tracheostomy is an ancient and time-honored technique for securing and maintaining an artificial airway. The American Academy of Otolaryngology—Head and Neck Surgery has proposed specific clinical indicators for the use of a tracheostomy (**Table 26-1**).[12] A number of indications for tracheostomy are widely accepted (**Table 26-2**).[11–18] As mentioned previously, a tracheostomy is generally considered an elective procedure done under nonemergent conditions after the airway has been secured by other techniques.[19–23] Its use as an emergency procedure is controversial. Used by battlefield surgeons during wartime, its reputation as a procedure of last resort is not without reason. When performed under emergency circumstances, it is fraught with danger.

A tracheostomy is frequently considered in the treatment of upper airway obstructions including epiglottitis, deep space neck infections, angioedema, airway foreign bodies, multiple lacerations to the floor of the mouth, and complex facial fractures. Although these conditions can create serious and immediate airway compromise, the airway can be managed in most cases with orotracheal

TABLE 26-1 Clinical Indications for Performing a Tracheostomy, as Proposed by the American Academy of Otolaryngology–Head and Neck Surgery

Upper airway obstruction, including
Obstructive sleep apnea
Bilateral vocal cord paralysis
Need for prolonged mechanical ventilation
Inability of patient to manage his or her secretions
Facilitation of ventilation support
Adjunct to manage head and neck surgery
Adjunct to manage head and neck trauma
Difficulty with intubation and need for airway

Source: Adapted from Weissler.[12]

TABLE 26-2 Commonly Cited Indications for Performing a Tracheostomy

Airway obstruction[13–15,17]
Tumor, trauma, hemorrhage
Edema, foreign body, infection
Congenital airway anomalies
Trauma to face and neck with airway compromise[13,14,16]
Inability to open mouth
Maxillomandibular fixation, trismus[18]
Angioedema[15,17]
Need for prolonged ventilatory support[14]
Impaired clearance of secretions
Need for aggressive pulmonary toilet[15]
Laryngeal injury[7,10,15]
Unstable cervical spine[16]
Laryngospasm[17]
Surgical airway in an infant[7]
Inability to intubate by other measures[16]

intubation. **An emergency tracheostomy is not the treatment of choice but rather the choice of last resort**.

There are a few clinical settings in which an emergency tracheostomy should be considered: laryngotracheal injury with airway disruption;[11,28,29] severe maxillofacial trauma; complete subglottic obstruction; and the need for an airway when all other methods have failed. With the exception of these limited applications, an emergency tracheostomy is discouraged.[11,14,32,33]

LARYNGOTRACHEAL TRAUMA

Most head and neck trauma patients can be managed with nonsurgical airway techniques. There are a number of options available, including orotracheal intubation, nasotracheal intubation, intubation guided by a lighted stylet or "lightwand," retrograde guidewire intubation, and fiberoptic-assisted intubation. Nasotracheal intubation should be avoided in patients with a potential head injury. If a surgical airway is necessary, a cricothyroidotomy is usually the procedure of choice.

Laryngotracheal injuries are rare but potentially life threatening. When suspected, immediate efforts should focus on getting the patient to the operating room. These injuries can result from either blunt or penetrating injury to the neck. They are often accompanied by edema, hemorrhage, subcutaneous emphysema, and fracture of either the thyroid or cricoid cartilages. In their presence, rapid access to the cricothyroid membrane may be limited, making it difficult to perform a cricothyroidotomy, and tracheostomy should be considered.[11,34–36] Blunt injury has been described when the anterior neck forcefully strikes a fixed object such as a rope or a cable. A classic example of this type of injury is forcefully striking the anterior neck against the steering wheel during high-speed motor vehicle accidents.[11,35,36] Penetrating injuries to the airway are usually apparent; however, blunt injuries to the trachea require a high index of suspicion.[36,37] In a review of 51 patients with blunt injury to the trachea, the most common presenting signs and symptoms included subcutaneous emphysema, respiratory distress, hoarseness or dysphonia, and hemoptysis.[36] In this same review, a high rate of endotracheal intubation failure was reported with the conclusion that emergent tracheostomy was the best means of airway control.[36] In cases of penetrating trauma to the larynx, physicians may consider obtaining emergent airway control directly through the wound as a temporary measure prior to operative management.[9]

Laryngotracheal disruption, occurring when the larynx and trachea become separated, is an unusual injury. This is the one injury in which a tracheostomy is the undisputed method for establishing and securing the airway. Patients with laryngotracheal disruption may exhibit varying degrees of respiratory distress, visible bruising over the anterior neck, hoarseness or aphonia, subcutaneous emphysema or blood-streaked sputum. A defect may be palpable in the neck. Soft tissue radiographs of the neck may reveal an interrupted air column. If the airway is disrupted, a "low tracheostomy" between the fourth and fifth tracheal rings should be performed. The severed airway will tend to retract into the thorax, and a low tracheostomy will offer the best chance of securing the dismembered segment. Misguided attempts to visualize the airway, intubate orally, or perform a cricothyroidotomy may further damage the already precarious airway. This is fortunately a rare injury with only a few case reports in the literature.[28,29] A tracheostomy performed in this setting is more treacherous than usual. Although a tracheostomy may be the only way to secure the airway, this airway intervention has a better chance of success when performed in the operating room.

SURGICAL AIRWAYS IN THE PEDIATRIC PATIENT

Surgical approaches to the airway are more difficult and complicated in pediatric patients, especially newborns and infants. In the child, the larynx is positioned more cephalad than in the adult, allowing relative protection by the mandibular arch.[9] It is more anteriorly located and significantly smaller than in adults, as well as more floppy and mobile. The infant's cricothyroid membrane, unlike that of the adult, is extremely narrow and cannot easily be used for access to the airway. For this reason, a surgical cricothyroidotomy should be avoided until a child is greater than 12 years old.[9,11] Attempts at creating emergency surgical airways in children are typically acts of desperation. A calm, reasoned approach to the pediatric airway and common respiratory problems is essential. Efforts should first be made to suction the airway clear of secretions, followed by ventilation with a bag-valve-mask device. **Direct visualization by laryngoscopy and orotracheal intubation should be attempted before resorting to a surgical airway.** If an unstable patient cannot be ventilated, a needle cricothyroidotomy can serve as a temporizing measure until a surgical team can be assembled and better control achieved.[9,11]

In the pediatric population, laryngotracheal injury is rare.[11] Typically, children sustain blunt anterior neck injury as the result of high-speed accidents involving bicycles, falls, and motor vehicles. Additionally, this injury type may be the result of sports-related activity. Clinical signs and symptoms of laryngeal or tracheal trauma mirror that of adults. Airway management in these patients can be achieved with a tracheostomy. However, this may be quite difficult and is only advocated by some authors.[9] Attempts to obtain surgical assistance should be sought immediately.

CONTRAINDICATIONS

Simply stated, an emergency tracheostomy is contraindicated when other methods can be used to secure the airway. There are a few instances when an immediate surgical airway is necessary. **Cricothyroidotomy is the procedure of choice when a surgical approach to the airway is required**. Compared to a tracheostomy, a cricothyroidotomy is faster and more direct; it relies predominantly on external landmarks, requires only a single operator, can be done with ambient lighting, and requires a limited amount of equipment.[12,24] In contrast, a tracheostomy is a procedure requiring multiple steps. It involves direct visualization to dissect through vascular structures and requires better light than is commonly present at the bedside. It is easier and therefore faster to execute if one has an assistant, proper suctioning equipment, and electrocautery. Without these advantages, the technique is difficult and likely to be complicated. A "timely trach" can be performed within 5 to 10 minutes.[12] However, reported times to definitive airway during elective open tracheostomies have ranged from 13.5 to 105 minutes.[24–27] Although this time frame may be adequate for urgent situations, it is too slow for the true emergency in a patient who lacks an airway.

EQUIPMENT

A tracheostomy requires an extensive amount of equipment. Appropriate supplies should be sterilized and assembled in a prepackaged tray. A list of required equipment is given in **Table 26-3**. If such a tray is not available, supplies that are immediately on hand have to suffice. A thoracotomy or a major procedure tray will contain most of the required equipment.

PATIENT PREPARATION

Patient preparation will depend largely on the circumstances dictating the procedure. If the patient is uncooperative, hypoxic, or thrashing about, rapid control will have to be established with a sedative. The ideal agent is one that sedates with minimal hemodynamic consequences, preserves spontaneous respirations, and leaves an intact

TABLE 26-3 The Supplies Required to Perform a Tracheostomy

Patient preparation	Setup
Cardiac monitor	Povidone iodine or chlorhexidine solution
Pulse oximeter	Surgical drapes to enclose the field
Intravenous line with saline	Sterile gown, gloves, and mask
Oxygen	
Ambu bag for ventilating patient	
Procedure	
Local anesthesia	Two pairs of scissors, one straight and one curved
10 mL syringe	Two tissue forceps without teeth
1% lidocaine	Two Allis forceps, to grasp the trachea
18 gauge needle	Two small rakes, for exposure
25 gauge needle	Mastoid retractor
#10 scalpel blade and handle	Trousseau dilator
#11 scalpel blade and handle	Two tracheal hooks
Two skin forceps	10 mL syringe
Eight small curved hemostats	Umbilical tape
Sterile 4 × 4 gauze squares, two dozen	Needle holder
Two Kocher forceps (if needed, to clamp the thyroid)	
Frazier suction catheter with suction tubing	
Suture ligatures (3–0 chromic, 3–0 silk, and 3–0 nylon)	
Tracheostomy tube, appropriate size for patient	
Water-soluble lubricant or anesthetic jelly	
Suction source and tubing	

gag reflex. If the patient is awake and cooperative, calm reassurance may allow the procedure to be performed under local anesthesia. If the patient is unconscious, a local anesthetic is sufficient.

Place a rolled towel under the patient's shoulders and neck if no contraindications exist (Figure 26-7). This detail cannot be emphasized enough. Full neck extension brings the airway anterior and increases the length of the supraclavicular trachea by as much as 2.6 cm.[9] It enlarges the surgical field for improved access. Neck extension tends to fix the airway in position and pull it taut. When the neck is in a neutral or flexed position, the trachea lies more posteriorly and is more "floppy." In this situation, it is easier for the operator to stray off midline. When the neck is flexed, the surgical field may be reduced to a dark hole with poor visibility. In the pediatric patient, a certain degree of extension is helpful, but full extension may occlude the airway.

FIGURE 26-7. Optimal patient positioning for a tracheostomy with the neck extended.

FIGURE 26-8. Hand positioning to palpate the anatomic landmarks.

Prior to beginning the incision, the physician should check the equipment. A tracheostomy tube that is appropriate for the patient's size should be selected. An average male will accommodate a size 7 or 8 Shiley tracheal tube. An average-size female will accommodate a size 6 or 7 Shiley tracheal tube. The cuff of the tracheal tube should be tested prior to use. As an alternative, an endotracheal tube can be used.

Identify the anatomic landmarks required to perform this procedure. Using the nondominant hand, place the thumb on one side and the middle finger on the other side of the patient's trachea (**Figure 26-8**). Identify the laryngeal prominence (Adam's apple) with the index finger. Slide the index finger caudally to identify the cricothyroid membrane, cricoid cartilage, and tracheal rings.

Clean the neck of any dirt and debris. Even during the resuscitation of an unstable patient, there should be adequate time for the use of aseptic solution as well as sterile technique. Prepare yourself by applying a mask, eye protection, sterile gown, and sterile gloves. Apply a sterile drape to isolate a surgical field. Infiltrate local anesthetic solution along the planned incision line. It was once thought that injection of local anesthetic into the trachea blunts the cough reflex and provides a sense of depth of the airway. A recent review of 97 patients who underwent an awake tracheostomy noted that this could result in cough, agitation, and less beneficial outcomes.[38]

Once the patient is positioned, prepped, and anesthetized, establishment of the airway should be just 2 to 3 minutes away. **The last step in preparation should be the mental decision that no other technique will suffice and the commitment to proceed with confidence.**

TECHNIQUE

In the most critical situation, the simplest technique is likely to be the most successful.[39] The right-handed operator should stand to the patient's right and fix the airway with their left hand (**Figure 26-8**). Left-handed operators should adjust their technique based on their preference for handedness. Apply the thumb and third digit of the nondominant hand on the thyroid cartilage while the index finger palpates the cricoid and tracheal rings (**Figure 26-8**). An awake or lightly anesthetized patient may swallow or gulp during

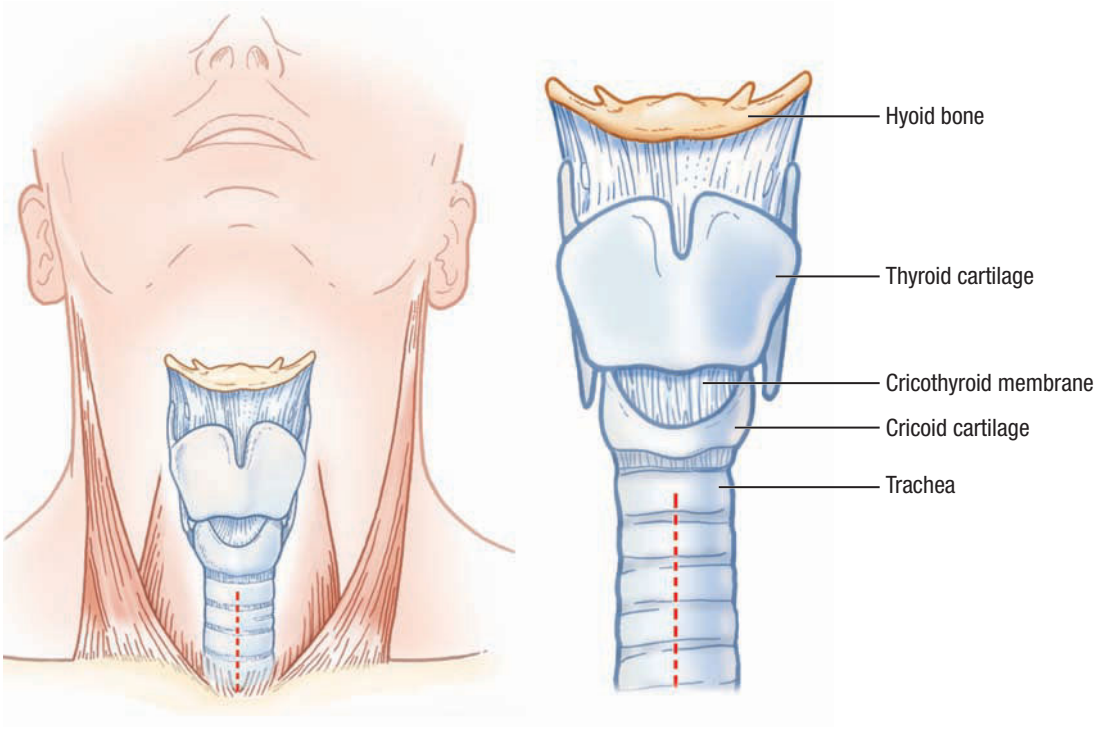

FIGURE 26-9. The skin incision is made in the midline, beginning below the cricoid cartilage and extending down toward the supraclavicular notch. An incision made with these landmarks will lie over the second through fourth tracheal rings.

the procedure, thereby moving the landmarks. Fixing the left hand firmly on the upper airway will minimize this distraction.

A vertical incision is preferred in the emergent setting because it allows greater exposure of the cricothyroid membrane and the trachea, and avoids traversing lateral structures.[11] Make a 3 or 4 cm vertical midline incision through the skin and subcutaneous tissues beginning just below the cricoid cartilage and extending inferiorly to the supraclavicular notch (**Figure 26-9**). A larger skin incision causes no harm as long as it remains superficial, to avoid damaging the cricoid cartilage. **Extreme care should be taken to ensure that the incision and further dissection remain in the midline.**[11]

Once the skin and subcutaneous tissue have been incised, attention should be directed toward clearing the pretracheal space and defining the tracheal rings. Divide the superficial and deep strap muscles in the midline and retract them away from the trachea (**Figure 26-10**). Bluntly dissect free and reflect away any blood vessels in front of the trachea. If they impede progress, they can be clamped with hemostats and divided. The thyroid gland lies above the trachea. Bluntly dissect between it and the trachea with a hemostat to mobilize the thyroid gland (**Figure 26-11**). An alternative option to consider in the emergent setting is to use the nondominant index finger to dissect the pretracheal space bluntly and reflect the thyroid isthmus either superiorly or inferiorly. This minimalist blunt approach lacks finesse but is effective and timely.[14]

Retract the thyroid gland upward (**Figure 26-12**). If this becomes difficult, it may be faster to divide the isthmus between two hemostats (**Figure 26-13**). The divided edges can be oversewn after the tracheostomy tube is in place. Once the thyroid has been divided, the operating field will be cluttered with hemostats and may be partially obstructed. Do not apply traction to the instruments, as this can avulse tissue, leading to bleeding and further obstruction of the surgical field.

When ready to make the tracheal incision, it may be helpful to have an assistant place a tracheal hook under the first tracheal ring and apply traction superiorly and anteriorly (**Figure 26-14**). Have the assistant hold the tracheal hook in position. This will elevate and immobilize the trachea. The assistant should direct their hands superior to the wound to keep the field unobstructed. If the neck is properly extended, this may be unnecessary. If at any time identification of the trachea becomes difficult, needle aspiration may be used to confirm the presence of an air-filled tube.

Make an incision in the trachea. The preferred tracheotomy is a midline vertical incision extending from the second through the

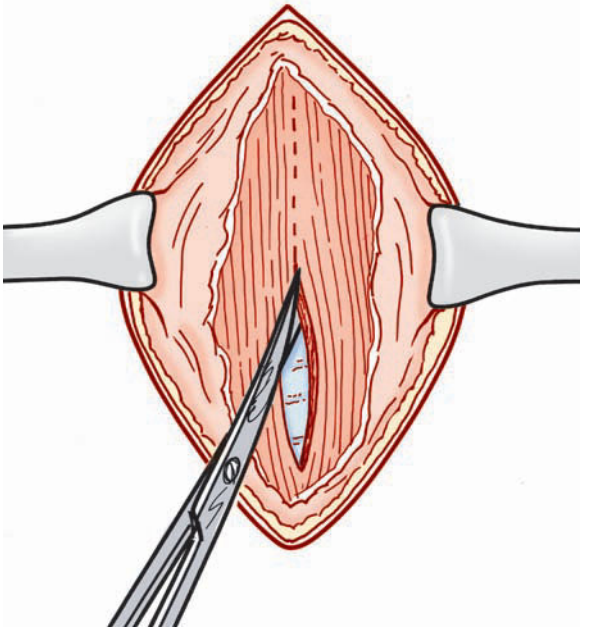

FIGURE 26-10. The skin and subcutaneous tissues have been retracted. The strap muscles are divided in the midline to expose the pretracheal space.

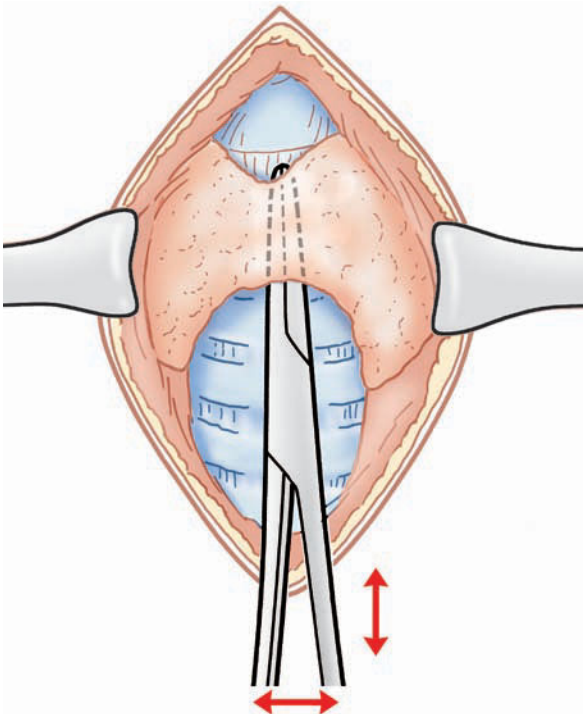

FIGURE 26-11. The thyroid gland is bluntly dissected from the trachea. Arrows represent movement of the hemostat.

fourth tracheal rings (**Figure 26-15A**). There are other options, but they are discouraged in the emergent setting because they stray from the midline (**Figures 26-15B** to **26-15D**). Insert a Trousseau dilator or hemostat into the incision. Use the dilator to open and widen the incision. Alternatively, the sides of the tracheal incision can be grasped and held open with Allis forceps (**Figure 26-16A**).

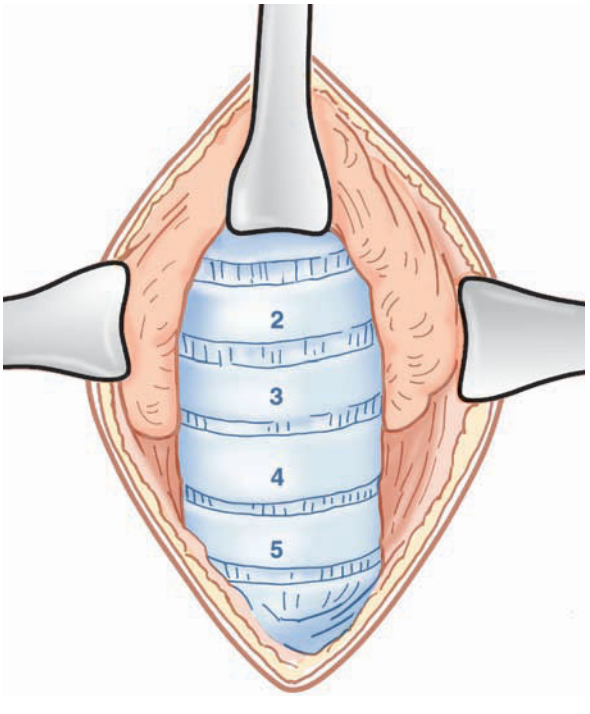

FIGURE 26-12. The thyroid gland is retracted upward and out of the surgical field.

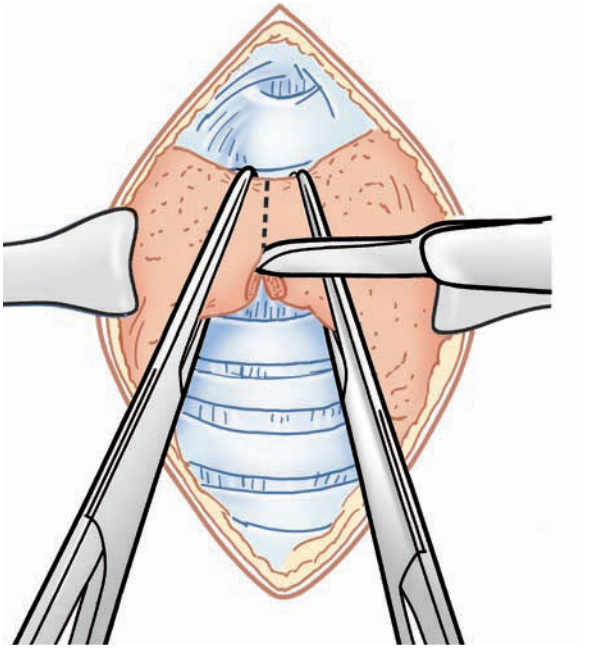

FIGURE 26-13. An alternative method of clearing the thyroid gland from the surgical field. The isthmus is clamped and transected.

Lubricate the appropriate size tracheostomy tube liberally. Insert the tracheostomy tube, with its obturator, through the tracheotomy while the incision is held open (**Figure 26-16A**). Advance the tracheostomy tube and inflate the cuff (**Figure 26-16B**). Hold the tracheostomy tube in place securely. Remove the obturator and insert the inner cannula. Attach a bag-valve device and begin ventilating the patient.

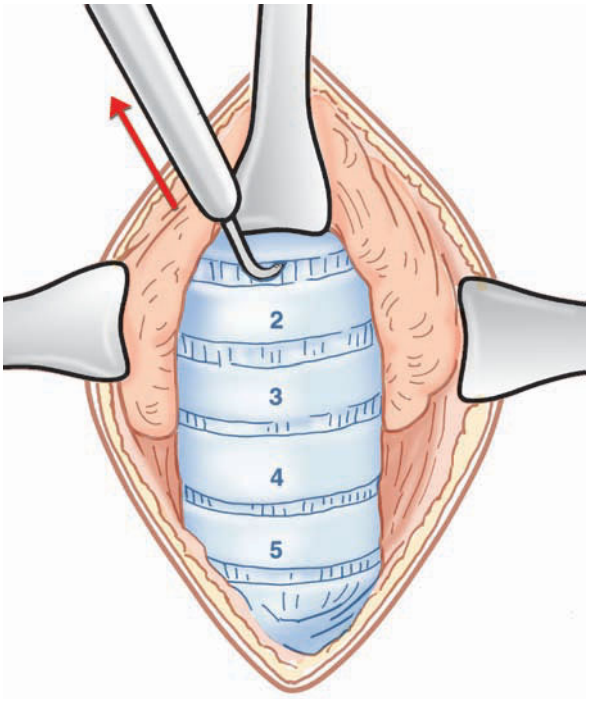

FIGURE 26-14. A tracheal hook is placed below the first tracheal ring to elevate and immobilize the trachea.

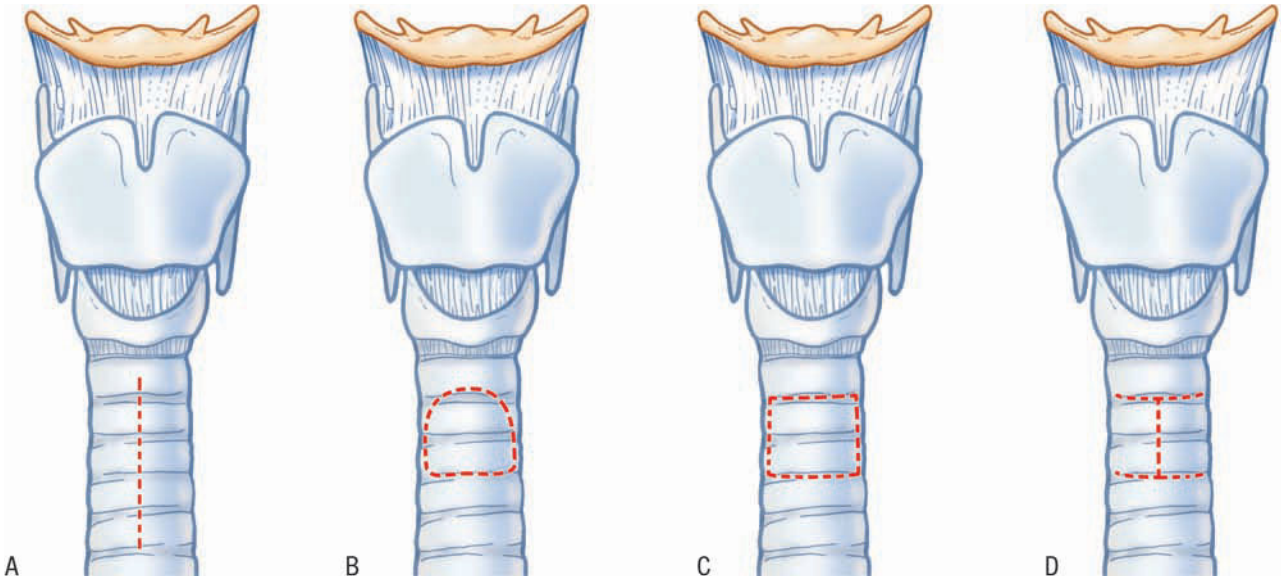

FIGURE 26-15. Types of tracheal incisions. **A.** A midline vertical incision through the second, third, and fourth tracheal rings. This is the preferred technique in an emergent procedure. **B.** A U-shaped inferiorly based window. **C.** A window has been created by excising the second and third tracheal rings. **D.** A T flap.

ALTERNATIVE TECHNIQUES

Since 1969, a number of authors have described a third invasive option for airway control, the percutaneous dilatational tracheostomy. Although techniques vary somewhat, they all rely on an initial puncture of the airway followed by progressive dilatation of a tract. Once a sufficiently large tract is formed, an airway tube is placed. There is now enough evidence to argue that percutaneous tracheostomies are competitive with, and perhaps preferable to, formal open tracheostomies done under elective conditions.[25,26,40–52] Several large series of percutaneous tracheostomies are now complete, but significant results are available only for elective tracheostomies done in patients who have already been intubated.[41,43,44,49] There are small case studies that have been published regarding the successful use of percutaneous dilatational tracheostomy in an emergency setting. These authors conclude that percutaneous dilatational tracheostomy is an effective airway, providing an alternative to endotracheal intubation. The resultant airway is stable and does not require conversion in the immediate postresuscitation period.[53] Furthermore, a recent case series of four patients undergoing percutaneous dilatational tracheostomy in the intensive care setting illustrated the possible benefits of performing the procedure in combination with ultrasound guidance.[54] The authors concluded that the use of ultrasound could identify patients unsuitable for the procedure, prevent puncture of aberrant vessels, estimate the distance from the surface of the skin to the trachea, and ensure accurate placement of the needle into the trachea.[54] While these studies are promising, larger studies are needed to determine the ultimate role of percutaneous dilatational tracheostomy in the emergency setting.[53] Cricothyroidotomy remains the procedure of choice for emergency surgical access to the airway.

ASSESSMENT

Once the airway is established, tracheostomy tube positioning should be confirmed by auscultation, ease of ventilation, and pulse oximetry. Obtain a chest and neck radiograph to confirm tracheostomy tube position and exclude a pneumothorax.

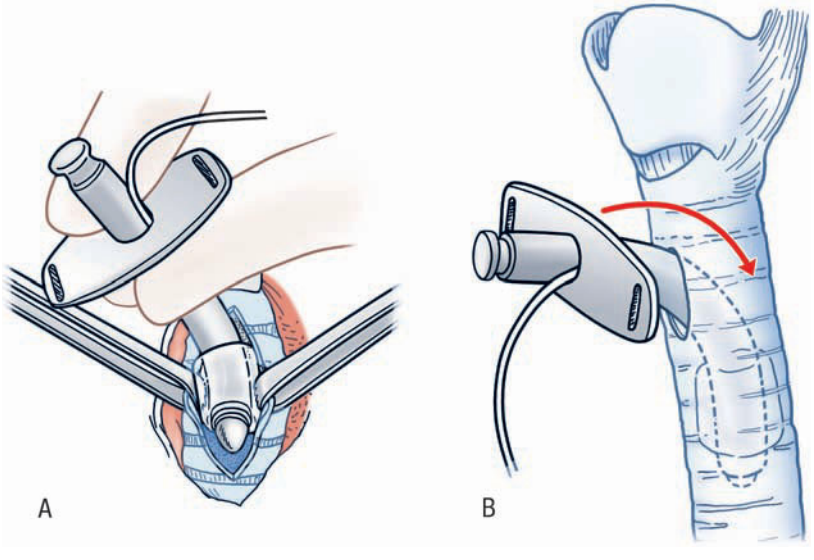

FIGURE 26-16. Insertion of the tracheal tube. **A.** The incision is held open with a Trousseau dilator, hemostat, or Allis forceps (shown here) as the tracheostomy tube is inserted. **B.** The tracheostomy tube is advanced and the cuff inflated.

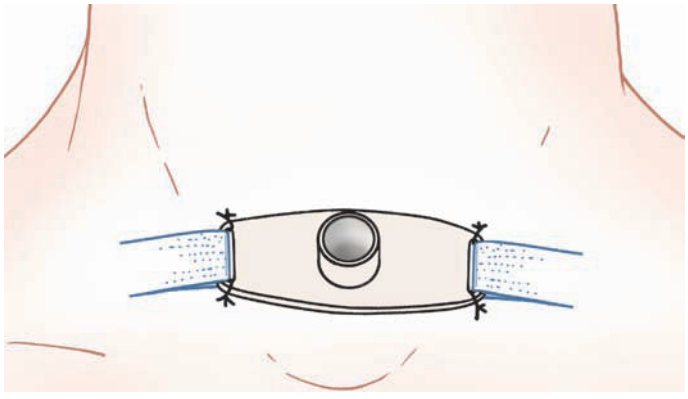

FIGURE 26-17. The tracheostomy tube is secured in place with umbilical tape ("tracheal tie"), then sutured.

TABLE 26-4 Complications of Tracheostomies

Immediate	Delayed	Postoperative
Hemorrhage	Hemorrhage	Disrupted tract
False passage	Tracheal stenosis	Displaced tube
Damage to surrounding structures	Subglottic stenosis	Obstructed tube, mucus plugging
Recurrent laryngeal nerve	Tracheoinnominate artery fistula	Delayed hemorrhage
Esophagus	Tracheoesophageal fistula	Subcutaneous emphysema
Posterior tracheal perforation	Fused vocal cords	Mediastinal emphysema
Common carotid artery	Delayed wound problems	Infection: wound, tracheitis, mediastinitis, and pneumonia
Internal jugular vein	Excess granulation tissue	Aspiration
Anterior jugular vein	Persistent stoma	
Pleura, pneumothorax		
Cricoid		
Air embolism		
Apnea		
Cardiac dysrhythmias		
Cardiac arrest

AFTERCARE

Once the airway has been established, inspect the wound to ensure hemostasis. Any clamped vessels or thyroid tissue should be tied. The skin edges do not need to be closed unless the skin incision was overly zealous. If the skin is reapproximated, close it loosely to avoid the development of subcutaneous emphysema. Secure the tracheostomy tube with umbilical tape wrapped around the neck. Suture the flange of the tracheostomy tube to the skin using 3-0 silk as an additional safeguard (**Figure 26-17**). If the wound is oozing, place a loose gauze pad between the skin and the tracheostomy.

Special care should be taken to protect the artificial airway. Suction the lumen frequently and as necessary to prevent obstruction from blood or secretions. Administer humidified oxygen through the tube to prevent dried and inspissated secretions from occluding it.

COMPLICATIONS

An elective tracheostomy is a relatively basic and common surgical procedure. Despite this, it has an unusually high complication rate. Authors report widely different morbidity rates, perhaps determined in part by the clinical settings if not their own biases. Reported morbidity ranges from 6% to 58%, with procedures done emergently having the highest rates.[20,21,23,24] However discomforting these numbers may be, the risk is certainly acceptable in the face of an unstable airway in a dying patient.

Complications from a tracheostomy can be divided into immediate operative complications, postoperative complications, and delayed complications. A summary of reported complications are listed in **Table 26-4**. **It cannot be stressed enough that the best way to avoid complications is to avert the need for a tracheostomy.** Under emergent circumstances, a variety of things can and do go wrong. It is best if one has thought about these possibilities, considered alternative strategies for airway management, and sought assistance from surgical colleagues. A more detailed discussion regarding chronic complications is found in Chapter 27 (Tracheostomy Care).

The most common problem with a hastily performed tracheostomy is hemorrhage. Most bleeding can be controlled with the application of direct pressure. An assistant may be invaluable in providing sufficient control until the airway is established. The search for a bleeding source during the procedure will waste valuable time and can usually wait until the airway is established. The best way to avoid this difficulty is strict hemostasis during the procedure and being careful to avoid the transection of any blood vessels. The next most likely problem is inadvertent injury to adjacent structures. This can be avoided by remaining strictly in the midline, positioning the patient properly, and using a tracheal hook. Additional problems that can be encountered include the creation of a false passage. This should not occur if the operator has visualized the trachea and remained in the midline. In pediatric patients, pneumomediastinum is one of the most frequent early complications of tracheostomy.[55]

The Emergency Physician should be cautious not to adopt methods for tracheostomies learned from elective procedures performed in the operating room under controlled circumstances. **The emergent tracheostomy must be carried out with the simplest, fastest, and most straightforward technique possible.** Tracheostomies done under elective conditions may use rescue stay sutures and more elaborate tracheal incisions. The added benefits of these features do not offset the additional time required to perform them.

Any physician who cares for patients under emergency circumstances should think through the clinical scenarios in which an emergent tracheostomy may be necessary. Expertise in surgical airway techniques should first be obtained in a laboratory setting. Unless one is poised to respond with a plan of action for the emergent airway and prepared with the necessary surgical skills, such situations create chaos and all too often end in disaster.

SUMMARY

A well-trained Emergency Physician must be prepared for any kind of airway emergency and should be skilled in a variety of approaches. Optimal airway management begins with optimal medical management of the patient, including the early identification of possible airway compromise and aggressive preventive treatment. Many airway problems can be averted with anticipatory action. In the armamentarium of airway procedures, a tracheostomy will be (and should be) a rare solution. The physician who is knowledgeable about and comfortable with alternative airway techniques, including surgical access, will be prepared to act decisively yet appropriately upon encountering a challenging airway crisis. While a cricothyroidotomy is the surgical airway procedure of choice, a tracheostomy should be considered for laryngeal injuries with airway disruption, or when all other methods have failed.

27 Tracheostomy Care

H. Gene Hern Jr.

INTRODUCTION

Tracheostomy care and management of tracheostomy complications are tremendously important to the Emergency Physician. Rapid assessment and understanding of tracheostomies and their potential complications can be lifesaving in the critically ill and tracheostomy dependent patient.

Tracheostomies have been performed since ancient times but have been perfected in the last few centuries. A Greek physician named Asclepiades of Bismuth was the first credited with performing a successful tracheostomy in 100 BC.[1] Two of the four physicians summoned to President George Washington's deathbed were said to have argued for tracheostomy as his only means of survival. In the 1800s, Trousseau reported successful tracheostomies in more than 2000 cases of upper airway obstruction secondary to diphtheria.[2] Chevalier Jackson, in the 20th century, perfected the tracheostomy technique and reduced the operative mortality from 25% to below 1%.[3] This is roughly what it remains today.

The important aspects of tracheostomy care include the assessment of respiratory distress in the tracheostomy patient, proper suctioning techniques, and assessment and evaluation of possible complications arising from the tracheostomy itself or its placement. For the purposes of this chapter, tracheostomy care will be divided into routine care and emergent care.

ANATOMY AND PATHOPHYSIOLOGY

The trachea is a fibromuscular tube with approximately 18 to 20 cartilaginous arches extending from the cricoid cartilage to the division into right and left mainstem bronchi (**Figure 26-4**). The surface of the tracheal mucosa is covered in respiratory epithelium. This epithelium is responsible for tracheal secretion, mucociliary "elevator" movement of secretions and debris, and humidification. The remaining part of the upper respiratory tract, which is bypassed by the tracheostomy, plays a major role in warming and humidifying inspired air.

The term tracheostomy and tracheotomy are widely interchanged in current parlance. Tracheotomy refers to the actual incision through the skin to the trachea, which is then kept open by a tracheotomy tube. A tracheostomy refers to the procedure in which the tracheal opening is sutured to the skin incision. This creates a more permanent orifice. The term tracheostomy will be used for the remaining sections of this chapter.

A tracheostomy is created by an incision at the level of the second or third tracheal rings. After the subcutaneous tissue is dissected and anatomic structures identified, an incision is made into the trachea. A hook is inserted into the incision and used to stabilize the trachea while a tube is placed into the trachea. The trachea is secured to the overlying skin and the tube is secured in place. Further details can be found in Chapter 26.

TRACHEOSTOMY TUBES

Tracheostomy tubes vary in their composition, angles, and types and the presence or absence of a cuff. The basic tube consists of an outer cannula and an inner cannula (**Figure 27-1**). The size of the tracheostomy tube is usually defined by its inner diameter. The outer cannula is the more permanent fixture in the tracheostomy. The inner cannula is a low-profile tube that inserts into the outer cannula. It can easily be removed and replaced. The inner and outer cannulas contain a locking mechanism by which the inner cannula is secured into the outer cannula. The proximal end of the inner cannula contains a standard 15 mm connector that allows direct connections to a ventilator or a bag-valve device.

FIGURE 27-1. The tracheostomy tube consists of an outer cannula (*left*) and an inner cannula (*middle*). The inner cannula inserts and locks into the outer cannula (*right*).

Pediatric tracheostomy tubes, it must be noted, have a much smaller inner diameter and do not accommodate inner cannulas (**Figure 27-2**). Since pediatric tracheostomy tubes are not made with an inner cannula, they require more frequent suctioning and changing.

Tracheostomy tubes are manufactured with and without cuffs (**Figure 27-3**). Older high-pressure, low-volume cuffs produced tracheal mucosal injury within hours. They have been replaced by high-volume, low-pressure cuffs that can be used for extended periods with minimal mucosal injury.

Obturators are solid devices that aid in the smooth insertion of the tracheostomy tube (**Figure 27-4**). When placed inside the outer cannula, an obturator will totally occlude the cannula and extend a few millimeters beyond the distal end. The smooth tip of the obturator allows the outer cannula to be inserted with minimal effort and prevents the edges of the cannula from getting caught and damaging tissue. Once the outer cannula has been inserted, the obturator is removed and replaced with a low-profile inner cannula.

FIGURE 27-2. The pediatric tracheostomy tube.

FIGURE 27-3. Tracheostomy tubes may be uncuffed (*left*) or cuffed (*middle*). The inflated cuff is a high-volume, low-pressure system (*right*).

FIGURE 27-4. The obturator is a solid device (*left*) that inserts into the proximal end of the outer cannula and projects from the distal end of the outer cannula (*right*).

ROUTINE CARE

The routine care of the patient with a tracheostomy includes humidification of air as well as cleaning and suctioning of the tracheostomy. Inspired air that bypasses the upper respiratory tract in patients with tracheostomies is not as warm or humidified as air inspired through the nose or mouth. When cold, dry air is inspired into the trachea, the mucociliary "elevator" becomes impaired, resulting in thicker secretions. It is important, especially in the postoperative period, to warm and humidify the inspired air for the patient with a tracheostomy.[4]

Care of the tracheostomy must include ensuring adequate cleanliness of the tube. Cleanse the skin site with diluted hydrogen peroxide, at a 50% concentration, applied to cotton-tipped swabs or other similar absorbent devices.[5] The skin surrounding the tracheostomy should be kept dry between cleanings with tracheal bandages or gauze sponges. It is important to note the underlying skin condition. Erythematous or macerated skin can become eroded or infected. Proper skin-care techniques should be used to ensure skin viability. Tracheal bandages or tape used to secure the tracheostomy in place should not be so tight as to compromise skin perfusion. A good rule of thumb is to have two finger breadths of laxity between the skin and the securing ties.[5]

SUCTIONING

Suctioning of the tracheostomy should be conducted when there are thick and tenacious secretions at the tracheostomy lumen or when the patient is having difficulty clearing secretions. Suctioning through the tracheostomy will eliminate debris and infectious agents, improve oxygenation, and prevent atelectasis. Other indications for suctioning include diminished or coarse breath sounds, unexplained decreases in oxygen saturation levels, or increased airway pressures.[6] Suctioning should not be done as part of "routine care" when there are few secretions or if the patient is adequately able to generate enough force to clear the secretions.[7] While the suctioning of tracheostomies is often essential to proper pulmonary toilet, it can also be hazardous. Known complications to tracheal suctioning include hypoxia, hypotension, atelectasis, infections, tracheal mucosal damage, vagus stimulation, arrhythmias, and even cardiac arrest.[6,8]

Suctioning can also be very frightening to the patient and must be done with some expediency and professionalism. These patients' anxiety levels are quite high, as their ability to breathe may be compromised by secretions, they may be hypoxic, and they have a decreased ability to communicate freely at baseline.[4]

EQUIPMENT

- Protective clothing (disposable gowns, gloves, face shields, goggles, and shoe covers)
- Bag-valve device
- Flexible multi-eyed suction catheter, less than half the diameter of the inner cannula
- Saline bullets
- Continuous wall suction
- Pressure regulator to maintain suction pressure

PATIENT PREPARATION

Place the patient in an upright or semirecumbent position. If possible, hyperextend the patient's neck. Preoxygenate the patient with 100% oxygen prior to suctioning. **Hypoxia is a common complication of suctioning and can be virtually eliminated with proper preoxygenation.** In addition, proper preoxygenation often prevents cardiac arrhythmias from occurring during suctioning.[8] Pretreatment with atropine in neonates and children has been suggested to minimize bradycardic episodes.[9]

It has been debated which technique of preoxygenation is best. Options include hand ventilation with a bag-valve device for five to eight breaths, hyperventilation with 100% O_2 via a nonrebreathing mask, or hyperventilation with 100% O_2 via a ventilator. The advantage of hand ventilation is that there is faster delivery of oxygen to the lungs rather than waiting for the higher percentage of oxygen to bleed down the ventilator tubing into the lungs. However, maintaining tidal volumes and positive end-expiratory pressure may be more important in particular settings. The bag-valve device may result in decreased cardiac output and hypotension secondary to increased intrathoracic pressures.[6] The method of preoxygenation is left up to the physician.

TECHNIQUE

Assemble and prepare the equipment. Set the pressure regulator to 60 to 80 mmHg for infants, 80 to 100 mmHg for children, and 100 to 120 mmHg for adolescents and adults. Higher pressures may cause injury to the tracheal mucosa. The suction catheter chosen should

be approximately one-half the diameter of the tracheostomy tube. The catheter has an open valve that must be covered to apply suction through the tip of the catheter. If available, apply cardiac monitoring and pulse oximetry to the patient prior to suctioning.

The procedure should be performed with aseptic technique. The physician should wash his or her hands and apply sterile gloves. The use of a face mask, eye protection, and a gown is highly recommended. The insertion of the suction catheter often induces the patient's cough reflex. Proper protective clothing will prevent the physician from being exposed to respiratory secretions.

Gently insert the suction catheter into the trachea (**Figure 27-5**). Advance it approximately 8 to 10 cm until the tip is at the level of the carina. **Suction pressure should never be applied during insertion of the suction catheter.** Withdraw the catheter approximately 2 to 3 cm and apply suction by placing a finger over the catheter's open valve.[10] **Continue to apply suction as the catheter is simultaneously rotated and withdrawn.** This technique will limit the amount of mucosal damage from the suction catheter. If the catheter is not being withdrawn when suction is applied, the mucosal surface will invaginate into the holes in the suction catheter tip. The resulting trauma may cause bleeding or erosion of the tracheal mucosal surface.[7]

Suction the airway for no more than 10 to 15 seconds.[7,11] This will ensure that the patient experiences a minimal amount of hypoxia. If the suctioning must be repeated, preoxygenation with 100% oxygen must precede each suctioning episode.

The standard use of saline to loosen secretions is somewhat controversial. Some authors have suggested that saline is used to break up thick and tenacious sputum and mucus.[9] There is little support for this assertion. It has been shown that saline instillation increases the cough reflex and stimulates a cough response, which may increase mucus clearance. Others have noted that little saline is actually recovered with suctioning and that saline itself may cause a gradual decrease in oxygen saturation.[6] The instillation of saline into the tracheostomy cannot be recommended at this time.

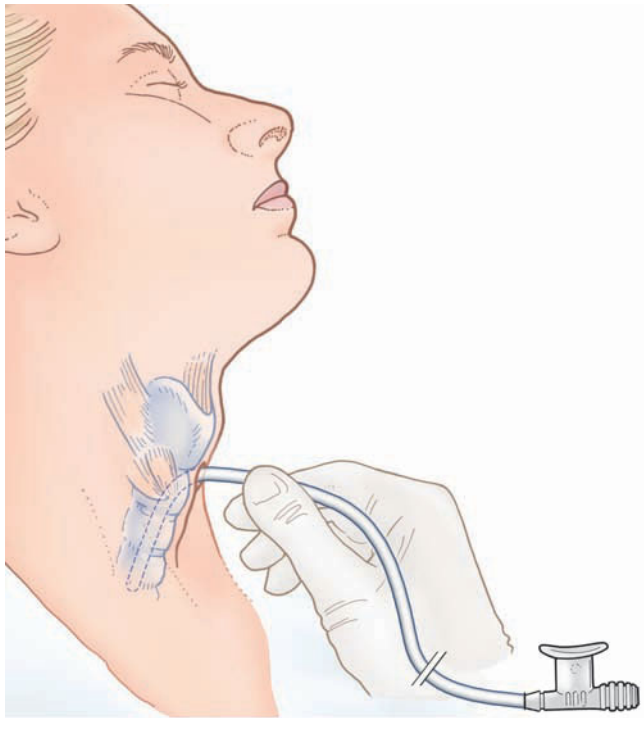

FIGURE 27-5. Insertion of a suction catheter. The vent is uncovered during insertion to prevent tracheal mucosal injury.

EMERGENT CARE

When a patient with a tracheostomy presents to the Emergency Department complaining of shortness of breath or respiratory distress, immediate attention must be given to them. Obstruction and hypoxia are frequent causes of morbidity in this patient population. What follows is a discussion of the algorithm for airway obstruction and respiratory distress in the patient with a tracheostomy.[9]

EQUIPMENT

- Protective clothing (disposable gowns, gloves, face shields, goggles, and shoe covers)
- Bag-valve-mask device
- Flexible multi-eyed suction catheter less than half the diameter of the inner cannula
- Saline bullets
- Continuous wall suction
- Suction pressure regulator
- Continuous ECG monitor
- Pulse oximetry
- Tracheal tubes of various sizes, at least the current size of the tube and one smaller
- Water-soluble lubricant
- Tracheal Airway kit (hook, dilator, and forceps)
- Endotracheal tubes
- Laryngoscope handle and blades
- Access to advanced airway equipment, including a fiberoptic scope

PATIENT PREPARATION

The evaluation of any patient with a tracheostomy who is in respiratory distress begins with placing the patient in a room capable of advanced airway management. Place the patient on 100% oxygen and obtain intravenous access, cardiac monitoring, and continuous pulse oximetry. Equipment should be readily available and accessible. This includes endotracheal and tracheostomy tubes of various sizes as well as a laryngoscope and laryngoscope blades.

The practitioner must evaluate the type of tracheostomy tube present.[12] Recognition of the type of tube will aid in the evaluation of possible complications and the management of the respiratory distress. For instance, if the tube has no inner cannula (pediatric tubes), the entire tracheostomy tube may have to be removed for further cleaning after suctioning is performed. If the tracheostomy tube has no cuff, the patient's respiratory distress may be due to aspiration of secretions or gastric contents.

TECHNIQUE

Inspect the tracheostomy tube for obvious signs of obstruction. The degree of obstruction will increase exponentially as the cross-sectional diameter of the tracheostomy tube decreases. As dried secretions, blood, or aspirated material gathers in the inner cannula, the amount of force required to create airflow through the tube increases dramatically. In addition, secretions may act as a ball-valve mechanism, allowing air to move inward but not outward.

An obvious obstruction or foreign body, if visible at the tracheostomy tube opening, must be removed. The practitioner must then suction the patient through the inner cannula using the technique described above. **Keep in mind the importance of preoxygenation.** If this does not adequately relieve the patient's respiratory

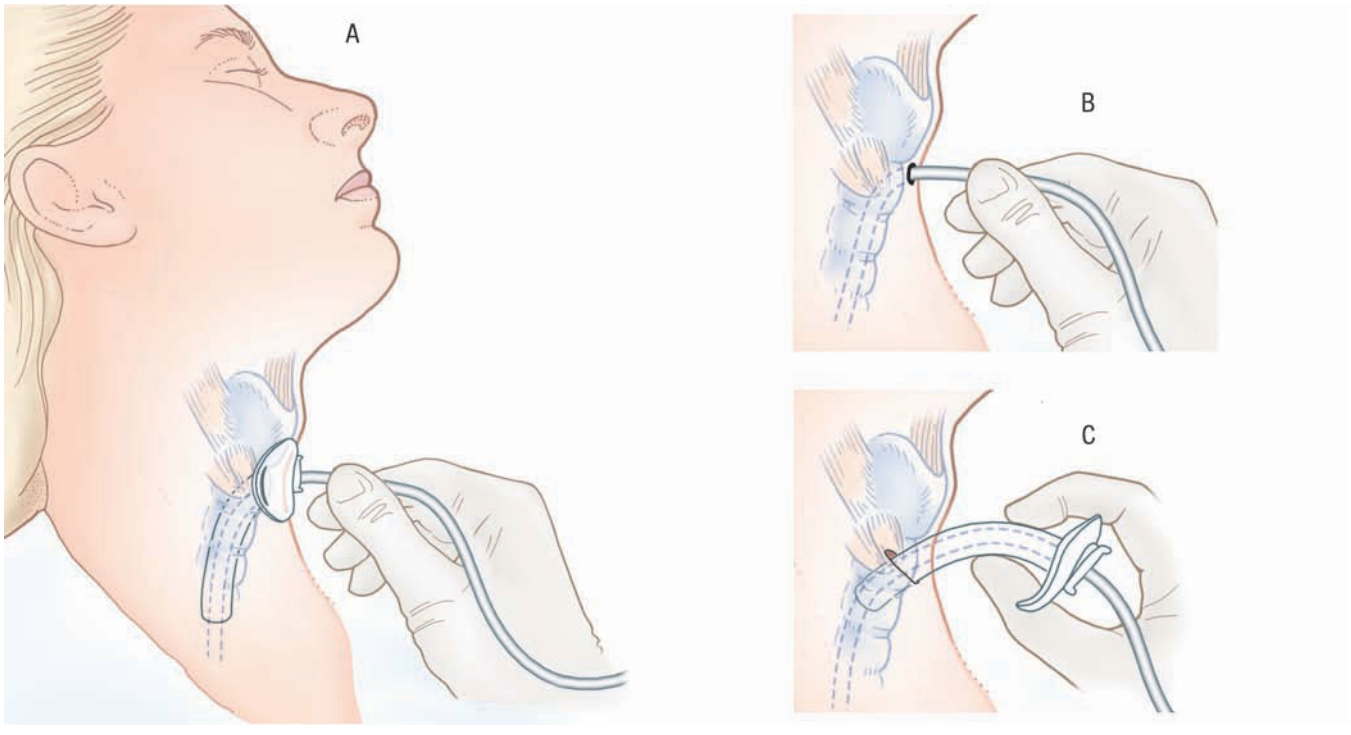

FIGURE 27-6. Removal of the outer cannula over a catheter. **A.** The catheter is inserted through the outer cannula to a depth of 8 to 9 cm. **B.** The outer cannula has been removed over the catheter. **C.** The new outer cannula is inserted over the catheter and into the trachea.

distress, remove the inner cannula. Inspect it for dried secretions and clean it later if necessary. The patient may again be suctioned, this time through the outer cannula. If no diminution of symptoms is noted, the outer cannula may need to be removed.

Before removing the outer cannula, it is important to have all the necessary equipment to replace it at the bedside. If the outer cannula has a cuff, deflate it. Remove the outer cannula with a smooth circular motion. Inspect it for a foreign body and dried secretions. The outer cannula may be cleaned then replaced or may be replaced with an entirely new tracheostomy tube. The practitioner may elect to use a fiberoptic scope or red rubber catheter to aid in tube placement. Each of these devices allows the tracheostomy tube to be placed over it and guided into the tracheal lumen.

If the tracheostomy is relatively new, less than 4 weeks old, it should be removed over a red rubber catheter (**Figure 27-6**). This will ensure that the tracheostomy tube is inserted into the trachea and not a false passage. Lubricate the red rubber catheter. Insert the catheter through the outer cannula and into the trachea (**Figure 27-6A**). Advance the catheter 8 or 9 cm. While holding the catheter securely, remove the outer cannula over the catheter (**Figure 27-6B**). Lubricate a new outer cannula. Insert the outer cannula over the catheter and gently advance it into the trachea (**Figure 27-6C**). Remove the catheter and insert the inner cannula into the outer cannula.

A suction catheter can be used as an alternative to a red rubber catheter. Attach the suction catheter to an oxygen source. Lubricate the end of the suction tubing. Advance an outer cannula over the distal end of the suction tubing. Insert the suction catheter into the tracheostomy to a depth of 8 or 9 cm. Place a finger over the open valve of the suction catheter to provide oxygen to the patient through the catheter. **This will prevent the patient from becoming hypoxemic during the procedure.** Advance the outer cannula over the catheter and into the trachea. Remove the suction catheter and insert the inner cannula into the outer cannula.

If no assist device is used, the tracheostomy tube can be replaced manually (**Figure 27-7**). Lubricate the obturator and insert it into the outer cannula. Inflate the cuff and check its integrity. Deflate the cuff. Lubricate the outer cannula liberally. Place the tip of the obturator perpendicular to the patient's neck and insert it with a semicircular motion (**Figure 27-7A**). Continue advancing the outer cannula with a semicircular motion as it curves into the trachea (**Figure 27-7B**). Remove the obturator and insert the inner cannula into the outer cannula. Begin ventilation of the patient if necessary.

If the new tracheostomy tube will not advance into the trachea, repeat the procedure with a tracheostomy tube one size smaller. **Do not force the tube, as this can create a false passage in the subcutaneous tissues of the neck.** If it still will not advance, attempt to insert an uncuffed tube. Alternatively, insert the tracheostomy tube over a catheter (**Figure 27-8**). Lubricate a red rubber catheter (or oxygen catheter) and insert it 8 or 9 cm through the tracheostomy (**Figure 27-8A**). Insert a lubricated outer cannula over the catheter and into the trachea (**Figure 27-8B**). Remove the catheter and insert the inner cannula. As a last resort, a tracheostomy hook and Trousseau dilator can be used to lift and open the tracheostomy site to allow the insertion of a tracheostomy tube.

ASSESSMENT

The adequacy of airway maneuvers in the patient with a tracheostomy resides in the patient's response to the interventions. If the patient's pulse oximetry and heart rate return to baseline and the patient appears more comfortable, secure the tracheostomy tube. Take care to ensure adequate skin care beneath the tracheostomy tube site.

If a patient remains in respiratory distress despite all appropriate actions, then further causes of respiratory distress must be evaluated. Obtain a chest radiograph. Consult a Pulmonologist for fiberoptic bronchoscopy to evaluate the patient for mucus plugging or foreign-body aspiration. Do not forget to consider other causes

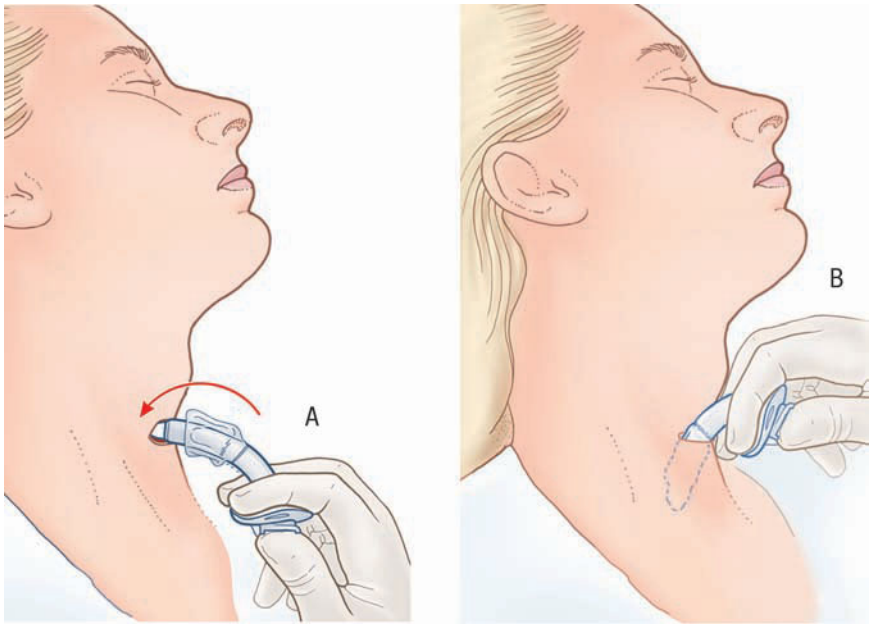

FIGURE 27-7. Manual insertion of a tracheostomy tube. **A.** It is positioned 90° to the tracheostomy site and advanced with a semicircular motion (*arrow*). **B.** The system continues to be advanced, following the curve of the tube, until the flange is against the skin.

of respiratory distress in the patient with a tracheostomy. This includes, but is not limited to, a pneumothorax, pneumonia, pulmonary embolus, congestive heart failure, and myocardial infarction.

AFTERCARE

The patient should be observed for a few hours to ensure the stability of the airway. During this time, further suctioning can be performed as required. Educate the patient and family about preventive measures regarding tracheostomy care.

Once the patient's respiratory distress has been addressed, the patient should be evaluated for further conditions that may preclude him or her from being discharged. Were there just some dried secretions in the inner cannula? Does the patient have a new source of secretions (bacterial pneumonia) that could not be managed at home? Are the caregivers at home knowledgeable about the tracheostomy and trained to deal with complications? If there is any question about the patient's ability to deal with further episodes of respiratory compromise, the patient should be admitted for further evaluation by an Otolaryngologist. The

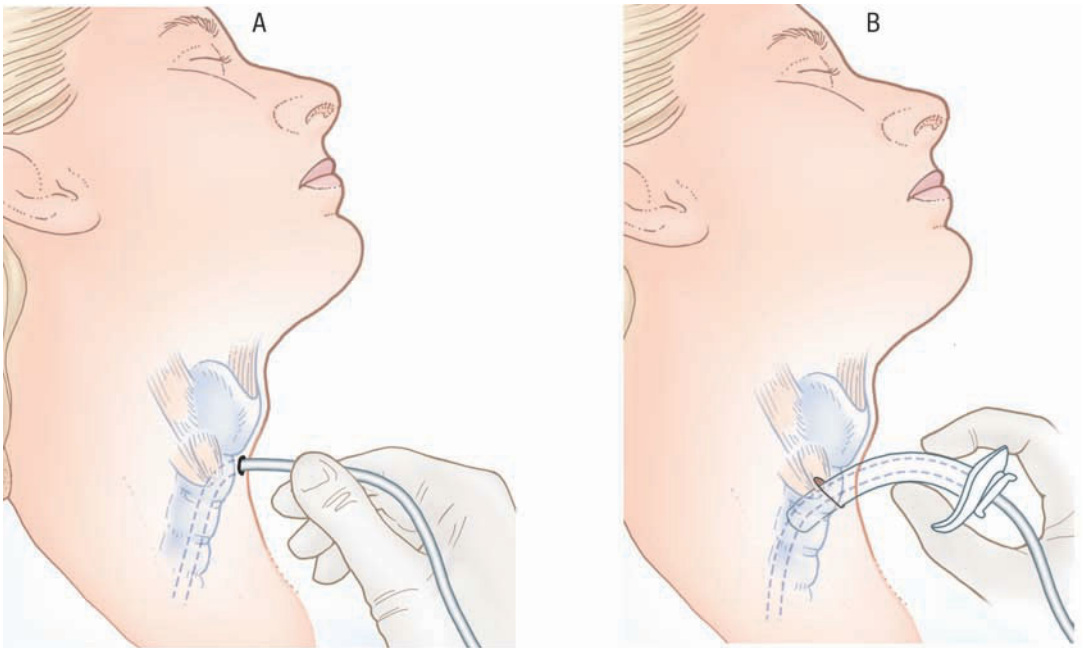

FIGURE 27-8. Insertion of the tracheostomy tube over a catheter. **A.** Insert the catheter through the tracheostomy to a depth of 8 to 9 cm. **B.** Advance the outer cannula over the catheter.

patient may require skilled home care or a skilled nursing facility in order to fully care for the tracheostomy.

COMPLICATIONS OF THE TRACHEOSTOMY

In addition to respiratory compromise from plugging of the tracheostomy with secretions, other complications may cause the patient to present to the Emergency Department. One retrospective review over a 7-year period showed that 33% of patients presented with dislodged tracheal tubes, 30% presented with infection (one-quarter of these had cellulitis around the tracheostomy, the rest had bronchitis or pneumonia), 18% had plugged tracheal tubes, 11% had bleeding, 5% had tracheal or stomal stenosis, and 3% had a pneumothorax.[2]

BLEEDING

Bleeding is a significant concern in the patient with a tracheostomy. While bleeding at the site of a recent tracheostomy may be a frequent complication, it may also be extremely serious. Bleeding can arise from granulation tissue, venous sources, or arterial sources including the great vessels. Tracheoinnominate fistulas are quite rare, occurring in less than 2% of cases, but they carry a mortality rate of 25% to 50%.[9] They may present as the classic "exsanguinating bleed" but often present with a less impressive sentinel bleed. **Any bleeding of more than a few milliliters of blood should raise concern for a possible fistula of the innominate artery. Prompt critical resuscitation measures and emergent consultation with a Vascular Surgeon and Otolaryngologic Surgeon is required.** Definitive management is surgical. Techniques for temporarily controlling bleeding from the innominate artery include local digital pressure, hyperinflation of the tracheostomy tube cuff, and traction on the tracheostomy tube. An alternative method is to deflate the tracheostomy tube cuff, reposition the cuff at the bleeding site, and then reinflate or hyperinflate the cuff. **When bleeding occurs, the tracheostomy tube should not be removed until the airway is secured by another means from above (orally or nasally).**

FREE AIR

Pneumothoraces, pneumomediastinum, and subcutaneous air occur in a small number of patients.[9] Pediatric patients are at a higher risk, as the dome of the pleura in a child is closer to the site of the operation. As patients "fight" a ventilator or attempt to inspire against an obstructed airway, they can generate tremendous negative inspiratory pressures. This can result in the dissection of air between the tissue planes and into the thoracic cavity, causing a pneumothorax. Small pneumothoraces and pneumomediastinum can be observed as they will most likely resorb with no further complications. A large pneumothorax will require drainage. **The possibility of a tension pneumothorax must always be considered in patients with tracheostomies and respiratory distress or hypotension.**

GRANULOMAS

Tracheal wall granulomas can develop at the tracheostomy site or near the tip of the tracheostomy tube. They are formed in response to mechanical trauma to the mucosa. Granulomas are sometimes a source of bleeding. Direct pressure or cautery may be required for hemostasis. Small granulomas are often observed, while large or symptomatic ones require excision.

INFECTIONS

Tracheostomy-related infections can present at any time. Stoma infections are considered to be local skin infections. Antibiotic treatment should be based on potential pathogens and local antibiotic resistance patterns. Tracheitis may be bacterial or viral in origin. Common bacterial etiologies include *Staphylococcus aureus*, group A streptococcus, and *Haemophilus influenzae*. The determination of a bacterial infection versus colonization should be based on clinical findings and culture results. Management of tracheitis includes broad-spectrum antibiotics for common pathogens, maintenance of a patent airway through suctioning, and possible bronchoscopy.

LARYNGOTRACHEAL STENOSIS

Laryngotracheal stenosis is a complication of long-term endotracheal intubation or direct tissue trauma from the tracheostomy. The tracheal tissues become irritated from the tracheostomy tube. This results in tissue edema that leads to erosions into the mucosa, ulcerations, and eventually scar tissue. Treatment involves surgery to remove the scar tissue and create an artificial airway to bypass the stenosis.

DEPRESSED SCAR FORMATION

The tracheostomy wound is left open to granulate and heal by secondary intention. This can result in skin and soft tissue atrophy and tissue adhesions to the anterior tracheal wall. As the tissue heals, scar contracture and a depress scar can result. This may result in patient discomfort with head movement or swallowing. Treatment requires surgical scar excision and revision.

SUPRASTOMAL COLLAPSE

Pressure placed on the tracheal cartilages by the tracheostomy tube results in cartilage inflammation, chondritis, and necrosis of the cartilaginous rings. Mild suprastomal collapse usually requires no treatment. Moderate and severe collapse may require a tracheal stent, suturing the anterior trachea to the skin and subcutaneous tissues, or pulling the anterior trachea anteriorly and securing it in place.

TRACHEOESOPHAGEAL FISTULA

A tracheoesophageal fistula is a rare complication of a tracheostomy. The tracheostomy tube can cause pressure necrosis on the posterior tracheal wall that continues to erode into the esophagus. The result is an open tract between the trachea and the esophagus. Patients often have difficulty eating, aspiration pneumonitis, or respiratory difficulty associated with eating and drinking. Treatment requires surgical management.

TRACHEOMALACIA

Tracheomalacia is the lack of support for the trachea by its cartilaginous rings. It can result from degradation of the cartilaginous tracheal rings from the tracheostomy tube or from a tracheoesophageal fistula. Bronchoscopy is required to assess the severity of the tracheal collapse prior to possible intratracheal stenting.

SUMMARY

Emergency Physicians should be familiar with tracheostomy equipment including the outer and inner cannulae, obturators, and cuff management. Patients presenting to an Emergency Department may require immediate and critical intervention to resuscitate them. Familiarity with various techniques to evaluate the patient with a tracheostomy should include tracheal suctioning, removal of the inner and outer cannulae, replacement of a tracheostomy tube, and evaluation for other emergent conditions relating to tracheostomies. This would include bleeding, infection, and pneumothorax at the very minimum. In addition, the Emergency Physician should be mindful of other conditions of the esophagus, trachea, or soft tissues that might complicate the care of the patient with a tracheostomy.

28 Transtracheal Aspiration

Joseph A. Salomone III

INTRODUCTION

Transtracheal aspiration is a technique for the collection of bronchial secretions for laboratory evaluation and culture. This technique is useful when standard sputum collection has not provided adequate material or determination of the infective agent(s). Specimens collected by this technique are free of contamination from nasal, oral, and pharyngeal secretions. This technique was first described in 1959.[1] Several modifications to the original technique have been made.[2–5] This technique may be more properly named transcricothyroid membrane aspiration.

ANATOMY AND PATHOPHYSIOLOGY

The most superficial portion of the cervical airway begins at the inferior thyroid cartilage and extends inferiorly to the thyroid isthmus (**Figure 28-1**). The inferior border of the thyroid cartilage is attached to the cricoid cartilage by the cricothyroid ligament. This is formed by a thicker central conus elasticus and laterally by thinner ligaments that are covered by the cricothyroid muscles (**Figure 28-1B**). The internal surface is covered by the mucous membrane of the larynx. Collectively, this is often referred to as the cricothyroid membrane or cricovocal membrane. The paired cricothyroid arteries cross from lateral to medial to form an arch that anteriorly crosses the upper one-third of the cricothyroid membrane. The pyramidal lobe of the thyroid occasionally extends superiorly to this level.

INDICATIONS

Transtracheal aspiration is indicated for the collection of tracheobronchial secretions for laboratory evaluation. Often, previous attempts to collect standard coughed and expectorated sputum samples have failed to yield adequate samples or reveal the etiology of a pulmonary infection. Patients who do not appear to be responding to the appropriate antibiotic regimen that was indicated by evaluation and culture of sputum samples may benefit from this technique to better determine the pathogen(s). This is particularly true in cases of atypical or mixed flora, as in suspected aspiration pneumonias, where this technique may yield superior culture results when compared to sputum samples.[6]

CONTRAINDICATIONS

Patients who are unable to cooperate with or tolerate the required positioning should not be selected for this technique.[7] Agitated patients requiring sedation that may affect respiratory effort should be avoided. Traumatically injured patients should have the cervical spine cleared for possible injury prior to performing the procedure. Patients with known or suspected blood dyscrasias (e.g., abnormal platelet counts, elevated prothrombin, or partial thromboplastin times) should not be subjected to this technique due to the increased risk of tracheal hemorrhage. The physician must be able to easily identify the patient's anatomic landmarks, including the thyroid and cricoid cartilages and the intervening cricothyroid membrane. Patients with abnormal or distorted anatomy should be excluded. Patients who are endotracheally intubated or have a tracheostomy do not require this procedure.

EQUIPMENT

- Sterile gown, gloves, and mask
- Pillow or padding for shoulders
- Povidone iodine solution or chlorhexidine solution
- Sterile gauze squares
- Normal saline solution, sterile and preservative-free
- Local anesthetic solution, 3 mL (1% lidocaine HCl)
- 3 mL syringes
- 30 mL syringe
- 25 to 27 gauge needles, ½ in
- 18 to 22 gauge catheter-through-the-needle
- 18 to 22 gauge catheter-over-the-needle, 3 in long
- 18 to 19 gauge needles, 1½ in
- Pulse oximeter
- Cardiac monitor
- Sterile specimen container
- Bandage, 1 in wide
- Sterile drapes or towels
- Resuscitation equipment including emergent airway management supplies

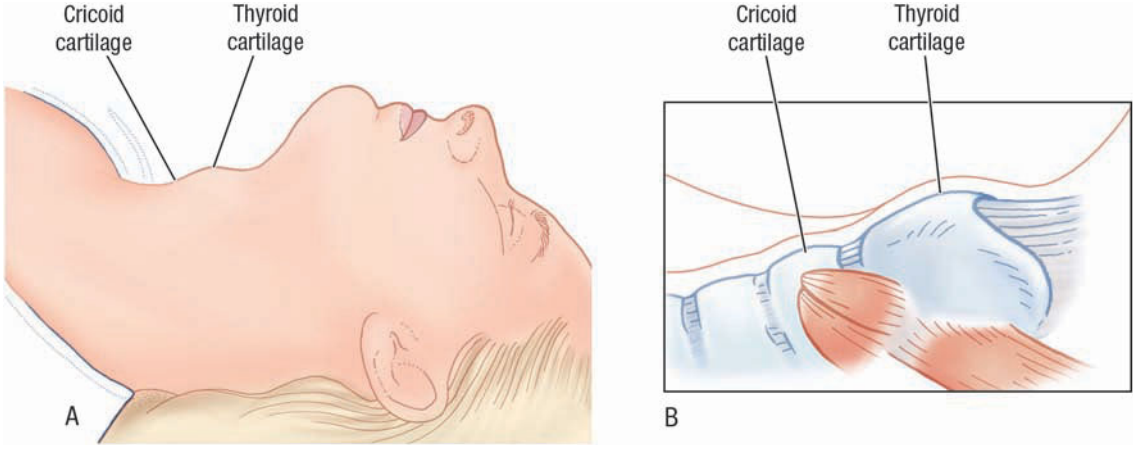

FIGURE 28-1. Anatomy of the airway structures of the neck. **A.** Topographic anatomy. **B.** The cartilaginous structures.

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative. Obtain an informed consent. Place the patient on cardiac monitoring and continuous pulse oximetry. Administer supplemental oxygen and establish intravenous access.

Sedation is not generally required. A small dose of midazolam (1 to 5 mg IV) may be used, if appropriate, for light sedation. Deep sedation should be avoided, as it may compromise respiratory efforts and increase the risk of aspiration of gastric contents.

Place the patient supine in bed. Place a pillow or appropriate padding under the patient's shoulders and upper back to allow for comfortable hyperextension of the neck. Identify by palpation the thyroid cartilage, laryngeal prominence (Adam's apple), cricoid cartilage, and cricothyroid membrane. These are the anatomic landmarks that will be used to identify the proper site for performing the procedure.

TECHNIQUE

CATHETER-THROUGH-THE-NEEDLE TECHNIQUE

The operator should follow universal precautions with the use of a mask, eye protection, a sterile gown, and sterile gloves. Using sterile technique, prepare the equipment. Draw 3 to 5 mL of sterile and preservative-free normal saline solution into a 30 mL syringe with a sterile needle. Attach an appropriately sized needle from a catheter-through-the-needle set (18 to 20 gauge for an adult, 20 to 22 gauge for a child) to a 3 mL syringe. An alternative technique is to draw up 1 to 2 mL of sterile saline into the syringe before attaching the catheter-through-the-needle. Draw up 1 to 3 mL of local anesthetic solution into a 3 mL syringe armed with a 25 to 27 gauge needle.

Position the patient as noted above. Using sterile technique, prepare the neck. Clean the anterior neck of any dirt and debris. Apply povidone iodine or chlorhexidine solution and allow it to dry. Place sterile towels or a sterile drape to isolate the anterior neck. Palpate the anterior neck and reidentify the thyroid cartilage, laryngeal prominence, cricoid cartilage, and cricothyroid membrane. Leave the nondominant index finger over the cricothyroid membrane for reference.

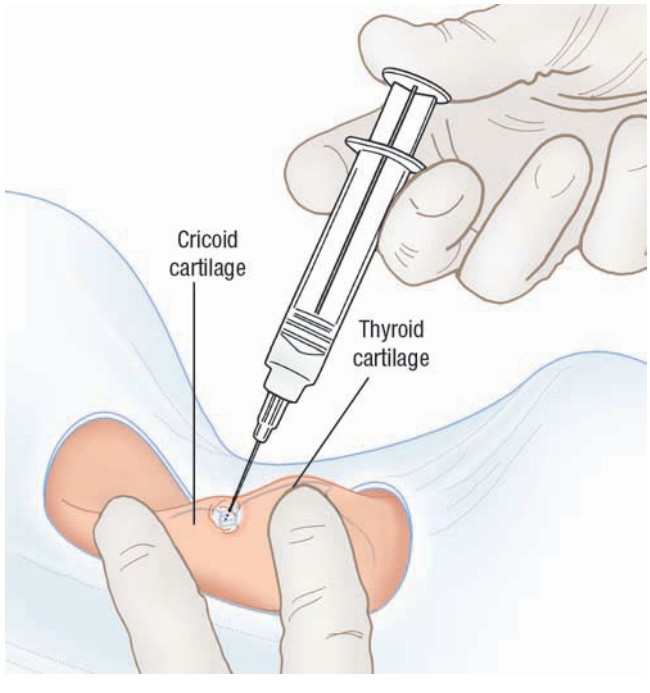

FIGURE 28-2. A subcutaneous wheal of local anesthetic solution is placed over the middle of the cricothyroid membrane.

Apply a small subcutaneous wheal of local anesthetic solution below the skin at the anterior midpoint of the cricothyroid membrane (**Figure 28-2**). Inject 0.5 to 1.0 mL of local anesthetic solution into the subcutaneous tissues down to the level of the cricothyroid membrane, taking care not to distort the anatomy. Reidentify the cricothyroid membrane by palpation. Insert the needle on the syringe, directed caudally and at a 30° to 45° angle to the skin (**Figure 28-3**). Continue to advance the needle while applying negative pressure to the syringe (**Figure 28-3A**). Stop advancing the needle when air is aspirated into the syringe. This signifies that the needle is inside the trachea. If using a saline filled syringe, air bubbles will be clearly visible within the saline. Hold the needle securely and remove the syringe. Insert the catheter through the needle (**Figure 28-3B**). While holding the catheter securely, withdraw the needle until the tip has exited the skin of the neck (**Figure 28-3C**). **Place the needle guard over the needle.** This will prevent shearing off of the catheter. Apply the 30 mL syringe containing saline to the catheter (**Figure 28-3C**).

Ask the patient to cough if they are not already doing so. Aspirate with the 30 mL syringe as the patient coughs. If no specimen is obtained, instill the sterile saline. Once again, ask the patient to cough if not stimulated by the saline. Aspirate until a specimen is acquired. An alternative to using a large syringe for aspiration is the use of low wall suction and a Lukens tube or a similar trap device to collect the specimen.

Remove the catheter, needle, and syringe as one unit. Hold direct pressure on the puncture site for 3 to 5 minutes. Apply a bandage or sterile dressing to the puncture site. Place the specimen in a sterile container and have it transported to the laboratory.

Many physicians are reluctant to use the catheter-through-the-needle system as there is the possibility of shearing off the catheter within the trachea. **This can be prevented by applying the needle guard over the needle immediately after it is withdrawn from the skin.**

CATHETER-OVER-THE-NEEDLE TECHNIQUE

The more commonly used technique is to use a catheter-over-the-needle (angiocatheter) system (**Figure 28-4**). The operator should follow universal precautions. Cleanse, prepare, and anesthetize the patient as above.

Using sterile technique, prepare the equipment. Draw 3 to 5 mL of sterile and preservative-free normal saline solution into a 30 mL syringe with a sterile needle. Attach an appropriately sized catheter-over-the-needle (18 to 20 gauge for an adult, 20 to 22 gauge for a child) to a 3 mL syringe. An alternative technique is to draw up 1 to 2 mL of sterile saline into the syringe before attaching the catheter-over-the-needle. Draw up 1 to 3 mL of local anesthetic solution into a 3 mL syringe armed with a 25 to 27 gauge needle.

Reidentify the cricothyroid membrane by palpation. Insert the catheter-over-the needle on the syringe, directed caudally and at a 30° to 45° angle to the skin (**Figure 28-4A**). Continue to advance the catheter-over-the-needle while applying negative pressure to the syringe. Stop advancing the catheter-over-the-needle as soon as air is aspirated into the syringe. This signifies that the needle is inside the trachea. If using a saline filled syringe, air bubbles will be clearly visible within the saline (**Figure 28-4B**). Hold the syringe securely and advance the catheter until its hub is against the skin (**Figure 28-4C**). Remove the needle and syringe. Apply the 30 mL syringe containing saline to the catheter (**Figure 28-4D**).

Ask the patient to cough if they are not already doing so. Aspirate with the 30 mL syringe as the patient coughs. If no specimen is obtained, instill the sterile saline. Once again, ask the patient to cough if not stimulated by the saline. Aspirate until a specimen is

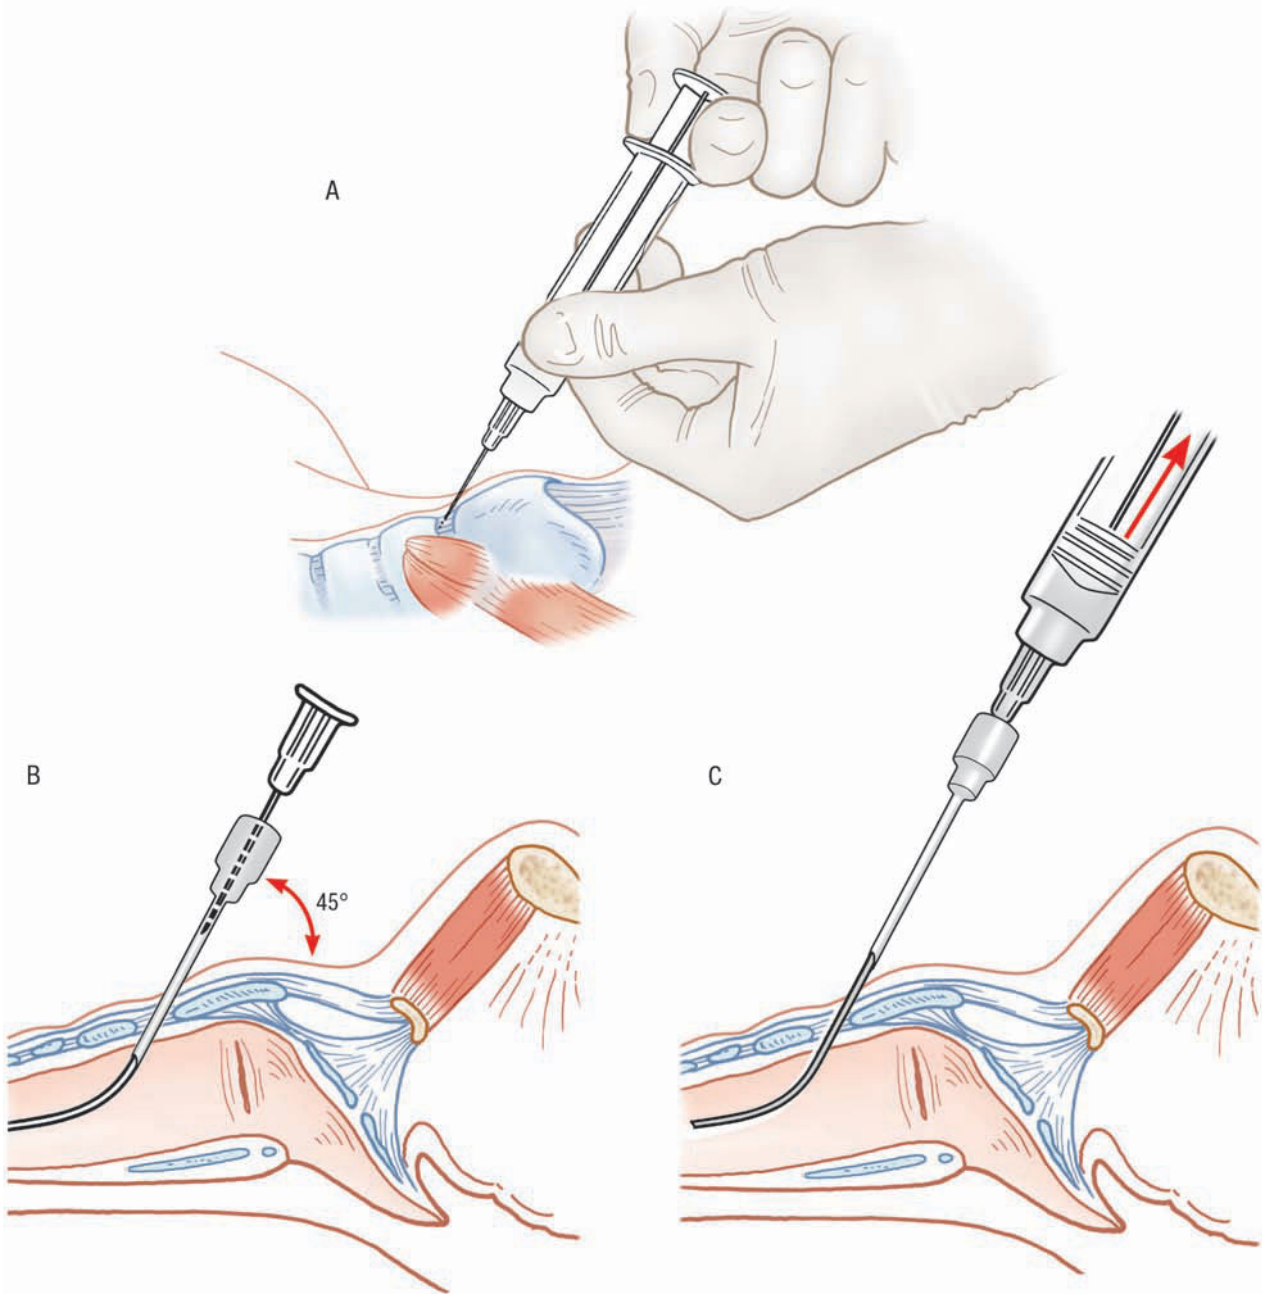

FIGURE 28-3. The transtracheal aspiration technique with a catheter-through-the-needle system. **A.** The needle is inserted through the cricothyroid membrane while negative pressure is applied to the syringe. **B.** The syringe has been removed and the catheter advanced through the needle. **C.** The needle has been withdrawn until its tip exits the skin. A syringe containing saline is attached to the hub of the catheter.

acquired. An alternative to using a large syringe for aspiration is the use of low wall suction and a Lukens tube or a similar trap device to collect the specimen.

Remove the catheter. Hold direct pressure on the puncture site for 3 to 5 minutes. Apply a bandage or sterile dressing to the puncture site. Place the specimen in a sterile container and have it transported to the laboratory.

ASSESSMENT

The patient should be observed for bleeding at the puncture site, the development of subcutaneous emphysema, any changes in sputum production, or hemoptysis. Obtain a chest radiograph immediately after the procedure to look for subcutaneous air and/or a pneumothorax.

AFTERCARE

The patient should remain on continuous pulse oximetry to monitor possible deterioration in respiratory status. Obtain a chest radiograph in 24 hours to look for subcutaneous air and/or a pneumothorax. Any procedure that might stimulate coughing should be avoided for at least 24 hours.

COMPLICATIONS

The complications range from minimal hemoptysis and localized subcutaneous emphysema to massive pulmonary hemorrhage and death.[8–13] Minimal hemoptysis was seen in 15% of pediatric patients in one study and commonly in several adult studies. Localized subcutaneous emphysema in the anterior neck occurred in 5% to 18%

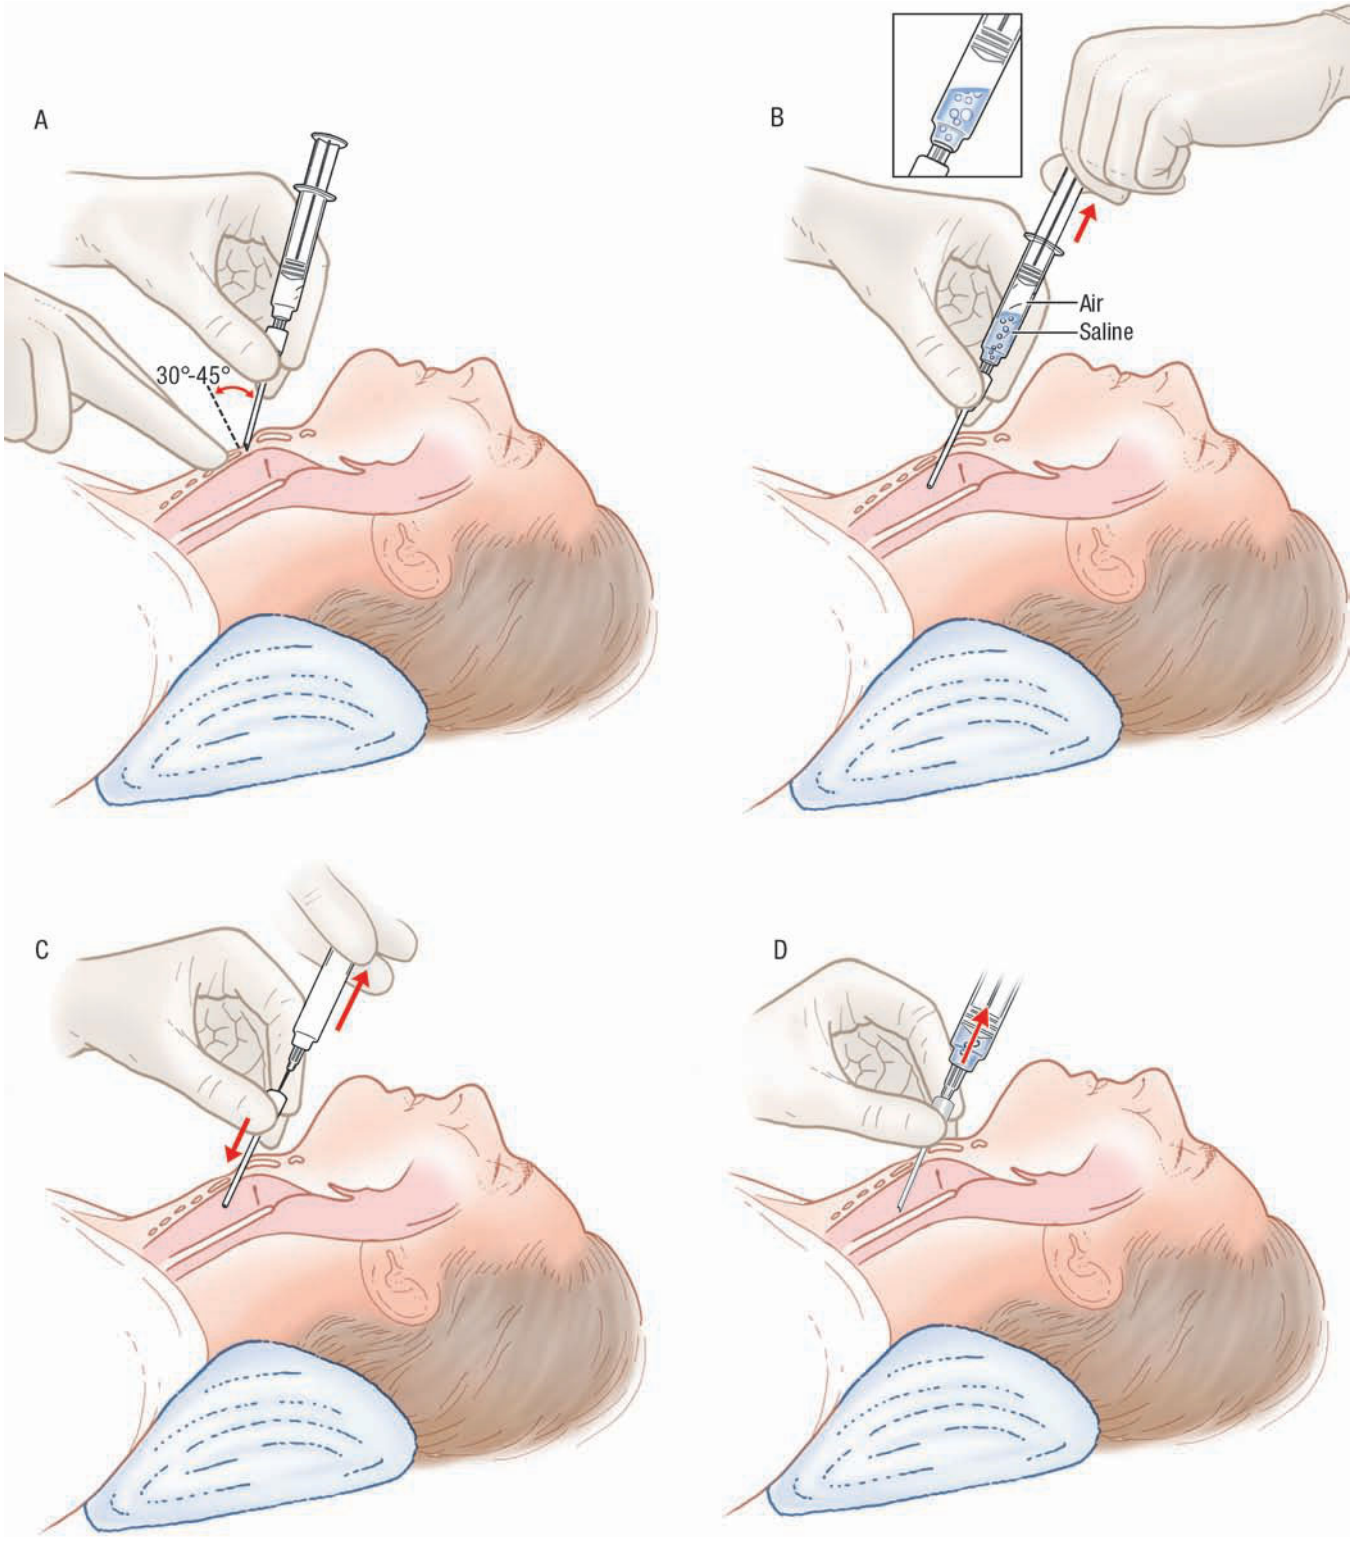

FIGURE 28-4. The transtracheal aspiration technique with a catheter-over-the-needle system. **A.** The catheter-over-the-needle is inserted through the cricothyroid membrane. **B.** Negative pressure is applied to the syringe. **C.** The catheter is advanced until its hub is against the skin. **D.** The needle and syringe have been withdrawn. A syringe containing saline is attached to the hub of the catheter.

of patients. There are rare reports of fatal endotracheal hemorrhage, profound coughing with development of massive subcutaneous and mediastinal emphysema, vomiting and aspiration of gastric contents, cardiac dysrhythmias, and sudden cardiac death. There is at least one case of fatal gastrointestinal hemorrhage from ruptured esophageal varices and Mallory–Weiss tears following "unrestrainable" coughing.

SUMMARY

Transtracheal aspiration is a useful technique for obtaining uncontaminated specimens for analysis and culture. The procedure is best used in those patients who have complicated courses or are failing to respond to appropriate treatment or when there is a high index of suspicion for aspiration pneumonia and more atypical infectious agents.

SECTION 3

Cardiothoracic Procedures

29 Cardiac Ultrasound

Gregory M. Press and Amy Rasmussen

INTRODUCTION

Pericardial tamponade is arguably the most dramatic ultrasound (US) finding for the Emergency Physician (EP). The diagnosis is difficult to make without cardiac US, and acute intervention can be lifesaving. Cardiac US has proven to be an invaluable tool for identifying critical pathology and directing decision making in the Emergency Department (ED).[1] A quick bedside US can assess a patient's cardiac activity, global cardiac function, presence or absence of effusion, and volume status. Cardiac US is an essential part of the evaluation of the trauma patient,[2] the cardiac arrest patient,[3,4] and the patient with undifferentiated hypotension.[5,6]

Cardiac ultrasonography can be one of the most challenging areas of emergency US. The EP must have a keen grasp of the spatial anatomy of the heart to properly perform and interpret the US examination. An EP can become competent in basic cardiac ultrasonography with practice. This tool can be utilized to gain great insight into the body's most vital organ. This chapter will cover basic cardiac anatomy, the indications for emergency echocardiography, techniques, and image interpretation.

ANATOMY AND PATHOPHYSIOLOGY

GENERAL ANATOMY AND PHYSIOLOGY

It is essential to know the anatomy of the heart before performing any US examination (**Figure 29-1**). The heart lies obliquely in the middle of the chest. It consists of four chambers: the left atrium, the right atrium, the left ventricle, and the right ventricle. The atria

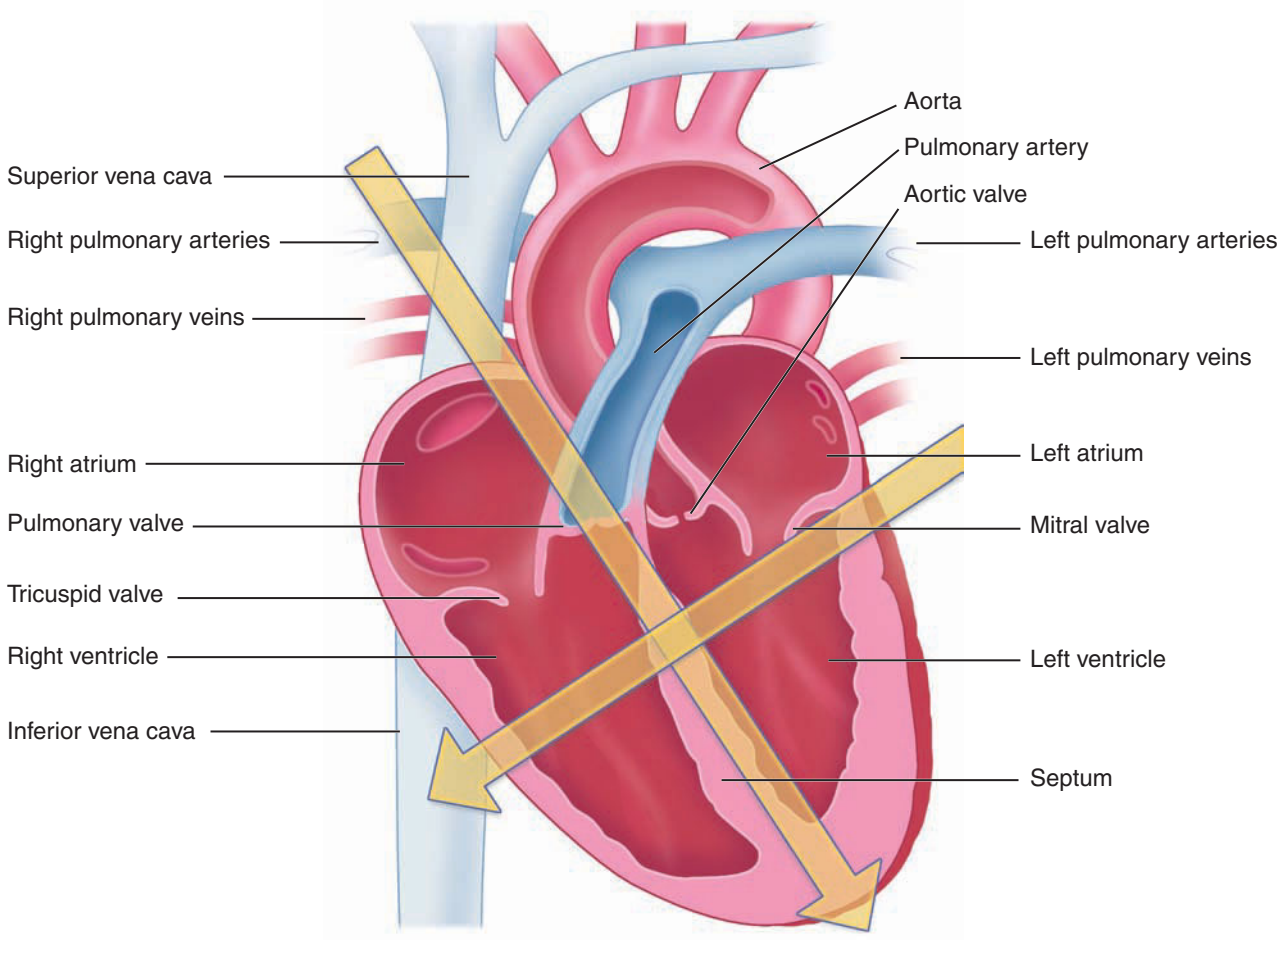

FIGURE 29-1. The cardiac anatomy. The long axis of the heart (*long arrow*) extends from the base to the apex. The short axis (*short arrow*) is a transverse slice perpendicular to the long axis.

are thin-walled muscular structures. The ventricles are more voluminous and muscular, with the left ventricle having the thickest wall. The base of the heart is the superior portion. It is formed by the left atrium, and to a lesser extent the right atrium. The apex of the heart consists of the inferolateral portion of the left ventricle. The anterior surface of the heart abuts the chest wall and is mainly formed by the right ventricle. The left ventricle forms the majority of the inferior surface, with the inferior portion of the right ventricle making a minor contribution. The heart has two axes; both are used extensively in ultrasonography. The long axis extends from the base to the apex, roughly along a line from the right shoulder to the left hip. The short axis slices the heart transversely and perpendicular to the long axis, roughly along a line from the left shoulder to the right hip.

The right heart delivers blood to the lungs to be oxygenated, and the left heart distributes it to the rest of the body. The right atrium receives deoxygenated blood from the body via the superior and inferior vena cava. Blood flows from the right atrium through the tricuspid valve and into the right ventricle during diastole. Blood is pumped from the right ventricle through the pulmonary valve and into the pulmonary artery during systole. The blood is oxygenated by the lungs then flows into the left atrium via the pulmonary veins. Blood flows across the mitral valve into the left ventricle during diastole. It is then pumped by the left ventricle for distribution to the body via the aorta during systole.

The heart is contained within the two-layered pericardial sac. The visceral pericardium is a single layer of cells in direct approximation with the epicardium. The tougher outer fibrous parietal pericardium surrounds the visceral pericardium. The two layers form a potential space that contains a small volume of fluid of approximately 20 to 50 mL.[7] This pericardial fluid allows the heart to freely move within the fibrous pericardium. Larger volumes of fluid can collect in this potential space in pathologic states.

PERICARDIAL EFFUSION

A pericardial effusion is a collection of fluid in the space between the visceral and parietal pericardium. Effusions can be due to trauma, uremia, infection, neoplasm, connective tissue disorders, iatrogenic complications, idiopathic conditions, chyle, and numerous other rare causes.[8] Cardiac tamponade occurs when the fluid collects rapidly, such as in the setting of trauma, where it can cause collapse of the ventricles and decreased cardiac output.[8,9] Fluid that collects more slowly will allow the parietal pericardium to expand accordingly and usually does not lead to cardiovascular collapse.[9]

CARDIAC ARREST

Cardiac arrest is the end result of numerous different pathologic states. Asystole is the complete absence of cardiac activity, or akinesis of the heart.[10] While atrial twitching may be visualized on US, the lack of ventricular activity is uniformly seen in asystole. Pulseless electrical activity (PEA) describes the state in which no pulses are palpable, but cardiac electrical activity is visible on ECG monitoring. Cardiac activity may or may not be present upon US of a heart in PEA. Cardiac arrest can occur from nonperfusing tachyarrhythmias and bradycardias. Cardiac motion is present in the case of ventricular fibrillation but is unorganized, preventing adequate cardiac filling and ejection of blood. Severe bradycardia causes the heart to beat at a rate too slow to provide adequate perfusion of the heart and other tissues.

CONGESTIVE HEART FAILURE

Congestive heart failure (CHF) is an increasingly common condition that distorts normal cardiac anatomy.[11] Dilation of the left ventricle, decreased ejection fraction, and decreased cardiac output are seen in systolic heart failure.[12] With a loss of healthy contractility and enlargement of the left ventricle, dilation of the other cardiac chambers generally ensues. Diastolic failure is due to prolonged exposure to high cardiac afterload as seen with aortic stenosis and uncontrolled hypertension.[13] This results in hypertrophy of the left ventricular myocardium. The thickened myocardium cannot relax appropriately to allow ventricular filling during diastole. Diastolic and systolic heart failure both result in a heart that appears globally enlarged. The point of maximal impulse (PMI) is lateralized due to enlargement of the left ventricle from either dilatation or hypertrophy. Both disease states can be visualized on US.

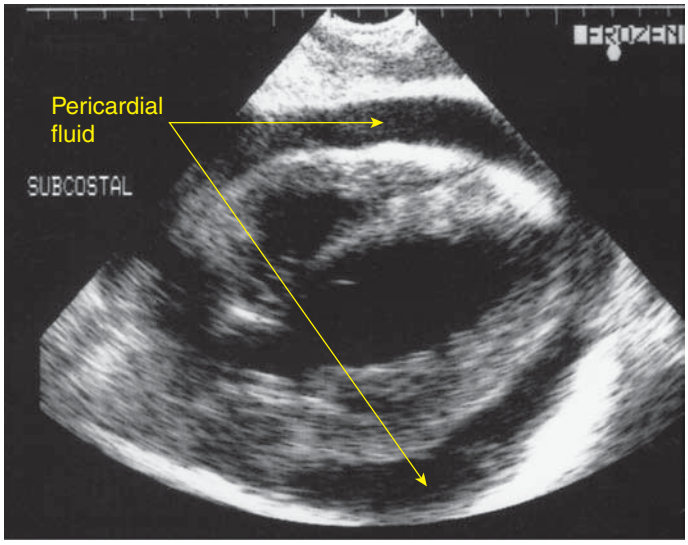

FIGURE 29-2. Free pericardial fluid is visualized as an anechoic stripe surrounding the heart. (Modified with permission from: Ma OJ, Mateer JM, Blaivas M: *Emergency Ultrasound*, 2nd ed. New York: McGraw-Hill, 2008.)

US FOR SUSPECTED PERICARDIAL FLUID

Pericardial fluid appears as an anechoic collection between pericardium and myocardium (**Figure 29-2**). Small effusions may layer posteriorly or appear as thin black stripes under the pericardium. Larger effusions extend anteriorly to surround the heart entirely. Epicardial fat may be confused for pericardial fluid but can usually be differentiated because it appears as an isolated thin hypoechoic layer along the anterior aspect of the heart (**Figure 29-3**).[18] Fluid generally appears anechoic and not hypoechoic like the epicardial fat. Loculated effusions are usually spherical or lenticular collections with echogenic borders and septae.

US FOR TRAUMATIC HEMOPERICARDIUM

Cardiac US has been used to diagnose hemopericardium in the setting of trauma, particularly penetrating injuries.[2,19] US is a rapid and noninvasive means of determining the need for operative intervention. The physical exam is generally unreliable in diagnosing a hemopericardium.[20] A subxiphoid pericardial window is invasive and unwarranted in low-risk patients.[2] Rozycki et al. evaluated the use of US performed by Surgeons, Cardiologists, and technologists for diagnosing a hemopericardium due to penetrating torso trauma. This study revealed a sensitivity of 100%, specificity of 96.9%, and an accuracy of 97.3%.[2] Plummer et al. demonstrated that a rapid sonographic evaluation of the heart performed by EPs expedites lifesaving management for victims of penetrating trauma.[19] Both length of time to operative intervention and mortality were significantly improved by ED cardiac US.

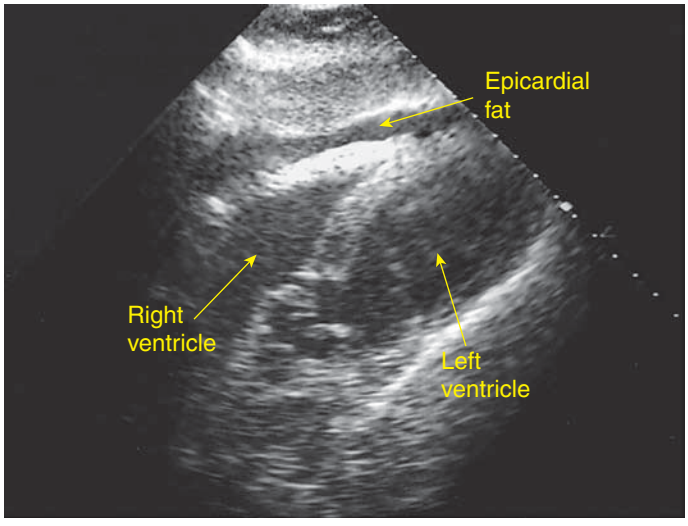

FIGURE 29-3. Subcostal long axis view of the heart demonstrating the epicardial fat pad anterior to the right ventricle. The epicardial fat pad is hypoechoic and not anechoic as usually seen with fluid. (Modified with permission from: Ma OJ, Mateer JM, Blaivas M: *Emergency Ultrasound*, 2nd ed. New York: McGraw-Hill, 2008.)

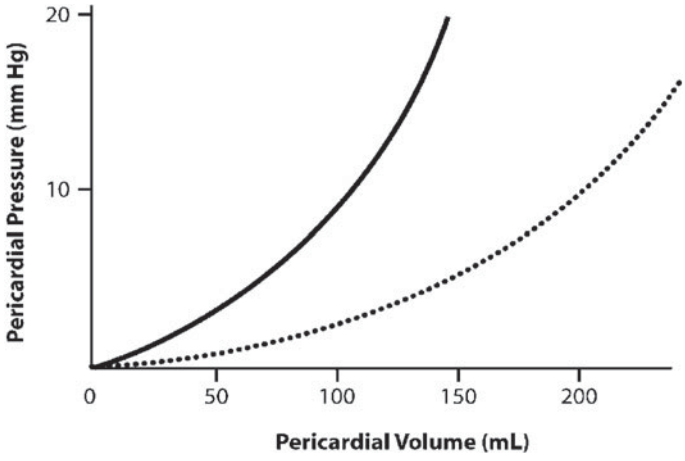

FIGURE 29-4. Pressure–volume relationship of the pericardial space. An acute effusion is represented by the solid line. A chronic effusion is represented by the dotted line. (Used with permission from: Ma OJ, Mateer JM, Blaivas M: *Emergency Ultrasound*, 2nd ed. New York: McGraw-Hill, 2008.)

The Focused Assessment with Sonography for Trauma (FAST) exam is the cornerstone of trauma ultrasonography.[17] This study consists of four views: three abdominal views and a single cardiac view. The incidence of hemopericardium is significantly lower for blunt trauma than for penetrating injuries. Substantial blunt force to the chest or deceleration injuries may result in myocardial or aortic tears and a hemopericardium.[21] Refer to Chapter 5 for the complete details of the FAST exam.

US FOR NONTRAUMATIC EFFUSIONS

The clinical suspicion for a pericardial effusion should prompt the EP to perform bedside ultrasonography. The diagnosis of pericardial effusion should be considered in any patient presenting with shortness of breath, chest pain, and decreased exercise tolerance. Hypotension, distended neck veins, pulsus paradoxus, a pericardial rub on physical examination, and low voltage or electrical alternans on ECG are all consistent with a pericardial effusion. Unfortunately, most of these findings are neither sensitive nor specific for a pericardial effusion or cardiac tamponade.[20] Hence, cardiac US is critical in making the diagnosis. It is important to note that chronic pericardial effusions are generally better tolerated than acute effusions. Pericardial compliance over time allows for a greater volume that exerts less pressure upon the cardiac chambers (**Figure 29-4**).[9]

Mandavia et al. investigated the ability of EPs to diagnose a pericardial effusion with US.[1] Of the 515 patients enrolled, 103 had pericardial effusion identified by the EPs for a sensitivity of 96% and a specificity of 98% according to the comparative standard.

US IN CARDIAC ARREST

US is useful for guiding the management of patients in cardiac arrest. Confirmation of asystole helps the EP in deciding to terminate resuscitation efforts. The sonographic findings of an arrested heart include still ventricular walls, sporadic nonperfusing twitches of the valves or myocardium, and at times a "smoky" appearance to the intracardiac blood without forward motion. Blaivas and Fox evaluated the predictive value of cardiac US in cardiac arrest.[4] Of 136 patients with cardiac standstill on US, 71 had an identifiable rhythm on the monitor. No patient with PEA and cardiac standstill survived to leave the ED.

PEA refers to a state in which the heart generates electrical activity on the ECG monitor but is unable to perfuse a palpable pulse. The spectrum of etiologies for this condition can be visualized with US, from "subpalpable hypotension" with contracting ventricles to terminal erratic cardiac twitches. In an observational study performed by Tayal and Kline, PEA patients without sonographic cardiac activity all died.[3] Several patients with sonographic motion of the myocardium had reversible causes such as a pericardial effusion survived. US has value in diagnosing several other etiologies of PEA including: cardiac tamponade,[1] myocardial infarction,[22] cardiogenic shock,[5,6] pulmonary embolism (PE),[23] aortic rupture,[24] hypovolemia, and hemorrhagic shock states.[14]

Circumstance may arise when ventricular fibrillation is not appreciated on the ECG monitor but is diagnosed by US. Fine ventricular fibrillation can look like asystole on the ECG monitor. Ultrasonography of fine ventricular fibrillation appears as rapid trembling of the ventricular myocardium versus the lack of any motion for asystole.

US FOR LEFT VENTRICULAR FAILURE

The high prevalence of CHF makes the assessment of left ventricular (LV) function particularly valuable in the ED. New-onset CHF is generally a clinical diagnosis for the EP. However, cardiac US allows for direct evaluation of LV function. Cardiac US may aid in distinguishing CHF from other causes of dyspnea such as chronic obstructive pulmonary disease, pneumonia, pericardial effusion, and PE.[25,26] US can help differentiate cardiogenic shock from other types of shock in a patient with unexplained hypotension.[6]

Moore and Agur investigated the use of bedside US for estimations of LV function in hypotensive patients.[27] They concluded that EPs can make accurate determinations. Randazzo et al. conducted a study in which EPs performed bedside cardiac US examinations on 115 patients.[28] Overall agreement between EP categorization of LV ejection fraction and formal Cardiologist echocardiogram was 86.1%.

Complex statistical calculation packages exist in echocardiography for determining the function of the left ventricle. However, the echocardiographer's estimation of LV ejection fraction has been shown to be quite accurate.[29] Rapid general assessment of LV function is suited for the EP. LV function can be categorized as hyperdynamic, normal, moderately impaired, and severely impaired for practical purposes in the ED. The more cardiac US's one performs,

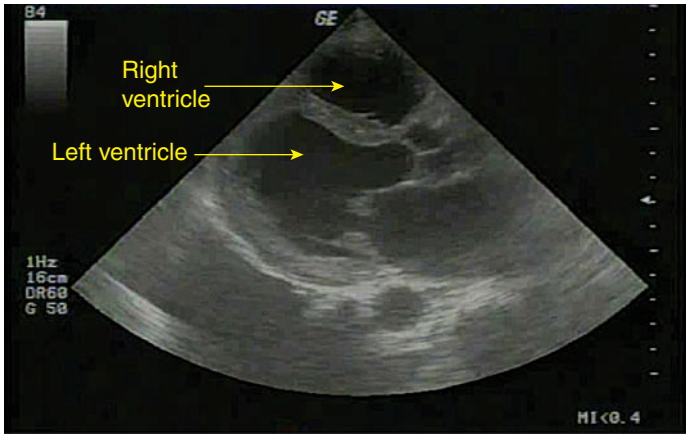

FIGURE 29-5. Parasternal long axis view of the heart in a patient with CHF. The enlarged left ventricle has limited contractility and a poor ejection fraction.

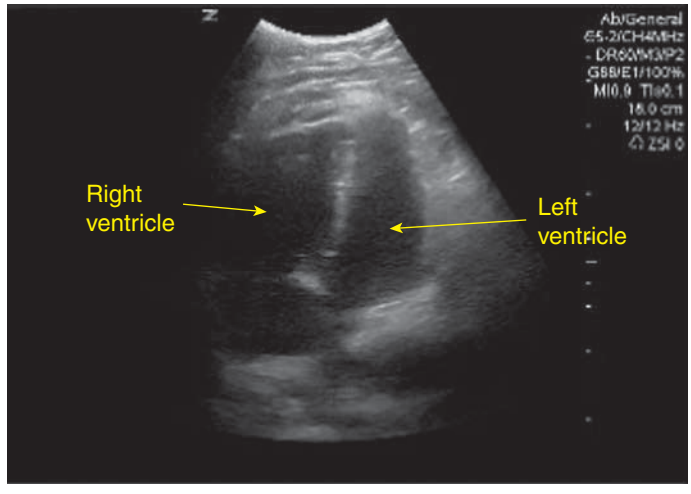

FIGURE 29-7. Right ventricular dilatation and bulging of the septum into the left ventricle are seen in the presence of a large PE.

the more comfortable one becomes categorizing a patient's LV function. A hyperdynamic heart is seen in the setting of hypovolemia or distributive shock. The tachycardic contractions cause the ventricular walls to nearly approximate or "kiss" each other. Hypokinetic contractions appear stiff. Patients with impaired LV function generally have dilated cardiac chambers, limited contractility, and limited inward movement of the ventricular walls during systole (**Figure 29-5**).

US FOR PULMONARY EMBOLISM

Patients with a large PE and hemodynamic compromise are often too unstable for conventional diagnostic imaging such as computed tomography and ventilation–perfusion scans. US can provide clues at the bedside for the diagnosis of a PE. The deep veins of the extremities can be assessed for clot.[30] A large obstructive PE will produce signs of right heart strain on cardiac US.[31,32] Dilation of the right ventricle should raise concern for a PE (**Figure 29-6**). Paradoxical bulging of the septum toward the left ventricle during diastolic filling is a sign of right heart strain (**Figure 29-7**).[32] Numerous other conditions such as emphysema, pulmonary hypertension, and right ventricular infarction cause right heart strain.[25,26] Konstantinides et al. showed that in hemodynamically stable patients with a PE and cardiac US findings of right heart dysfunction, administration of thrombolytic therapy reduced the need for escalation of treatment but did not affect mortality.[33]

US TO ASSESS SHOCK STATES

Bedside US is a valuable tool in the management of patients with undifferentiated shock. US provides a direct view into the cardiovascular system and allows the EP to make determinations about the hemodynamic status of a patient. Shock due to heart failure, cardiac tamponade, and PE was described previously. Hypovolemic and distributive shock generally presents with a tachycardic hyperdynamic heart. Rose et al. presented a protocol for the sonographic evaluation of the heart, peritoneal space, and aorta for undifferentiated hypotension.[5] Jones et al. concluded that implementing a similar protocol resulted in a more focused differential diagnosis and a more accurate ultimate diagnosis for patients in shock.[6]

Central venous pressures (CVP) and right atrial pressures can be estimated by US evaluation of the inferior vena cava (IVC) and the internal jugular veins, respectively.[16,34] An IVC diameter of 1.5 to 2 cm is considered normal (**Figure 29-8**).[16] A larger diameter

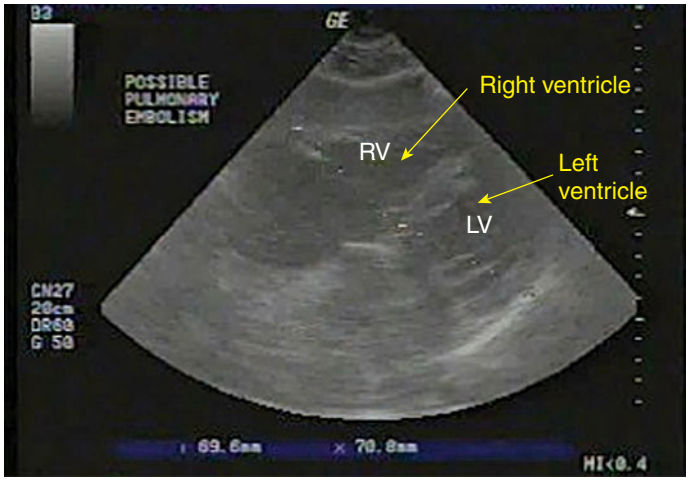

FIGURE 29-6. Concern for a PE is raised by the dilatation of the right ventricle. The diameter of the right ventricle is essentially equal to the diameter of the left ventricle.

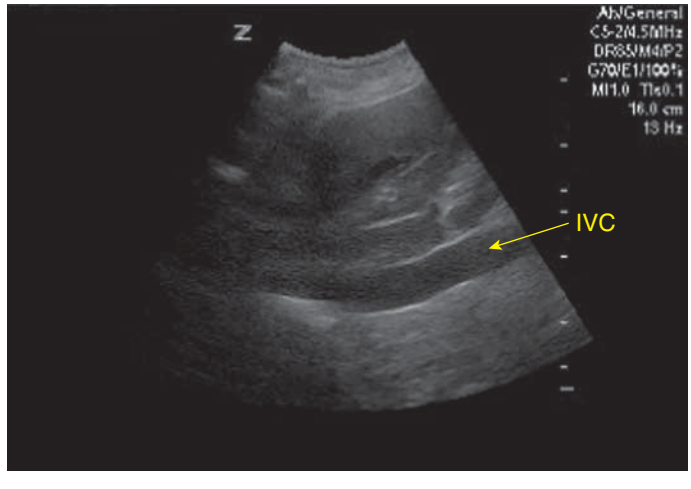

FIGURE 29-8. The normal caliber of the IVC as it passes beneath the liver in the caudal-cephalad direction.

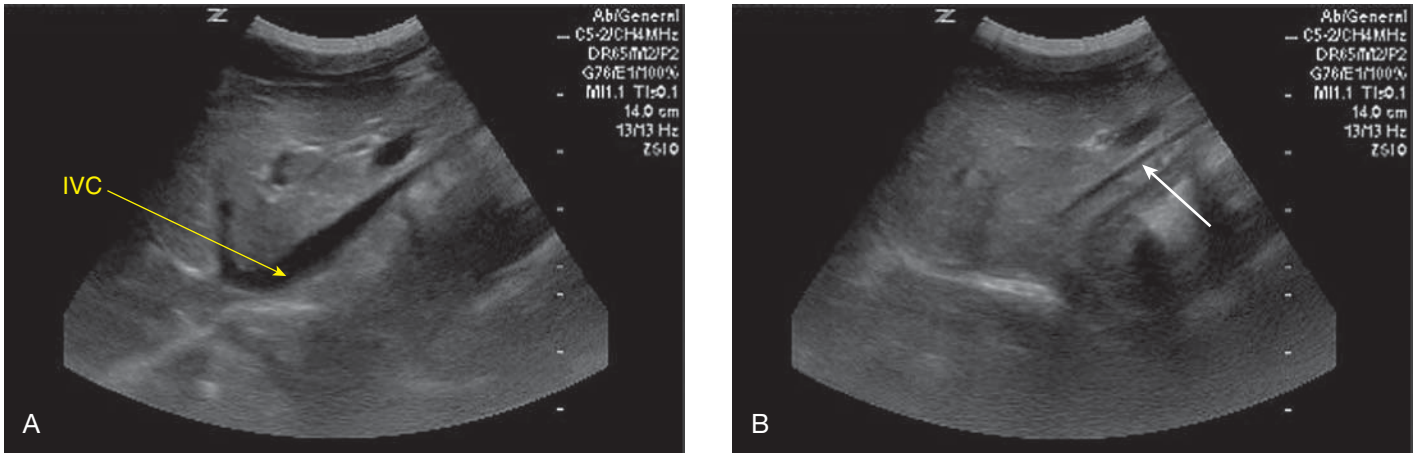

FIGURE 29-9. Longitudinal view of the IVC. **A.** The diameter of the IVC is narrow in this septic patient. **B.** Upon inspiration, the IVC collapses nearly completely (*white arrow*).

indicates elevated CVP while a smaller diameter is indicative of depressed CVP. The diameter of the IVC varies with respiration. Negative intrathoracic pressure produced by inspiration causes the IVC to collapse (**Figure 29-9**). A collapse of 50% is considered normal, with greater collapse indicative of low CVP and negligible collapse indicative of high CVP.[14–16] Simply stated, "fat" great veins are consistent with an elevated CVP and "flat" great veins are consistent with a low CVP.

INDICATIONS

The list of indications for cardiac US in the ED is continually expanding (**Table 29-1**). The two indications first described for ED US were for the identification of pericardial fluid (traumatic and nontraumatic) and the evaluation of cardiac activity.[17] These are still the primary examinations the EP must gain comfort in performing. Additional echocardiographic studies can be undertaken once these two have been mastered. This includes, but is not limited to, evaluation for left ventricular failure, chamber dilatation, myocardial wall motion defects, PE, evaluation of shock states, cardiac valve thrombus or vegetations, valvular dysfunction, procedural guidance (i.e., pericardiocentesis and transvenous pacer placement), and estimation of CVP by great vein measurements.

Numerous other indications exist for emergency US. EPs have begun to use cardiac US to evaluate wall motion defects in the setting of myocardial infarction.[22] Valvular abnormalities such as stenosis, regurgitation, thrombus, and vegetations (**Figure 29-10**) can also be assessed by emergency cardiac US.[35] The evaluation for cardiac myxomas, cardiac tumors, septal defects, dynamic function, and pediatric echocardiography are other cardiac US considerations in the future for the EP.

TABLE 29-1 Indications for Emergency Cardiac Ultrasonography

Primary indications	Advanced indications
Pericardial effusion	Cardiac chamber dilation
Cardiac arrest	Central venous pressure estimates
Traumatic hemopericardium	Intracardiac thrombus identification
	Left ventricular function
	Myocardial wall motion defects
	Procedural guidance
	Valvular dysfunction
	Valvular vegetations

CONTRAINDICATIONS

US is a noninvasive diagnostic modality. It is contraindicated only if it would delay and negatively impact a clinically obvious need for emergent operative intervention. The cardiac US exam should not be performed unsupervised by providers who have not been adequately trained.

EQUIPMENT

- US machine
- US gel
- Phased array low frequency US probe
- US probe cover or glove

A complete discussion of US equipment is beyond the scope of this chapter. Decisions regarding machines and probes depend on the user, cost, and intended applications. The cardiac US exam can be performed with a good quality low frequency probe. Probes with smaller footprints allow for easier viewing between the ribs.

The vast majority of cardiac US examinations performed by EPs are performed via the transthoracic approach. The preferred probe for transthoracic imaging is a small footprint, low frequency, phased

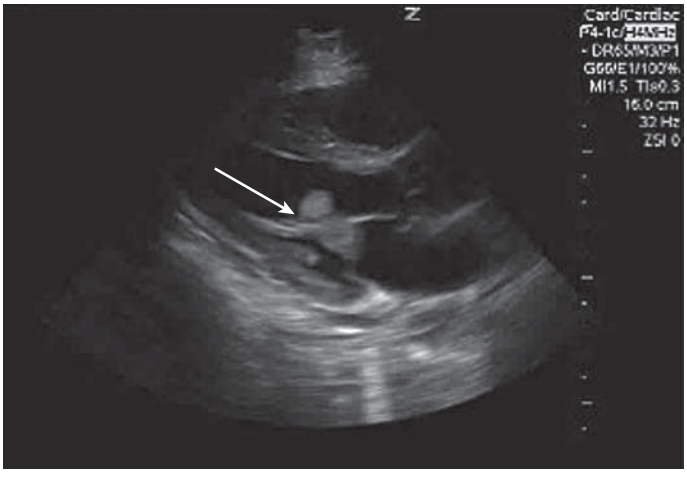

FIGURE 29-10. An infectious thrombus (*white arrow*) is located on the anterior leaflet of the mitral valve in this parasternal long axis view.

array, or microconvex probe (**Table 3-2**). Curved sequential probes can be used and may produce superior images. The large footprint of these probes can be cumbersome when trying to image between ribs or in a small subxiphoid space.

The US probe is generally used directly against the patient's skin, with gel between them. Place the probe in a probe cover or glove to prevent contamination of the probe if the patient's skin is covered with blood, urine, feces, or other substances. Place US gel in the probe cover or glove before inserting the probe. Squeeze out any air in the space between the tip of the probe and the probe cover or glove.

PATIENT PREPARATION

Little to no preparation is required to perform the cardiac US exam. Wipe any debris and liquids from the patient's skin in the areas to be scanned. Place the US probe in a probe cover or glove, as described above, if the patient's skin is contaminated with blood, vomit, other body fluids, or other substances that may contaminate or damage the probe.

TECHNIQUES

Echocardiography is a complex field. US is a dynamic tool that is well suited to imaging an organ in motion such as the heart. Much information about cardiac function and flow can be gained from complicated statistical calculation packages, advanced Doppler, and M-Mode measurements. This section focuses on the primary views most relevant to the EP with the hope of providing a foundation for more in-depth study of advanced cardiac US techniques in the future.

ORIENTATION INDICATOR

The probe orientation indicator in echocardiography is conventionally set to the right side of the screen. In Radiology, the probe indicator is set to the left side of the screen. Some controversy exists in EM as to which side of the screen to have the probe indicator for cardiac US. The approach preferred by the present authors is to set the orientation indicator on the left side of the screen, consistent with its location for other emergency US indications. It is impractical to switch the location of the indicator in the middle of a FAST exam or when performing multiple studies in a hypotensive patient. To obtain the conventional echocardiographic views, the probe must be rotated 180° from the conventional emergency US position. The left–right reversal of the indicator and the rotation of the probe result in the same image displayed on the screen. Most modern machines have a cardiac preset that automatically adjusts a number of factors to maximize cardiac imaging. It is important for the sonographer to be aware that this preset places the orientation indicator on the right side of the image. Left–right inversion is easily achieved on most machines.

SUBXIPHOID VIEW

The subxiphoid view is probably the most commonly used view by EPs. It provides visualization of the four heart chambers and allows for a superior evaluation for pericardial fluid. It can be performed without interruption of cardiopulmonary resuscitation or the insertion of chest tubes and subclavian central venous lines. The subxiphoid view is often the easiest view to incorporate into the FAST exam. This view can be limited in patients with a protuberant abdomen, abdominal pain, abdominal injuries, free air below the diaphragm, and/or nausea.

Place the probe in the subxiphoid space. Angle the probe cephalad into the patient's chest with the marker aimed to the patient's right (**Figure 29-11A**). Hold the probe with your fingers out from the underside or topside to allow for a shallow angle (approximately 20°) between the probe and the patient. The shallow angling of the transducer risks breaking contact between the footprint and skin.

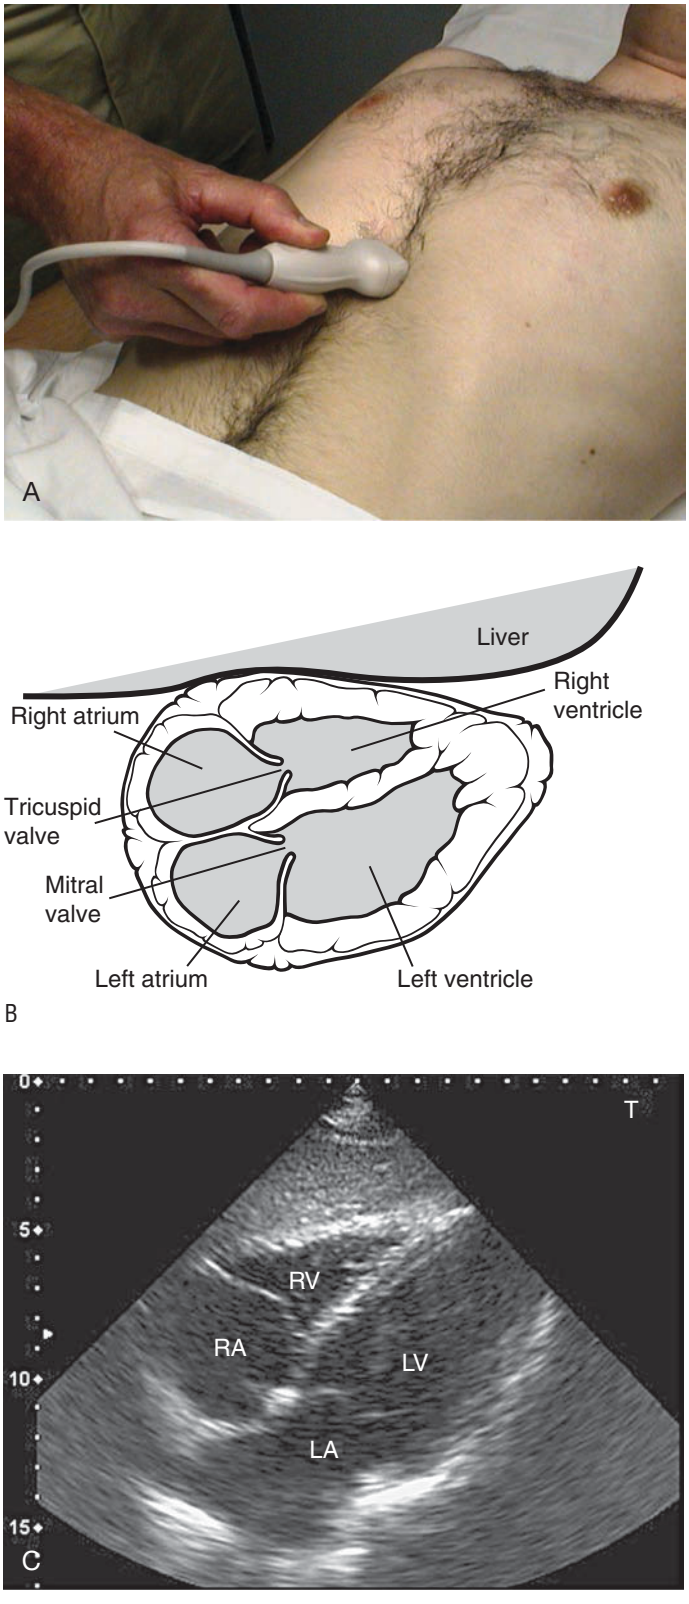

FIGURE 29-11. The subxiphoid view. **A.** Patient and probe positioning. **B.** Diagram of the US image. **C.** The US image. (Used with permission from: Ma OJ, Mateer JM, Blaivas M: *Emergency Ultrasound*, 2nd ed. New York: McGraw-Hill, 2008.)

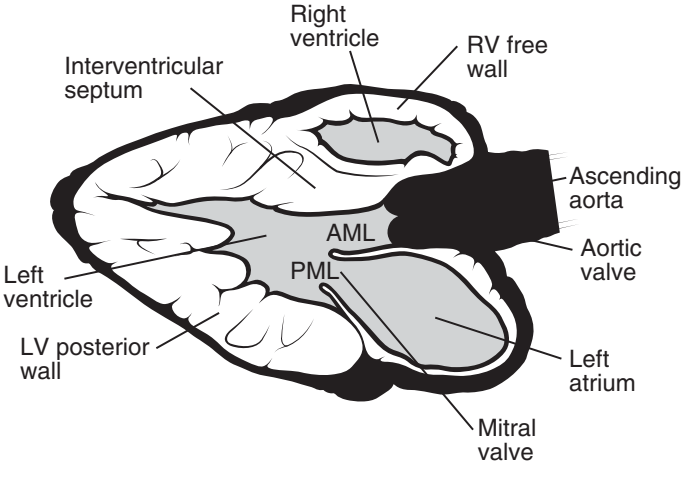
Apply an adequate amount of gel and firm pressure into the subxiphoid space to maintain contact.

To obtain a complete view of the heart, the US beam depth must be increased beyond that typically used for most other cardiac and abdominal imaging. To grasp the spatial orientation of this view, bear in mind that the probe is aimed from the inferior aspect of the heart. The US beam first traverses the left lobe of the liver, and hence, liver tissue is seen at the top of the image (**Figures 29-11B & C**). The plane of the beam then slices through the right-sided chambers, the septum, and then the left-sided chambers (**Figures 29-11B & C**). The echogenic pericardium is seen surrounding the myocardium.

Adjustments in a number of planes may improve the quality of the image. First, try to increase or decrease the steepness of the angle of the probe. While the heart lies more to the patient's left, so does the stomach, which contains air that scatters the US beam. The liver, on the other hand, serves as a good "acoustic window" or a transmitter of the beam allowing for better image acquisition. Taking advantage of imaging through the liver often involves veering from just right of midline, a slight counter clockwise rotation of the probe, and angling toward the patient's left shoulder. Ask the patient to take a deep breath to bring their heart inferiorly and into the scanning plane to improve the image.



PARASTERNAL LONG AXIS VIEW

The parasternal long axis view may not be familiar to most EPs. It often is easier to obtain, provides clearer images, and is better tolerated by the patient. Place the probe to the left of the sternum, along the long axis of the heart (**Figure 29-12A**). Hold the probe perpendicular to the chest wall with the marker aimed toward the apex of the heart or the PMI. This is roughly toward the patient's left hip. Unfortunately, shadowing from bone and scattering from air in the lung surrounds the heart. Place the probe between two ribs and just lateral to the sternum, but not over lung tissue. The third or fourth intercostal space affords the best view.

The right ventricle sits underneath the probe and is visualized in the near field of the screen (**Figures 29-12B & C**). This view also provides an excellent glimpse into the left side of the heart. The left ventricle lies beneath the right ventricle. The interventricular septum is well visualized and extends to the apex of the heart on the left side of the screen. The base of the heart can be visualized on the right side of the screen (**Figure 29-12C**). The left ventricle empties into the aortic outflow tract, with the aortic valve and root usually visible. The left atrium lies deep, and the mitral valve can be seen opening into the left ventricle (**Figures 29-12B & C**). To visualize the apex of the heart in the center of the screen, slide the probe in the direction of the marker (toward the PMI) and in the opposite direction to the center of the base of the heart. The descending aorta may be visualized in a transverse slice along the underside of the heart and is an important landmark in distinguishing pericardial from pleural fluid. Pericardial fluid collects posteriorly and will appear as a black stripe separating the myocardium from the pericardium and descending aorta (**Figure 29-13**). Pleural fluid, on the other hand, will reside outside of the bright pericardium and tapers to a stop at the descending aorta.

Adjustments on the tilt of the probe may optimize the view. Place the patient in the left lateral decubitus position to bring the heart closer to the chest wall and improve the image. Slide the probe laterally, to a more cephalad intercostal space, or open its rotation with a counter-clockwise turn to better optimize the view for patients with CHF. Move the probe to a more caudal intercostal space, close the angle of the probe with a clockwise rotation, or use the subxiphoid view to better optimize the view for patients with emphysema and an inferiorly displaced heart.

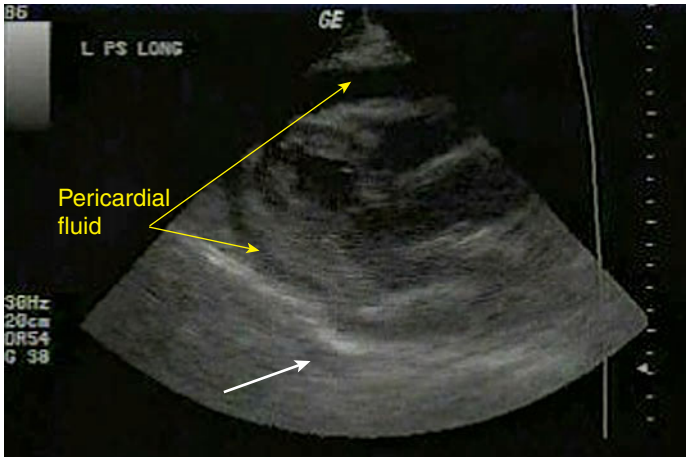

FIGURE 29-13. The parasternal long axis view of a pericardial effusion. Pericardial fluid separates the myocardium from the pericardium and the poorly visualized descending aorta (*white arrow*).

PARASTERNAL SHORT AXIS VIEW

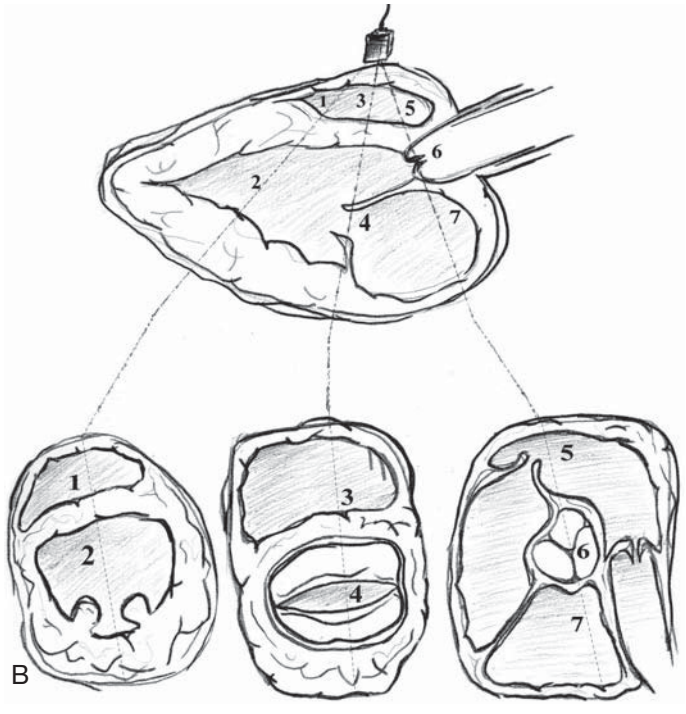
The parasternal short axis view slices through the heart transversely. Place the probe similar to the parasternal long axis view, but with the probe rotated 90° to rest along the heart's short axis (**Figure 29-14**). Aim the marker toward the patient's right hip. The left ventricle appears as a prominent circle in the center of the screen, with the right ventricle resting atop it as a flatter or a crescent-shaped chamber (**Figures 29-14B & 29-15**). Tilting or sliding the probe along the heart's long axis toward the patient's left hip allows visualization of the apex of the heart. Tilting or sliding the probe toward the patient's right shoulder allows visualization of the base of the heart. The ventricles should cone down to a tip at the apex. When tilting back up from the apex through the heart, the papillary muscles (**Figure 29-15**) and mitral valve with its "fish-mouth" appearance (**Figure 29-16**) will come into view. Continue tilting the probe upward toward the base of the heart. The three leaflets of the aortic valve will be seen centrally (**Figure 29-17**). At this point, the scan is beyond the left ventricle, allowing the atria to be visualized as well as the right ventricle emptying into the pulmonary artery.

APICAL FOUR-CHAMBER VIEW

The apical four-chamber view is obtained by placing the probe at the PMI, just inferior to the left nipple and angling up through the heart (**Figure 29-18**). Aim the marker toward the patient's right. This study is relatively simple to perform by transitioning from the parasternal short axis view. Slide the probe down to the apex of the heart and then tilt it upward toward the base of the heart (**Figure 29-18A**). The image reveals a side-by-side view of the ventricles in the near field and the atria in the far field (**Figures 29-18B & C**). The lung adjacent to the heart impedes imaging. Place the patient in the left lateral decubitus position to alleviate scattering. The left ventricle appears larger and has thicker walls than the right ventricle. The mitral valve sits slightly lower than the tricuspid valve. Ventricular function, flow across the valves, and septal defects can be assessed with this view. This view allows for comparing chamber size and evaluating for right ventricular dilatation if there is concern for an obstructive PE.

SUBCOSTAL INFERIOR VENA CAVA VIEW

Sonographic evaluation of the IVC can provide valuable hemodynamic information to the EP.[14,15] This view is also referred to as the subxiphoid long axis view. Place the probe in the subxiphoid



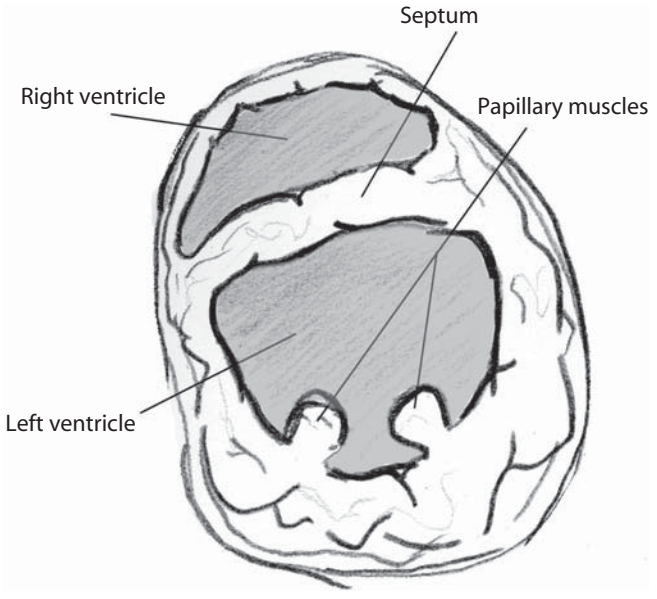


FIGURE 29-14. The parasternal short axis view. **A.** Patient and probe positioning. **B.** Diagram of the three US views depending on probe angulation. (Used with permission from: Ma OJ, Mateer JM, Blaivas M: *Emergency Ultrasound*, 2nd ed. New York: McGraw-Hill, 2008.)

space, perpendicular to the patient's abdominal wall and with the marker aimed toward the patient's head (**Figure 29-19A**). The longitudinal IVC will appear posteriorly, beneath the liver and the bowel, as a long black cylinder. It is important to distinguish the IVC from the aorta. The aorta lies on the patient's left side, is more "pipe-like" in appearance, is noncompressible when pressure is applied by the US probe, and has a recognizable pulsatility. The IVC is compressible when pressure is applied by the US probe and varies in diameter with respiration (**Figures 29-19C & D**). It may be beneficial to start in the transverse plane in which both the IVC and the aorta are visualized (**Figure 29-20**). Starting with the transverse view, rotate the US probe 90°, maintaining the IVC in the center of the screen to obtain the longitudinal view

A

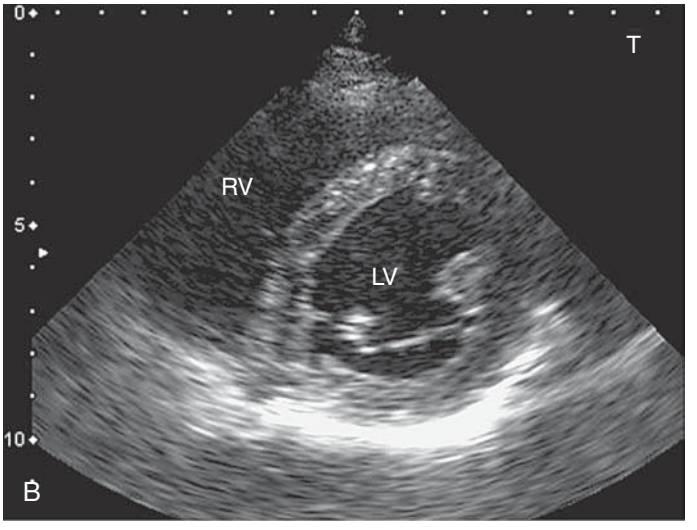

FIGURE 29-15. The parasternal short axis view at the level of the papillary muscles. **A.** Diagram of the US image. **B.** The US image. (Used with permission from: Ma OJ, Mateer JM, Blaivas M: *Emergency Ultrasound*, 2nd ed. New York: McGraw-Hill, 2008.)

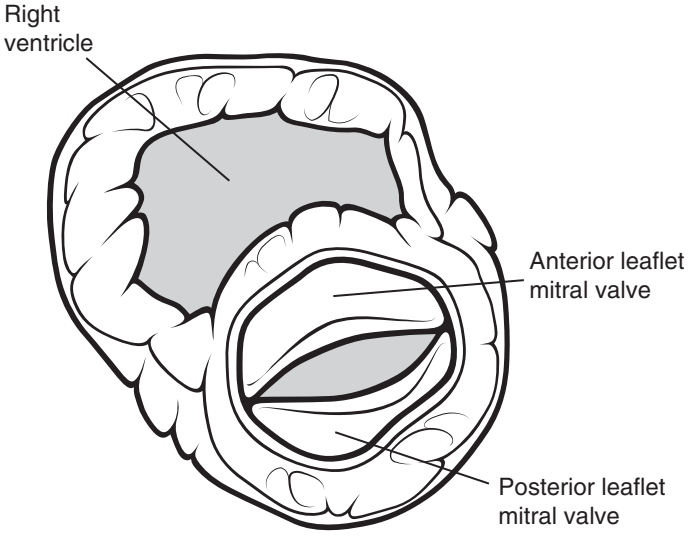

(**Figure 29-19**). Tilt the probe cephalad to visualize the IVC entering the right atrium (**Figures 29-19C & D**).

Measurements of the IVC proximal to its entrance into the right atrium allows for a noninvasive estimate of CVP. The negative pressure generated in the chest by inspiration draws blood cephalad and decreases the diameter of the IVC (**Figures 29-19C & D**). Normal dimensions for the IVC include a diameter of 1.5 to 2.0 cm and an inspiratory collapse of 50%.[14,15] A smaller diameter and greater inspiratory collapse are indicative of a low CVP.[14–16] A larger diameter and lesser inspiratory collapse reflect a high CVP.[14–16] Obtain estimates by having the patient sniff deeply and freeze the image postinspiration. Use the cine-rewind feature on the US machine to identify images or frames that allow for the measurement of the maximal and minimal IVC diameters through the respiratory cycle (**Figure 29-19**). M-Mode tracing of the respiratory cycle allows for precise measures of the inspiratory and expiratory IVC diameters (**Figure 29-21**).

US GUIDANCE FOR PERICARDIOCENTESIS

US-guided pericardiocentesis has proven to be safe and is the method of choice for most institutions.[36] A brief description of the procedure is provided in this section. Please refer to Chapter 36 for the complete details regarding pericardiocentesis.

Emergent pericardiocentesis can be guided by US using either a static or a dynamic approach. For the static approach, visualize the effusion by US and determine the best approach for needle placement. Remove the probe from the patient and proceed with the

A

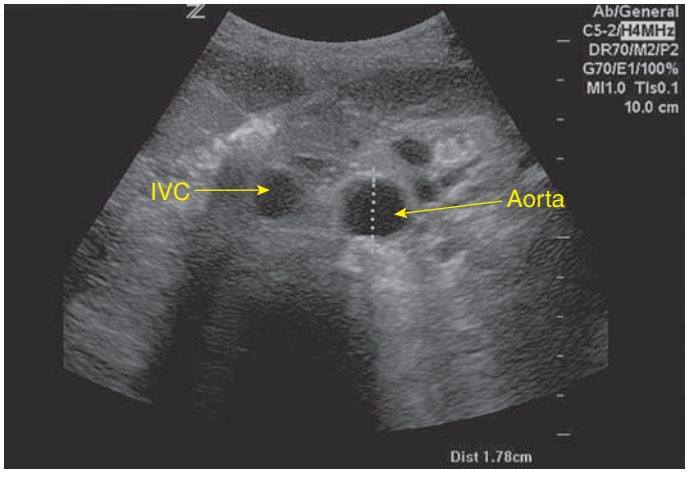

FIGURE 29-20. The transverse IVC view. The IVC is located to the right of the patient's aorta.

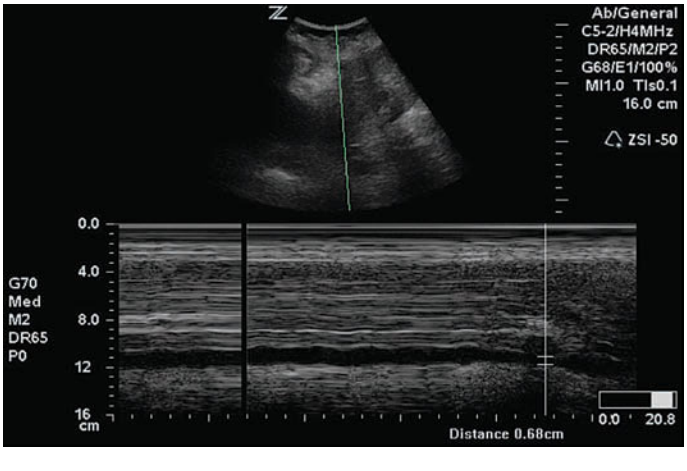

FIGURE 29-21. M-Mode tracing of the IVC. Respiratory variation is seen. The dark stripe represents the diameter of the IVC over time. Measurements are taken at the point of inspiratory collapse (*white lines*).

pericardiocentesis procedure. For the dynamic approach, the heart is visualized throughout the procedure to guide needle placement. Sterile technique is required for the US probe and cord. The availability of a second ultrasonographer or an assistant for dynamic guidance is helpful, particularly if an agitated-saline injection is attempted.

The pericardiocentesis site depends on the patient's body habitus, the location of the maximal visualized effusion, and the US views obtainable. The two most common sites for needle insertion are the subxiphoid space and left anterior parasternal chest wall.

For the static approach, visualize the path of needle penetration with the corresponding US image. Measure the distance from the top of the image to the pericardial space to determine the depth of needle insertion. It is important to note that the liver is often visualized in the anticipated needle trajectory with the subxiphoid US view. Use the parasternal long axis view because the pericardium is more superficial in this view. This author prefers the parasternal long axis approach for these reasons. Proceed with the pericardiocentesis procedure.

For the dynamic approach, insert the needle directly adjacent to the transducer. Angle the probe to interface with the plane of needle insertion (**Figure 29-22**). Aim the US probe marker cephalad and between the ribs to provide good visualization of the intercostal space. Insert the needle over the superior edge of the rib and along the plane of the US beam. It is optional to use color Doppler in the near field to ensure the intercostal and internal mammary arteries are not punctured. Advance the needle while aspirating with the syringe as the needle is advanced. The pericardium may "tent" as the echogenic needle presses upon it (**Figure 29-23A**) and then enters the pericardial space (**Figure 29-23B**).

Injection of agitated saline may be attempted to confirm needle placement in the pericardial space. Agitate the saline by rapidly injecting saline back and forth from one syringe into another through two ports of a three-way stopcock: with the third port connected by sterile tubing to the pericardiocentesis needle. Once microbubbles have formed, inject the agitated saline into the pericardial space. The fluid will appear on US as a bright white scattering within the pericardial sac.

US GUIDANCE FOR CARDIAC PACING

US can be used to confirm capture of transcutaneous (Chapter 31) or transvenous (Chapter 33) cardiac pacing.[37,38] It is difficult to appreciate mechanical capture by simply looking for electrical changes on the ECG monitor. Transcutaneous cardiac pacing discharges often cause simultaneous jerking of the patient that masks a palpable pulse. Cardiac US evaluation during cardiac pacing allows visualization of mechanical contractions of the heart. During placement of the transvenous cardiac pacing wire, it can be visualized passing through the right atrium and tricuspid valve into the right ventricle. A subcostal view of the IVC can confirm errant passage of the wire down the IVC.

SUMMARY

Limited ED cardiac ultrasonography provides real-time information to answer specific questions. It is not intended to replace formal cardiac echocardiography. There is a body of evidence that shows non-Cardiologists can accurately and safely perform limited cardiac US exams. The use of cardiac US in the ED has risen from a few basic examinations into a sophisticated series of exams in a very short time. This chapter provides an introduction to ED cardiac ultrasonography. The EP can become very comfortable with cardiac US as a supplement to the evaluation and management of patients. ED cardiac ultrasonography is a very valuable tool that can easily be incorporated into the daily clinical practice of Emergency Medicine.

30 Cardioversion and Defibrillation

Payman Sattar

INTRODUCTION

The application of electricity to the heart induces depolarization of the myocardial cells in a uniform fashion. This may interrupt reentry circuits that are inducing an arrhythmia. Once depolarization of the myocardium has been achieved, the sinus node may then resume its normal pacing function. This is accomplished with the transthoracic application of a direct-current electrical shock.

The techniques of cardioversion and defibrillation are relatively straightforward and practically identical. The main differences are the indications and use of synchronization with cardioversion. **The purpose of cardioversion is to deliver a precisely timed electrical current to the heart to convert an organized rhythm to a more hemodynamically stable rhythm. The purpose of defibrillation is to deliver a randomly timed high-energy electrical current to the heart to restore a normal sinus rhythm.** These techniques are currently performed by emergency medical technicians, nurses, paramedics, physicians, and a variety of other healthcare workers on a daily basis. This chapter discusses the techniques of manual cardioversion and defibrillation. A discussion of Advanced Cardiac Life Support (ACLS), cardiac rhythms, chemical cardioversion, and Pediatric Advanced Life Support is beyond the scope of this work. The technique of automatic external defibrillation is not discussed.

INDICATIONS

CARDIOVERSION

In general, electrical cardioversion is performed either electively or emergently. In the Emergency Department, the role of electrical cardioversion is usually limited to urgent or emergent situations or when medical therapy has failed.[1,2] This includes symptomatic reentry tachycardias (e.g., supraventricular tachycardia, atrial fibrillation, atrial flutter, and Wolff–Parkinson–White syndrome) and hemodynamically stable ventricular tachycardia associated with acute myocardial infarctions, altered levels of consciousness, chest pain, congestive heart failure, dizziness, dyspnea, hypotension, presyncope, pulmonary edema, shock, or syncope.

In the Emergency Department, electrical cardioversion is often preferred to chemical cardioversion for many reasons. Electrical cardioversion is simple and quick to perform. It is effective—in most cases almost immediately. It may be more successful than chemical cardioversion. The complications are usually minimal. Potential allergic reactions and toxic effects are nonexistent with electrical cardioversion.

DEFIBRILLATION

Defibrillation is indicated when ventricular fibrillation or ventricular tachycardia has not spontaneously converted to an organized rhythm. Ventricular fibrillation and ventricular tachycardia are rarely spontaneously reversible and are not compatible with life. Defibrillation must be performed immediately if the patient is found pulseless, unconscious and apneic, or during the ACLS protocol. "Fine" ventricular fibrillation can be present and may be confused with asystole. It may be secondary to low gain amplitude or improper lead positioning. If "quick-look" paddles are being used, they may be rotated 90°. If a monitor is being used, select a different lead and/or increase the gain to determine if the cardiac rhythm is fine ventricular fibrillation or asystole. Ventricular fibrillation or ventricular tachycardia secondary to myocardial ischemia or infarct, electrolyte abnormalities, long-QT syndromes, hypothermia, or drug toxicity (e.g., digoxin, tricyclic antidepressants, antiarrhythmics, antihistamine, and macrolide antibiotic combinations) may convert to a more stable rhythm with defibrillation.

CONTRAINDICATIONS

CARDIOVERSION

Cardioversion is contraindicated for several cardiac rhythms or conditions. Do not cardiovert a patient with a rhythm of ectopic atrial tachycardia, junctional tachycardia, multifocal atrial tachycardia, sick sinus syndrome, or sinus tachycardia. Cardioversion is not effective for these rhythms and may result in a worse (i.e., ventricular fibrillation or ventricular tachycardia) postshock rhythm. **Cardioversion of atrial fibrillation should not be attempted unless it is known with certainty that the rhythm initiated within the last 48 hours.** Cardioversion of chronic atrial fibrillation, or atrial fibrillation having lasted longer than 48 hours, may dislodge atrial thrombi, resulting in thrombus embolization and end organ injury (e.g., stroke). There is some controversy in the literature regarding the cardioversion of atrial flutter greater than 48 hours old without anticoagulation.[3,4] In general, elective cardioversion of atrial flutter should not be performed if the rhythm has lasted for longer than 48 hours. Often times, atrial fibrillation and flutter can coexist. **Do not cardiovert a patient with a known thrombus in the atria, atrial appendage, or ventricle without first consulting a Cardiologist. Cardioversion in patients with digoxin toxicity should be avoided.** Cardioversion in digoxin toxicity is usually ineffective and has been associated with postshock ventricular tachycardia and ventricular fibrillation.[5] Cardioversion is also contraindicated when the patient is without a pulse or has an underlying cardiac rhythm of asystole.

Alterations in the chemical or metabolic milieu of the myocardium may cause subsidiary pacemakers to become more dominant and overtake the sinus mode. This is referred to as enhanced automaticity and can be due to drugs (e.g., digoxin), hypoxia, or electrolyte abnormalities (e.g., hypokalemia or hypomagnesemia). Uniform depolarization with electricity does not terminate this abnormality, as uniform depolarization already exists. The rhythms that may occur are sinus tachycardia, ectopic atrial tachycardia, multifocal atrial tachycardia, and the digoxin toxic rhythms. Treatment of the underlying etiology is the treatment of choice.

DEFIBRILLATION

There are few contraindications to defibrillation. The main contraindication is in a patient who has made it clear that they does not wish to be resuscitated. Defibrillation should not be used for arrhythmias other than ventricular tachycardia or ventricular fibrillation.

EQUIPMENT

- Cardioverter-defibrillator unit
- Conductive jelly or pads
- Suction source, tubing, and catheter
- Airway management supplies
- Advanced Cardiac Life Support (ACLS) medications
- Intravenous sedative agents

FIGURE 30-1. Two examples of cardioverter-defibrillator units.

- Cardiac monitor
- Noninvasive blood pressure monitor
- Pulse oximeter
- Oxygen source and tubing
- Nasal cannula or face mask to deliver oxygen

THE CARDIOVERTER-DEFIBRILLATOR UNIT

The typical cardioverter-defibrillator unit performs both cardioversion and defibrillation (**Figure 30-1**). A list of available features on a typical unit is listed in **Table 30-1**. Newer models feature lower power outputs to accommodate their use in children, pediatric and adult paddles, biphasic waveforms, and cardiac pacing capabilities. Each Emergency Physician should be familiar with the specific unit at their facility. The general features of the unit are discussed below.

The unit is self-contained. It plugs into a standard electrical outlet. The unit also contains rechargeable batteries, which allow it to be portable. An oscilloscope provides real-time monitoring of the patient's cardiac rhythm. A continuous electrocardiographic (ECG) rhythm strip providing documentation on paper is standard with each unit, producing a hard copy to attach to the patient's medical record. Numerous dials or electronic touchpads with digital displays allow the operator to set the working mode, energy level, pacemaker settings, and oscilloscope input (e.g., ECG leads or "quick-look" paddles). The depolarizer within the machine provides direct electric current for cardioversion and defibrillation.

The synchronizer permits the discharge of electric current based on the patient's ECG waveform. It searches for the R and S waves of the ECG tracing to determine the proper time to discharge the current. It avoids delivering the current during the repolarization phase of the myocardial action potential, when the heart may convert to ventricular fibrillation or ventricular tachycardia. When the operator pushes the button to discharge the unit, a brief delay is noted while the synchronizer searches for an appropriate time to discharge the current.

TABLE 30-1 Characteristics of a Typical Cardioverter-Defibrillator Unit

Adult and pediatric paddles
Cardioversion capability
Continuous ECG rhythm-strip documentation on paper
Defibrillator capability
Depolarizer
On/off switch
Oscilloscope to monitor cardiac rhythms
Pacing capabilities
Portability
"Quick-look" paddles
Safety mechanism to prevent accidental electrical discharge
Synchronizer
Standard ECG leads (three) to attach to the shoulders and lower extremity
Wide range of energy selection

TABLE 30-2 Recommended Initial and Subsequent Monophasic Energy Levels for Cardioversion or Defibrillation

Cardiac rhythm	Initial energy setting	Subsequent energy settings*
Adults		
Atrial fibrillation	100 J	200, 300, 360 J
Atrial flutter	50 J	100, 200, 300, 360 J
Supraventricular tachycardia	50 J	100, 200, 300, 360 J
Ventricular tachycardia	200 J	300, 360 J
Ventricular fibrillation	200 J	300, 360 J
Children		
Supraventricular tachycardia	0.5 J/kg	1.0 J/kg
Ventricular tachycardia	2.0 J/kg	4.0 J/kg
Ventricular fibrillation	2.0 J/kg	4.0 J/kg

*To be performed sequentially in this order.

MONOPHASIC VERSUS BIPHASIC UNITS

In the past, all cardioverter-defibrillator units generated monophasic waveform current to deliver the shock. Biphasic waveform current generating units were developed in the late 1990s. The biphasic units deliver more current at a lower energy level to cardiovert or defibrillate (**Tables 30-2 & 30-3**). They have also been shown to be more effective in cardioverting and defibrillating a patient. Unfortunately, biphasic units are significantly more expensive than monophasic units. Determine which type of unit is available at your facility to determine the proper energy levels to administer.

TYPES OF ELECTRODES

The electrodes are referred to as either paddles or patches depending on their configuration. The paddles or patches must be firmly applied to the patient's torso. They allow a "quick look" and transmit

TABLE 30-3 Recommended Initial and Subsequent Zoll® Biphasic Energy Levels for Cardioversion or Defibrillation

Situation	Initial energy setting	Subsequent energy settings*
Adults		
Defibrillation	120 J	150, 200, 200 J
Synchronized cardioversion	70 J†	120, 150, 150 J
	75 J‡	
Children		
Defibrillation	2.0 J/kg	2.0, 2.0, 2.0 J/kg

†E Series.
‡M Series, CCT, R Series.

the patient's cardiac rhythm to the oscilloscope, letting the operator make medical decisions before the ECG leads are attached to the patient. Each paddle has a button on which a thumb is to be placed. This serves as a safety mechanism. Both buttons must be depressed simultaneously to discharge the current. This prevents accidental and premature discharge of current, which may injure the patient, the operator, or bystanders. Most newer units use self-adhesive, single patient use, disposable patches as an alternative to paddles. The patches apply to the torso similar to ECG leads. They connect by cables to the cardioverter-defibrillator unit.

Paddles or patches come in various shapes and sizes. Adult paddles or patches are round, oval, or rectangular in shape. They measure 8 to 10 cm in greatest diameter. They can be used on children weighing more than 10 kg or over 1 year of age, adolescents, and adults. Pediatric paddles or patches also come in a variety of shapes and measure 4 to 6 cm in greatest diameter. The pediatric paddles are to be used in children weighing less than 10 kg or less than 1 year of age. Some units contain both adult and pediatric paddles or the ability to use both adult and pediatric patches. In these units, the adult electrode slides off the paddle handle to reveal the pediatric-size electrode.

In choosing the proper paddle or patch for a small child, the cutoff of 10 kg and 1 year of age is relative. Choose the largest paddle or patch that will achieve complete and full contact with the child's chest wall. Larger paddles and patches will allow a greater amount of myocardium to be depolarized while decreasing the current density applied, so as to minimize myocardial injury. The paddles or patches must be at least 2 to 3 cm apart to prevent electrical bridging and burn injury to the child. Using paddles or patches that are too large will deliver the electric current over too great an area and decrease its effectiveness. The opposite is true in adults (using paddles or patches that are too small will deliver the electric current over a small area, which makes it too intense and increases the potential damage to the myocardium).

ELECTRODE POSITIONING

The paddles or patches may be positioned in several different patterns.[6,7,13] The most commonly used positions are anterolateral for paddles (**Figure 30-2**) and either anterolateral or anteroposterior (**Figure 30-3**) for patches. Anterolateral paddles or patches are positioned with the anterior paddle at the right upper sternal border

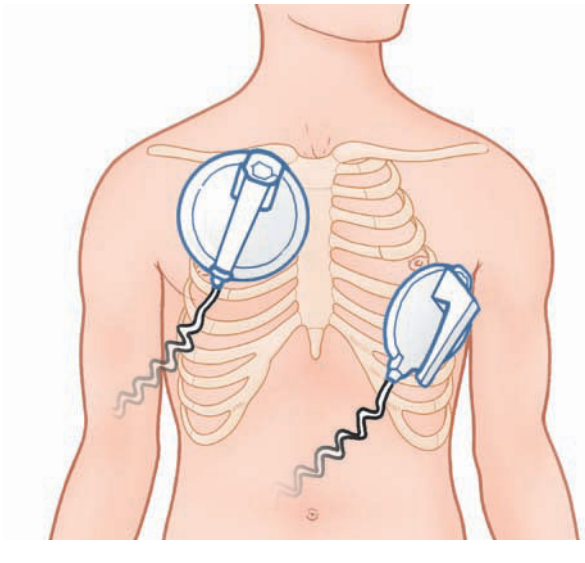

FIGURE 30-2. Anterolateral pad and paddle positioning.

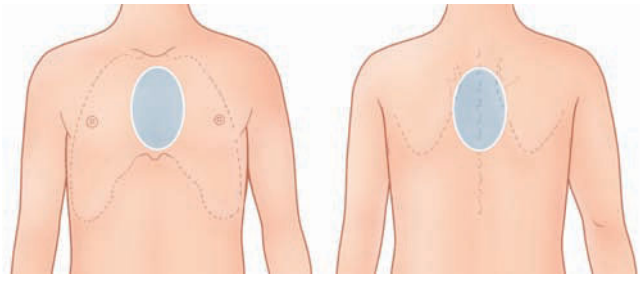

FIGURE 30-3. Anteroposterior pad and paddle positioning.

over the second and third intercostal spaces. The lateral paddle or patch is placed in the left midaxillary line centered over the fourth and fifth intercostal spaces. Anteroposterior placement is often used with disposable patches rather than paddles (**Figure 30-3**). The anterior patch is centered over the sternum, and the posterior patch is placed between the scapulae. A randomized and prospective trial evaluated the anteroposterior versus anterolateral patch position in converting atrial fibrillation.[13] The anteroposterior patch position was more effective in converting the rhythm. If pediatric paddles are required but not available, adult paddles can be substituted.[6] Roll the child onto their right side and place the paddles in the anteroposterior position. Other paddle positions include the laterolateral (axilla-to-axilla) position and the parasternal-infraclavicular (oblique, left anterior chest to right posterior infrascapular) position.[7]

CONDUCTIVE CONTACT MEDIUM

Electrically conductive contact medium should always be applied between the electrode and the patient's chest wall. Conductive gel pads are commercially available and primarily used. The contact material helps to maximize current flow, minimize resistance, reduce transthoracic impedance, and prevent thermal or electrical burns to the chest wall. The self-adhesive disposable patches are prelubricated with contact medium and need no additional contact medium.

Contact medium is required with the older units that use paddles. Self-adhesive, disposable conductive gel pads can be used. An alternative is the gel or paste form of contact medium. The contact medium should be applied to the paddles generously. It should not connect the paddles, because then it would divert the electric current along the chest wall, away from the heart, and cause burns to the chest wall. If contact medium is not available, saline-soaked gauze squares can be used in an emergency. The saline must be squeezed out of the gauze squares to prevent the accumulation of liquid on the chest wall, which could bridge the two paddles.

PATIENT PREPARATION

Place the patient supine on a bed. Attach the cardiac monitor, noninvasive blood pressure monitor, pulse oximetry, and oxygen to the patient. Obtain intravenous access. Suction and resuscitation equipment should be readily available in case it is needed. Cardioversion is scary and extremely uncomfortable for patients. Briefly explain the procedure to the patient, including the risks, benefits, and complications. Premedicate the patient prior to cardioversion if no contraindications exist, the patient is hemodynamically stable, and they can tolerate a delay to cardioversion. The choice of the appropriate sedative agent is physician-dependent. Commonly used agents include etomidate, ketamine, midazolam, methohexital, propofol, and thiopental. Diazepam and lorazepam are not often used because of the long delay to onset of action.

TECHNIQUES

Stand at the patient's left side. Turn on the cardioverter-defibrillator unit. Set the display to the "quick-look" paddles. Instruct the nurses to apply the ECG leads to the patient. Grasp the left paddle (sternum) with the left hand and the right paddle (apex) with the right hand. This is the anterolateral paddle position. Apply the paddles and observe the patient's cardiac rhythm. Set the mode as asynchronous (defibrillation) or synchronous (cardioversion) based on the patient's cardiac rhythm. Set the energy level (**Tables 30-2 & 30-3**). **Older defibrillator units deliver monophasic waveform energy. Newer units deliver biphasic energy, which has been shown to be more effective, and deliver more current at lower energy settings.**

Apply conductive pads to the patient's torso in the anterolateral position. Alternatively, apply conductive jelly to the paddles liberally and rub them together to coat the electrode surface completely. Apply the paddles firmly to the torso in the anterolateral position. **The paddles should be separated from each other by at least 2 to 3 cm to prevent arcing of the current and injury to the patient.**

Prepare to deliver the electric current to the patient. Charge the paddles. This must be done on the unit or the paddles before the initial and each subsequent discharge. It takes approximately 2 to 5 seconds to charge the paddles following activation of the charge button. **Ensure that nurses and other assistants are not touching the patient or the stretcher by saying "clear."** The assistant ventilating through a bag-valve device attached to an endotracheal tube does not need to drop the bag, as plastic is nonconductive. Turn off any open oxygen sources during shock delivery. **The person who will deliver the charge to the patient should ensure that their body is not in direct contact with the patient or the stretcher.**

Reevaluate the patient's cardiac rhythm. If still required, deliver the charge by simultaneously pressing the discharge buttons on each paddle. Observe the monitor and reevaluate the patient's cardiac rhythm. The unit can be recharged to deliver another electric charge to the patient if indicated.

The technique using self-adhesive disposable patches on newer units is similar with a few exceptions. Apply the patches in the anteroposterior position. No supplemental contact medium is required. The desired energy level is selected (**Tables 30-2 & 30-3**). Charge the cardioverter-defibrillator unit by pressing the charge button on the unit. Press the discharge button on the cardioverter-defibrillator unit to deliver the charge to the patient. Again reevaluate the need for further therapies as above.

Occasionally, the cardioverter-defibrillator unit may not deliver a shock. Check that the unit is plugged in, no touching or bridging of the pads or gel has occurred on the patient's chest, and that the paddles are charged. The cardioverter-defibrillator unit may not be able to properly sense the R-wave in synchronization mode with a rapid supraventricular rhythm. Reattempt to deliver the shock by holding down the discharge button for 15 seconds. This will give the cardioverter-defibrillator unit more time to determine and find a proper time to deliver the shock. Switching to asynchronous mode will allow the delivery of the shock, but risks shocking at the inappropriate time and converting the rhythm to ventricular tachycardia or ventricular fibrillation. Consider intravenous medication to slow the heart rate or chemically convert the rhythm rather than applying an asynchronous shock.

AFTERCARE

No specific aftercare is required related to the procedure of cardioversion or defibrillation. If using a cardioverter-defibrillator unit with paddles and conductive gel or paste, it is possible to cause a thermal burn to the skin. This should be treated as any other skin burn. Continuously monitor the patient after they are cardioverted or defibrillated. Almost all patients receiving cardioversion or defibrillation will be admitted to the hospital. Occasionally, a successfully cardioverted patient may be discharged home. The decision to discharge the patient should be made in consultation with the patients' Primary Care Physician and a Cardiologist.

COMPLICATIONS

Complications of cardioversion and defibrillation can range from none to death. Thermal and electrical burns are potential injuries. Skin burns may result, the severity of which increases depending on the energy level utilized and the number of shocks delivered. Care must be taken to avoid contact between the ECG monitor leads and the paddles, or of the paddles with each other, as sparks or fire may result. Burns can be minimized by utilizing electrically conductive contact media and firmly applying the paddles to the patient. Remove any fluid materials on the chest wall (i.e., conductive jelly, saline, sweat, urine, and water), as they can form a bridge between the paddles or pads and result in arcing and thermal burns to the thorax. Also, remove any nitroglycerin patches or ointments from the patient's torso. Ensure that there are no open oxygen sources that could ignite when the unit is discharged. If performed properly, repeated shocks will produce only a mild erythema to the chest wall. Systemic emboli may occur from clots in the left atrium becoming dislodged if the underlying rhythm prior to the cardioversion or defibrillation is atrial fibrillation.

Occasionally hypertension, other arrhythmias, or heart block may develop. If a synchronized or nonsynchronized shock is delivered on the T wave, ventricular fibrillation may result.[9–11] This usually occurs immediately and can be corrected with an nonsynchronized countershock. Ensure that the unit is in synchronous mode, not asynchronous mode, when cardioverting an organized cardiac rhythm. Always observe the monitor before delivering a countershock to ensure that it is required. If the T wave is large, change the monitor lead so that the T wave is smaller than the R wave and the unit will not cardiovert during a vulnerable period. Ventricular fibrillation that occurs within 30 to 60 seconds after the delivery of a synchronous shock is often due to digoxin toxicity and is difficult or impossible to correct. Transient ST-segment elevation may occur.[12]

Creatine kinase enzyme elevations may occur, most being skeletal muscle in origin.[10] Cardiac enzymes can also become elevated. The higher the energy level used and the more countershocks given, the greater the muscle damage that may result. Usually, no significant permanent myocardial damage occurs.

Do not apply the paddles or patches directly over an implanted defibrillator or pacemaker. The electric discharge can permanently damage these devices. Adjust the paddle or patch position so they are not directly over these devices.

Avoid injury to yourself or others by ensuring that no one is in contact with the bed or the patient when the shock is administered. Such injuries can range from mild shocks and burns to cardiac dysrhythmias. An improperly functioning unit can cause injury despite being used properly. Periodic maintenance and calibration of the unit is necessary.

SUMMARY

Cardioversion and defibrillation are the processes of applying electric current to a patient's chest to terminate a dysrhythmia. Cardioversion is a safe and effective method of converting reentry arrhythmias. If the patient is stable, a trial of medical therapy is warranted. If the patient is "unstable," cardioversion should be initiated as soon as possible. Consider administering parenteral

sedation, as cardioversion is anxiety-provoking and painful for the patient. Cardioversion should be performed in the synchronized mode. Always be prepared for ventricular fibrillation or ventricular tachycardia as a result of cardioversion of an organized rhythm. ACLS medications and airway support must be readily available. Defibrillation is essentially cardioversion of unstable ventricular tachycardia or ventricular fibrillation. It is performed like cardioversion except that synchronization and sedation are not required.

31 Transcutaneous Cardiac Pacing

Todd M. Larabee

INTRODUCTION

First documented as a technique in 1872, transcutaneous cardiac pacing (TCP) was successfully demonstrated in two patients with underlying cardiac disease and symptomatic bradycardia by Paul Zoll in 1952.[1] Studies involving open-chest and transvenous pacing, as well as open-chest cardiac massage, were occurring simultaneously by other groups. Zoll recognized the clinical difficulty of these approaches for the treatment of "ventricular standstill" in an emergent setting.[1,2] Zoll and colleagues performed animal experiments using electrodes placed in various positions prior to the use of subcutaneous needle electrodes at points "in a line transversing the ventricles" as described in the initial case report.[1] In 1956, they described the use of their procedure during eight surgical cases in which cardiac arrest occurred, with five patients successfully surviving to discharge.[2] At this time, cardiac monitoring during surgery was not routinely performed, thus the underlying rhythm being paced was not specifically determined in all reported cases.

Further work related to TCP seems to have lapsed until the 1980s, when several groups studied the technique for treatment of symptomatic bradycardias, asystolic cardiac arrest, and bradyasystolic cardiac arrest both in-hospital and in the Emergency Department. The results of these investigations were summarized by Hedges et al.[3] They concluded that TCP is as successful as transvenous cardiac pacing in obtaining electrical and mechanical capture in bradyasystolic arrests. TCP was easier to initiate than transvenous cardiac pacing. However, TCP did not improve the overall survival rates for these patients.[3]

TCP was recommended for cardiac emergencies by the International Liaison Committee on Resuscitation (ILCOR) guidelines beginning in 1980, and is currently recommended for treatment of symptomatic bradycardias, especially when the conduction block is at or below the His-Purkinje level.[4,5] TCP is no longer indicated for the treatment of asystolic cardiac arrest as there are no improvements in the rate of hospital admission or survival to hospital discharge in this setting.[5–7]

With current technology and equipment, TCP offers several advantages when compared to the placement of a transvenous cardiac pacemaker in the Emergency Department. The procedure requires minimal training and can be performed quickly. TCP is a noninvasive procedure and is not associated with the major complications of placing a transvenous cardiac pacemaker. This includes inadvertent arterial puncture, hemorrhage, pneumothorax, or cardiac tamponade from cardiac rupture. **TCP is an ideal early and temporary intervention for patients requiring stabilizing cardiac pacing support until more invasive procedures can be arranged in the proper clinical setting.**

ANATOMY AND PATHOPHYSIOLOGY

In the normal heart, electrical impulses originating in the sinoatrial (SA) node create an action potential that is conducted along the intrinsic cardiac nerve pathways to the atrioventricular (AV) node and disseminated through the His-Purkinje system. This action potential stimulates electrolyte flux, myocardial muscle depolarization, and subsequent cardiac muscle contraction. Electrical propagation and myocardial contraction occur separately in the atria and ventricles, with the atria contracting slightly ahead of the ventricles during ventricular diastole. This timing delay assists in filling the ventricles prior to their next ventricular systolic phase. The intrinsic heart rate is controlled by a balance of input from the sympathetic nervous system acting directly on the cardiac muscle and the parasympathetic nervous system acting most prominently at the SA and AV nodes.

The intrinsic heart rate can be disrupted due to a wide variety of disease processes. The usual blood supply for the SA node is from an early branch of the right coronary artery. Coronary artery disease can disrupt blood flow and oxygen supply to the myocardium, creating areas of cardiac ischemia that affects the conduction system, the impulse production, or conduction at the SA and AV nodes. Cardiac ischemia can result in action potential conduction delays and heart blocks, with resultant symptoms in the patient of bradycardia and hypotension. Electrolyte disturbances (e.g., hyperkalemia), structural heart disease, drug toxicity (e.g., calcium channel blockers and β-blockers), systemic toxins (e.g., cyanide), or systemic hypothermia are other causes of intrinsic conduction delays and heart blocks that can be considered in the differential diagnosis.

TCP delivers an extrinsic electrical impulse that overrides the intrinsic cardiac action potential. Initial pulse durations used were short at 1 to 2 milliseconds (ms). They have now been extended to 20 to 40 ms to decrease the threshold current or the current needed for cardiac muscle stimulation. The longer pulse duration also decreases patient comfort, as it is the degree of skeletal muscle contraction generated by the TCP pulse that determines patient discomfort.[8] Most TCP devices can generate up to 200 milliamps (mA) of current, while mean pacing currents needed to obtain capture have been shown to range from 40 to 100 mA.[8–11]

INDICATIONS

Transcutaneous cardiac pacing is technically the fastest and easiest method of emergency cardiac pacing. It is a temporary intervention prior to implementation of transvenous cardiac pacing or placement of a permanent cardiac pacemaker for primary cardiac dysfunction or until the underlying etiology of the bradycardia can be reversed. It is indicated for patients with symptomatic bradycardia from any etiology in whom pharmacologic interventions such as atropine have been unsuccessful. It can be effectively applied in the prehospital setting by EMS personnel, in a clinic, in the Emergency Department, or in the hospital. In patients with bradyarrhythmias that are expected to be transient (e.g., digoxin toxicity or AV block in the setting of an inferior wall myocardial infarction), TCP is quick, simple, and not associated with the morbidity or mortality of transvenous cardiac pacing.

It is indicated in patients with AV conduction blocks and sinus node dysfunction. It should be performed in symptomatic patients (e.g., syncope, presyncope, dizziness, fatigue, etc.) with complete or third-degree AV block, asystolic pauses exceeding 3 seconds, or an escape pacemaker rate less than 40 beats per minute. Patients with type I or type II second-degree AV block who are symptomatic should be transcutaneously paced. Symptomatic bifascicular block is also an indication for temporary TCP. Patients with sinus node dysfunction are candidates for pacing. Sinus node dysfunction

includes sinus pause with symptoms of cerebral hypoperfusion (e.g., syncope, presyncope, and dizziness), chronic sinus node dysfunction with or without symptoms but with escape rates of less than 40 beats per minute, or symptomatic sinus bradycardia.

TCP electrodes should be placed on patients in anticipation of potential clinical deterioration and bradyarrhythmias in the appropriate setting.[10] For example, a patient with a β-blocker overdose may present with a slow or normal heart rate but are otherwise asymptomatic. In this clinical scenario, hemodynamic deterioration is possible. Preparation for TCP (i.e., electrodes applied and connected to a generator unit, unit in standby mode, etc.) can be easily accomplished while further efforts related to the diagnosis and treatment are undertaken. If the patient develops bradyarrhythmias, the transcutaneous pacer can be immediately activated without the delays associated with obtaining the equipment and setting up the system.

TCP can also be used for overdrive cardiac pacing in event of a supraventricular or ventricular tachydysrhythmia such as ventricular tachycardia, torsade de pointes, or paroxysmal supraventricular tachycardia in the patient who is clinically stable.[12–15] A major limitation to overdrive cardiac pacing would be the maximum rate that the pulse generating unit can achieve. The technique requires pacing the patient at a rate of 20 to 60 beats per minute faster than the tachydysrhythmia.[14] Patients do not usually tolerate transcutaneous overdrive pacing due to the accompanying chest wall contractions and discomfort. The transvenous or transthoracic routes are preferred for overdrive pacing of the myocardium.

CONTRAINDICATIONS

There are no absolute contraindications to TCP. Hypothermia has been considered a relative contraindication to TCP. The associated bradycardia seen during hypothermia is thought to be a result of direct myocardial depression and decreased metabolic rate.[16,17] Concerns related to ventricular irritability, dysrhythmias, and resistance to defibrillation have led to the idea that electrical manipulation of the hypothermic myocardium should be avoided.[18] There are, however, case reports of successful TCP use during rewarming for severe hypothermia.[19] TCP is also relatively contraindicated for prolonged bradyasystolic cardiac arrest due to the overall poor resuscitation rates and outcomes of these patients.[6,7,10] TCP is no longer indicated for the treatment of asystolic cardiac arrest as there are no improvements in the rates of hospital admission or survival to hospital discharge in this setting.[10]

EQUIPMENT

- Pulse generator and monitor unit
- Pacing cable attached to the monitor
- Pacemaker patches or electrodes:
  - 6×7 cm^2 for infants and young children
  - 13×15 cm^2 for older children and adult
- ECG patches or electrodes (if pacemaker patches and unit do not monitor patient)
- ECG cable attached to cardiac monitor (if pacemaker patches and unit do not monitor the patient)
- Intravenous access supplies
- Sedative and analgesic medications
- Povidone iodine or chlorhexidine solution
- Skin razor

Most commercially available cardiac defibrillators used in the Emergency Department are a combination cardioverter, defibrillator, and cardiac pacer with an associated ECG monitor. (**Figure 31-1**) The unit is usually available on all code carts in the Emergency Department and throughout the hospital. The Emergency Physician should become familiar with their specific institutional equipment prior to an emergent situation requiring its use.

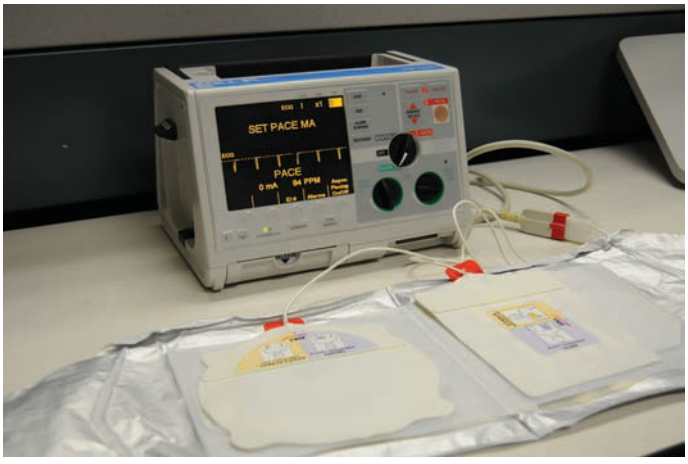

FIGURE 31-1. The cardiac monitor/defibrillator with TCP capabilities and attached surface patches.

The pacing patches are either round or rectangular, and come packaged as pairs with illustrations to demonstrate proper placement of the electrode (**Figure 31-2**). The negative electrode will be labeled "front" or "apex." The positive electrode may be labeled "back" or "posterior." Most modern TCP electrodes are disposable, single patient use, and multipurpose. The one electrode can be used to perform cardioversion, defibrillation, ECG monitoring, and TCP. Some older units may not have this flexibility and require separate ECG leads.

PATIENT PREPARATION

If time allows, discuss the procedure with the patient and/or their representative. This should include the reason for performing the procedure, the risks of the procedure including pain-related issues and how pain will be addressed, and the benefits of the procedure including expected symptom improvement. There is a small risk of developing a ventricular tachydysrhythmia during TCP.[20]

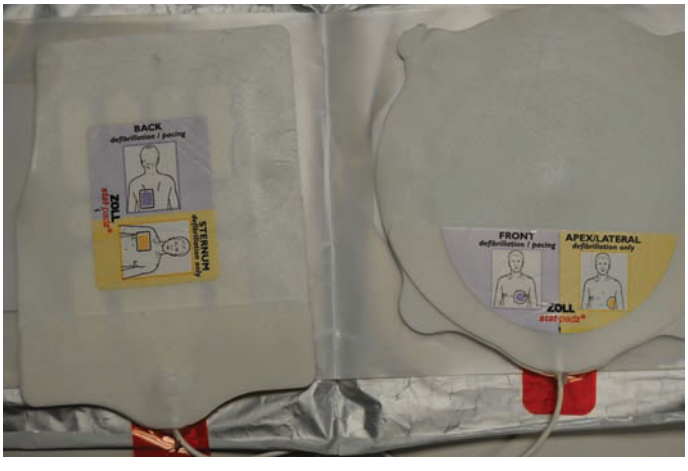

FIGURE 31-2. TCP electrodes with diagrams demonstrating placement on the electrode.

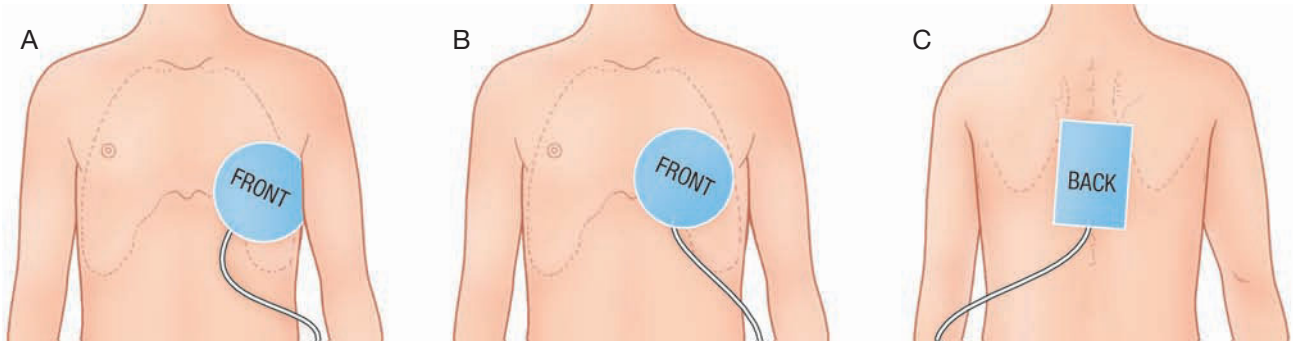

FIGURE 31-3. Placement of TCP electrodes. **A.** Anterior (negative) electrode placed over the cardiac apex. **B.** Anterior (negative) electrode position centered over the V_3 lead position. **C.** Posterior (positive) electrode position.

A written and signed consent documenting this conversation is always preferred. However, it is not required in an emergent situation. Documentation of the conversation in the medical record should be adequate in an emergent situation. Preparation for transvenous cardiac pacing (Chapter 33) can be simultaneously undertaken in the event that TCP is unsuccessful.

The patient's skin should be relatively clean and free of debris. Warm, soapy water can be used as a cleansing agent. Avoid potentially flammable cleansing solvents such as alcohol-based solutions. The skin should be dry. Trim the patients back and chest hair if the patient is hirsute and the pacing patches are poorly adherent. Trimming is preferred to shaving to avoid skin disruption or abrasions that may cause increased pain, skin irritation, and bacteremia during the procedure. If shaving is required, and pacing is not emergently required, first apply povidone iodine or chlorhexidine to the area and allow it to dry. This will decontaminate the skin prior to shaving.

Administer sedative and analgesic medications to manage the discomfort related to the chest wall skeletal muscle contractions associated with TCP.[20] Pain levels associated with TCP were found to be moderate to moderately severe (mean of 3.2 on a five-point scale) in 30 healthy volunteers.[11] One volunteer quit the study due to the severity of the pain.

TECHNIQUES

PAD PLACEMENT

Two pacing electrodes must be applied to the thorax (**Figure 31-2**). Place the front, anterior, or negative labelled electrode on the anterior chest wall, and centered over the apex of the heart (**Figure 31-3A**) or over the V_3 lead position (**Figure 31-3B**). In females, the anterior electrode should be positioned by lifting the breast and placing it under the fold of the breast and against the chest wall. Place the back, posterior, or positive labelled electrode directly behind the anterior electrode and to the left of the thoracic spine, between the spine and the scapula (**Figure 31-3C**). Avoid trapping air or debris under the pad during placement. As an alternative, the positive electrode may be placed on the right upper chest and the negative electrode over the apex of the heart (**Figure 31-4**).

PACING

Once the pacing electrodes are positioned, connect the cable from the electrodes to the pacer/monitor unit. Turn the output current (mA) dial as low as possible (**Figure 31-5**). Set the pacing rate between 80 and 90 beats per minute. Select the pacer function of the pacer/monitor unit. Turn the unit on. Gradually increase the current output by 5 to 10 mA at a time until capture is achieved (**Figure 31-6**). Note the mA output value that is required to initiate TCP. This is known as the threshold current. Increase the output current approximately 10%, or 5 to 10 mA, above the threshold current. Maintain the output current at this level.

In the near-arrest or unconscious patient, start with the output current set at maximum. Turn the unit on. Dial the output current down until capture is lost. This is the threshold current. Raise the output to restore capture. Increase the output current approximately 10%, or 5 to 10 mA, above the threshold current. Maintain the output current at this level.

Some pacer/monitor units can operate in a "standby mode." This mode can be used for patients who are at risk of developing symptomatic bradycardia, but who are currently clinically stable. Set the unit to "pacing mode." Attach the pacer electrodes to the patient and the unit. Initiate a brief period of TCP at a rate slightly faster than the patient's intrinsic rate to determine the threshold current and if capture is possible. Turn the unit off. Set a reduced rate on the pacer dial. This rate should be below the patient's current heart rate but also be the minimal heart rate acceptable to the Emergency Physician for the patient. Switch the unit to "standby mode" and turn it on. If the patient's heart rate falls below the value set on the unit, the pacer function will automatically engage.

OVERDRIVE PACING

When performing overdrive TCP, full cardiac resuscitation equipment should be available and ready at the bedside, as rhythm acceleration and subsequent hemodynamic instability are possible. The pacer electrodes and pacing unit setup remain the same to perform overdrive TCP for a tachydysrhythmia.

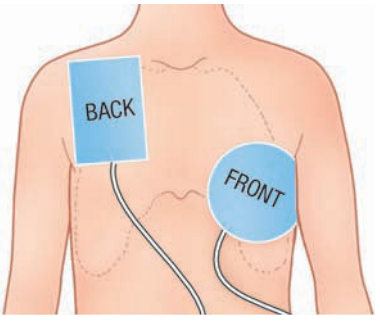

FIGURE 31-4. Alternative transcutaneous pacing electrode positions. The negative electrode is positioned over the cardiac apex. The positive electrode is positioned on the right anterior chest wall.

FIGURE 31-5. Monitor dials demonstrating separate defibrillation and pacing functions; also demonstrating electrical current (mA) and heart rate dials to set for TCP.

Administer sedative and analgesic medications as required. Set the current output at 120 mA, as this current generally will exceed the threshold value for most patients. Turn on the unit and initiate asynchronous cardiac pacing at a rate of 20 to 60 beats per minute higher than the intrinsic rate of the tachydysrhythmia.[14] Once capture is achieved, decrease the current output to just above the threshold current. Slowly lower the pacing rate to decrease the patient's heart rate to the desired level. TCP for overdrive pacing may not be possible due to the upper heart rate limit of the available pacing unit.

PACING PEDIATRIC PATIENTS

There is limited data available on the use of TCP in the pediatric population. The indications for the procedure, however, are the same as those in adults. The technique used to accomplish TCP is the same as in an adult. TCP is often more effective in children because their smaller chest wall results in a lower transthoracic resistance to the pacing current.

There are, however, special considerations when performing TCP in the pediatric population. TCP was undertaken in newborns with complete AV node block.[21] This small case series of two patients, as well as others, documented significant thermal injury to the underlying skin.[21,22] This was most likely related to the newborn's thin and fragile skin. Increased monitoring of the skin surrounding the electrodes is mandatory in children, especially in cases of prolonged TCP. Pediatric-sized transcutaneous pacing electrodes are available and should be used to limit surface contact. One study comparing the use of adult versus two specially sized pediatric electrodes for TCP demonstrated a lower mean current output with the smaller pads (63 mA vs. 51 to 53 mA).[23] Appropriately sized electrodes are available for children under 15 kg (33 lbs) and should be used.

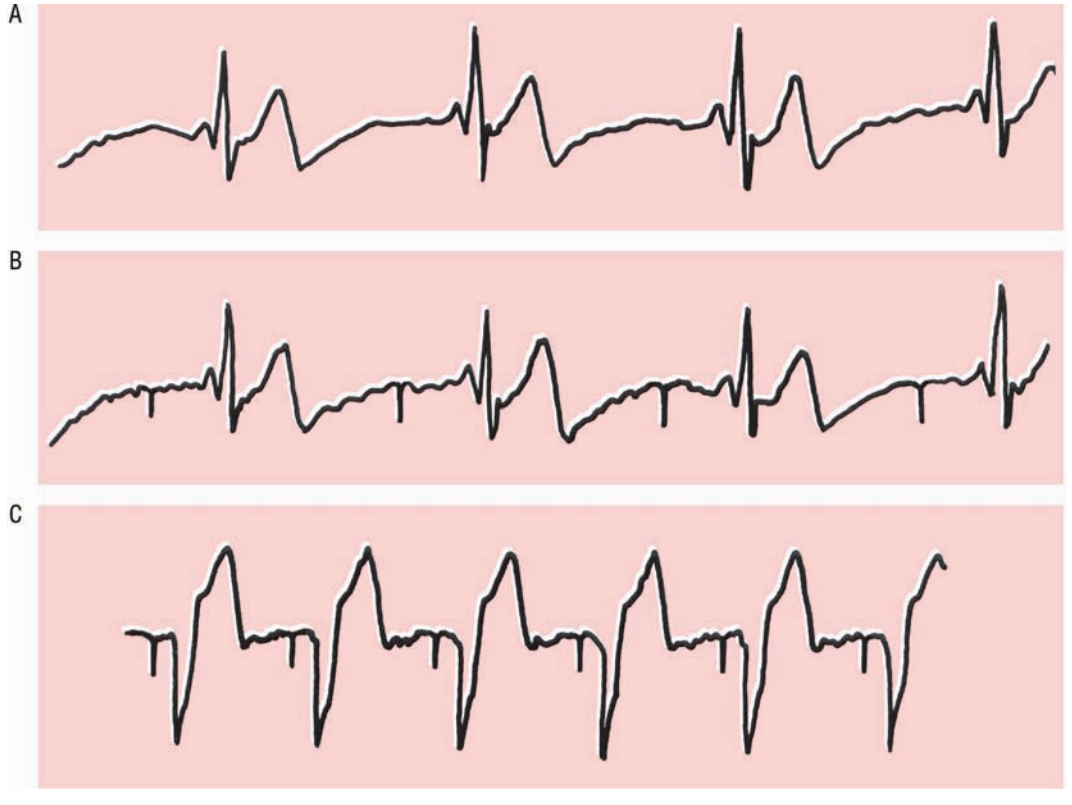

FIGURE 31-6. Assessing electrocardiographic capture with transcutaneous pacing. **A.** Intrinsic patient bradycardic rhythm. **B.** No electrical capture as TCP is below the threshold level. **C.** TCP with electrical capture.

Only one study has documented the outcomes of TCP in pediatric out-of-hospital cardiac arrest.[24] In six drowning victims and three sudden infant death syndrome patients who received TCP by EMS providers, only two patients achieved electrical and mechanical capture, both with an initial rhythm of asystole. In total, seven patients presented with asystole and two patients presented with ventricular fibrillation. Only one patient, with an initial rhythm of asystole, survived to hospital discharge but was severely neurologically impaired and died 6 months later. Further study in this area is warranted.

ASSESSMENT OF SUCCESSFUL PACING

The Emergency Physician must assess the patient for both electrical capture and associated mechanical capture when considering whether or not the procedure was successful. Successful capture is usually characterized by a wide QRS complex, since it is ventricular in origin, and a broad T wave. It is easy to mistake the wide, slurred afterpotential following an external pacing spike for electrical capture. **Electrical capture is best judged by the presence of a consistent ST segment and T wave after each generated pacer spike (Figure 31-6C).** Paced beats below the patient's intrinsic cardiac rate may not produce an associated QRS complex (**Figure 31-6B**), and electrical capture is not achieved. In this situation, the pacing rate must be increased to achieve capture. **Table 31-1** discusses common causes of failure to capture and suggested solutions.

Once electrical capture is achieved, mechanical capture must be ensured by either a palpable pulse rate or arterial catheter blood pressure monitoring. The patient will have a pulse rate that is exactly equal to that of the paced rhythm on the cardiac monitor if mechanical capture is achieved. Assess the pulse using palpation of the carotid or femoral artery to avoid confusion with skeletal muscle contractions generated by the pacing current. If the palpated pulse rate is less than that of the paced rate, mechanical capture has not been achieved. Increase the threshold current. Mechanical capture is also achieved when the invasive arterial blood pressure line demonstrates a pulse rate that is exactly equal to that of the paced rhythm on the cardiac monitor.

Threshold current values will vary depending on the clinical situation. Transcutaneous pacing thresholds tend to be lowest in healthy individuals or in patients with minimal hemodynamic compromise. In these settings, the threshold is usually in the range of 40 to 80 mA.[10,28] Most patients are paced using a current in the range of 20 to 140 mA.[10] No clear correlation has been established between the pacing threshold and patient age, weight, body size, chest diameter, or etiology of heart disease.[10,29,30] However, thresholds are usually elevated following thoracic surgery or in patients with COPD, a pneumothorax, a pericardial effusion, heavy thoracic chest wall musculature, and after positive-pressure ventilation.[10]

Success rates in achieving ventricular capture vary widely depending on the setting where TCP is being used. Success rates appear to be highest when TCP is used prophylactically or early (within 5 minutes of bradycardic arrest). In these settings, success rates may exceed 90%.[10] Zoll et al. reported a 78% success rate in diverse clinical situations.[10] The time to the initiation of TCP largely determines the success rate. With prolonged pacing, there can be changes in pacing threshold leading to capture failure. Failure to capture may be encountered due to a variety of reasons.

Ultrasound has been used as a method to confirm electrical and mechanical capture.[25,31,32] Use ultrasound to determine the ventricular contraction rate. The patient will have a heart rate that is exactly equal to that of the set paced rate if mechanical capture is achieved. This eliminates the artifact seen on the ECG monitor from chest wall muscle contractions. Refer to Chapter 29 for the complete details of cardiac ultrasonography.

AFTERCARE

The most important assessment in the aftercare period is to ensure continuous electrical and mechanical capture. This should be accomplished by frequent checks of the cardiac monitor, palpation of a pulse, and measurement of a blood pressure. This is more easily established using an arterial line. Threshold current values can change with prolonged TCP. The system can be somewhat tenuous in practical use, so frequent checks are advisable. Insert a transvenous cardiac pacer in the Emergency Department or make arrangements with a Cardiologist to place one in the catheterization lab if the patient requires prolonged TCP.

Patient comfort must be continuously re-assessed. Pain can be due to chest wall muscle contractions or other causes (**Table 31-2**). Do not assume that pain is from chest wall muscle contractions until other etiologies are ruled out. Repeated doses of sedative and/or analgesics may be required to ease the discomfort of chest wall muscle contractions. Periodically assess the skin under the electrodes for burns or damage. Reposition the electrodes if skin erythema or any sign of a burn is present. This is especially important

TABLE 31-1 Common Causes of Failure to Capture and Suggested Solutions

Etiology	Solution
Suboptimal electrode placement	Reposition electrodes, avoiding the spine, scapula, and sternum
Negative electrode placed posteriorly	Place negative electrode anteriorly over the cardiac apex or the V_3 lead position
Poor skin-electrode contact	Clean skin of sweat and debris; dry skin thoroughly; trim hair
Faulty electrical contact	Check electrical connections
Generator battery depletion	Change battery; plug generator into an electric outlet
Increased intrathoracic air	Reduce positive-pressure ventilation; relieve pneumothorax
Pericardial effusion	Pericardiocentesis; pericardial window
Myocardial ischemia/ metabolic derangement	CPR; ventilation; correct acidosis; correct hypoxia; correct electrolyte abnormalities
High threshold	Use stimuli of longer pulse width; shave hair for improved pad attachment; apply pressure to pads; apply pads with fresh gel

Modified from: Ellenbogen KA, Wood MA: *Cardiac Pacing and ICDs*, 5th ed. Oxford: Blackwell, 2008.

TABLE 31-2 Causes of Painful Transcutaneous Pacing and Suggested Solutions

Etiology	Solution
Conductive foreign body beneath electrode	Remove foreign body
Electrode over skin abrasions (shaved)	Reposition electrodes; avoid shaving beneath electrodes
Apprehensive patient or low pain tolerance	Administer parenteral narcotics and/or benzodiazepines
Sweat or salt deposits, saline, conductive jelly, blood, or vomitus on skin	Cleanse and dry skin
High threshold to pacing	Use longer pulse-width stimuli
Thoracic wall muscle contractions	IV sedation and/or analgesics

Modified from: Ellenbogen KA, Wood MA: *Cardiac Pacing and ICDs*, 5th ed. Oxford: Blackwell, 2008.

in patients who are young children, unconscious, or have altered mental status as they cannot complain of pain.

COMPLICATIONS

There are few major complications related to this procedure. One of the most important complications to consider is the failure to recognize underlying rhythm changes in the patient or loss of electrical or mechanical capture once the procedure is completed. A rhythm change to ventricular fibrillation is easy to miss and can be ascribed to pacing artifacts and chest wall muscle contraction. These complications are mitigated by close patient and monitor surveillance during TCP. Tachydysrhythmias related to TCP have been documented, but the overall risk for this complication is considered small.[14] Myocardial damage from TCP has been examined in animals and humans without significant findings.[2,26,27] Thermal injury to the skin from the electrodes is a known complication, especially in situations of prolonged TCP, but can be minimized with careful observation and electrode adjustments. Pain is the most commonly reported complication (**Table 31-2**) and needs to be continually addressed. The most common etiology of the pain is from chest wall muscle contractions.

SUMMARY

TCP is a temporary method of cardiac pacing in patients with severe symptomatic bradyarrhythmias due to high-grade AV blocks, sinus node dysfunction, bradyasystolic cardiac arrest, or rarely for overdrive pacing to suppress ventricular and supraventricular tachyarrhythmias. It is comparatively easy to perform and requires minimal training. Once capture is achieved, the current output should be set at a level slightly higher (5-10 mA) than the pacing threshold. Successful TCP can be established in 80% to 90% of patients. Discomfort and pain due to muscle contraction are the most common side effects. Most patients will require sedation and/or analgesics to tolerate TCP for a significant length of time.

32 Transthoracic Cardiac Pacing

Simon M. Pulfrey

INTRODUCTION

Transthoracic cardiac pacing is a historic technique of pacing the heart with an electrode introduced percutaneously into the ventricular cavity using a needle trocar introducer. There is sparse literature on transthoracic cardiac pacing, and the benefits and complications are not well defined. Before the advent of effective and efficient transcutaneous pacing, transthoracic pacing was a faster alternative to transvenous pacing in the patient with an acutely unstable dysrhythmia. Presently, the indications for transthoracic pacing are extremely rare. The technique of transthoracic pacing is included in this text as it is occasionally performed in situations where transcutaneous pacing is unavailable or ineffective.[1–3]

The history of electrical stimulation of the heart dates back to 1862 when Walsh discussed the possibility of causing the heart to contract through stimulation of the sympathetic nervous trunk by an induced current.[4] By 1910, it was largely understood that the neuromuscular mechanism of the heart was electrically dependant. In 1932, Hyman used a needle electrode to carry stimulating current directly to heart muscle.[5] Zoll accomplished the first successful clinical application of external cardiac pacing in 1952 by resuscitating two patients in asystole following bradycardia from a high-degree AV block.[6] He concluded that external cardiac pacing was a safe and effective means of resuscitating ventricular standstill. Unfortunately, Zoll's devices caused significant chest pain, skeletal muscle spasm, superficial skin burns, and disrupted electrocardiographic patient monitoring.[6] The quest for alternative pacing modalities continued with the refinement of the transesophageal technique, initially suggested by Zoll in 1952, and clinically demonstrated by Shafiroff and Linder in 1957.[7] In 1958, Thevenet et al. reported the emergency use of a lumbar puncture needle introduced 5 mm into the myocardium, through which a conducting wire was introduced, to produce transthoracic cardiac pacing.[8] In 1959, Furman and Robinson passed a transvenous wire catheter and successfully applied an electrical current to the endocardial surface of the right atrium.[9] Transvenous pacing subsequently became the most widely accepted method of emergency cardiac pacing until the reemergence of Zoll with a modified external pacing system in 1981.[10]

ANATOMY AND PATHOPHYSIOLOGY

The heart is the only muscle of the body that generates its own electrical impulses. The initial cardiac impulse starts in the right atrium of the heart at the sinoatrial (SA) node. The sympathetic and parasympathetic nervous system controls the rate of impulse generation at the SA node. Once the electrical stimulus is generated, it is conducted along the internal conduction pathways of the heart to the muscular atrial and ventricular walls. A delicate balance between electrolyte flux to create action potentials, myocardial integrity to allow impulses to become contractions, and an intact conduction system must be maintained. The blood supply to the conduction system of the heart originates from the right coronary artery. Arrhythmias and conduction delays are often the result of inadequate blood flow to the heart due to ventricular infarction and coronary artery occlusion.

INDICATIONS

Considering the proven efficiency and efficacy of transcutaneous pacing modalities, the indications for transthoracic pacing appear extremely limited. Preston estimated a 40% success rate in achieving pacing by the transthoracic route.[11] Transcutaneous pacing success rates of greater than 80% have been routinely demonstrated.[12]

Transthoracic cardiac pacing is a simple procedure and can be accomplished rapidly. **Transthoracic pacing should be reserved for clinical situations where there is no transcutaneous pacing available, or when transcutaneous pacing in the perimorbid patient has been unsuccessful and the placement of a transvenous pacer is thought to be too time consuming.**[13,14]

Unstable bradydysrhythmia is the obvious indication for emergency cardiac pacing. Several case reports document successful transthoracic pacing intervention in two patients with asystolic arrest.[1] Other studies document successful pacing out of asystole in patients with in situ pacemakers.[15] A more recent and prospectively designed study of approximately 300 patients with witnessed or early asystole demonstrated no improved outcome with early transcutaneous pacing intervention by first response emergency medical personnel.[16] It can be concluded that although emergency transthoracic cardiac pacing has a very low success rate in asystole, the procedure may be lifesaving in the rare case.

Transthoracic cardiac pacing would be most effective following cardiac arrest from primary cardiac disease.[13] Transthoracic cardiac pacing may not be effective in cardiac arrest secondary to hypovolemia (e.g., trauma), severe electrolyte or acid–base abnormalities,

sepsis, or drug intoxication. Transthoracic cardiac pacing may be lifesaving when bradycardia or asystole secondary to prolonged ischemia during hypovolemic shock persists despite correction of the underlying pathology.

The use of transthoracic cardiac pacing in unstable patients is more controversial. Transthoracic cardiac pacing may be considered in patients with unstable sinus bradycardia, junctional bradycardia, atrial fibrillation with high-degree atrioventricular (AV) block, and AV dissociation with inadequate ventricular response, producing pulmonary edema, seizures, ventricular fibrillation, or ventricular tachycardia.[13]

CONTRAINDICATIONS

Transthoracic cardiac pacing should not be performed in stable, awake patients. It is also contraindicated if the patient has a dysrhythmia that could be quickly and easily corrected by medication, cardioversion, or electrical defibrillation.

Transthoracic cardiac pacing may be ineffective in pulseless electrical activity and ventricular fibrillation. In ventricular fibrillation, the heart becomes insensitive to pacemaker activity, and in pulseless electrical activity, any mode of pacing is ineffective.[20–23] Bellet et al. demonstrated that a pacemaker was ineffective in patients with prolonged cardiac arrest.[15] Patients with cardiac arrest for more than 5 to 10 minutes could not be resuscitated with the use of cardiac pacing; but patients who had pacemakers placed within 2 to 4 minutes after cardiac standstill were successfully resuscitated. Hence, as shown in many studies, transthoracic cardiac pacing may be ineffective if used as a last alternative, as any technique of pacing would be.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Transthoracic cardiac pacing wires/kit
- Pacemaker generator
- 10 mL syringe
- Water-soluble lubricant
- Sterile gauze 4 × 4 squares
- Sterile drapes
- Sterile gloves and gown
- Face mask
- Cap

The widely used instrumentation for transthoracic cardiac pacing is a sterile, one-time-use, prepackaged kit. One example is the Elecath 11-KTM 1 kit (**Figure 32-1**). The apparatus consists of a 37 cm bipolar J-shaped pacing wire, a 6 inch 18 gauge blunt-end steel cannula with a pointed inner trocar, and a plastic electrical connector that accepts the pacing wire and can be attached to a battery-powered external pacemaker generator. The cannula and trocar function as a catheter-over-the-needle.

PATIENT PREPARATION

Explain to the patient the risks and benefits of the procedure if they are awake and alert. A signed consent is not required and time is often lacking to obtain a signature. Document in the medical record that the patient was informed of the risks and benefits of the procedure. Place the patient supine. Clean the chest and subxiphoid area of any dirt and debris. Apply povidone iodine or chlorhexidine solution to the chest and subxiphoid area. Allow it to dry if time permits. Apply sterile drapes to delineate a sterile field.

Cardiopulmonary resuscitation (CPR) can be continued during most of the procedure but should be stopped while the intracardiac needle is being inserted to avoid possible damage to the lung or myocardium. Full ventilation of the lungs is recommended during subxiphoid cannula placement to depress the diaphragm and thus minimize the risk of injury to the liver and stomach. Insert a nasogastric tube to decompress the stomach prior to performing the procedure.

The Emergency Physician should prepare themselves and the equipment. Put on a cap, mask, sterile gloves, and sterile gown. Open the transthoracic cardiac pacing kit onto a sterile field. Lubricate the trocar liberally and insert it securely into the steel cannula.

TECHNIQUE

Quickly identify the anatomic landmarks necessary to perform this procedure and determine the approach to be used. The cannula-over-the-trocar can be inserted through the left fifth intercostal space either parasternally, 4 cm lateral to the midsternal line, or 6 cm lateral to the midsternal line (**Figure 32-2A**). The tip of the cannula-over-the-trocar should be aimed toward the second costal cartilage. Alternatively, the cannula-over-the-trocar can be inserted through the left xiphocostal junction and aimed toward the right shoulder, left shoulder, or sternal notch (**Figure 32-2B**).

If bedside ultrasound is available, the parasternal approach through the fifth intercostal space may be the technique of choice. Without ultrasound, the simplest and quickest approach is to insert the trocar at the left xiphocostal junction and aimed toward the sternal notch. This technique is described below.

Briefly stop CPR. Insert the cannula-over-the-trocar from the left xiphocostal region at a 30° to 40° angle to the skin and directed toward the sternal notch. Advance the cannula-over-the-trocar approximately three-fourths of its length. Hold and stabilize the cannula and withdraw the trocar. Attach a 10 mL syringe to the cannula. Apply negative pressure to the syringe. If the cannula is within the ventricle, the aspiration of blood into the syringe confirms

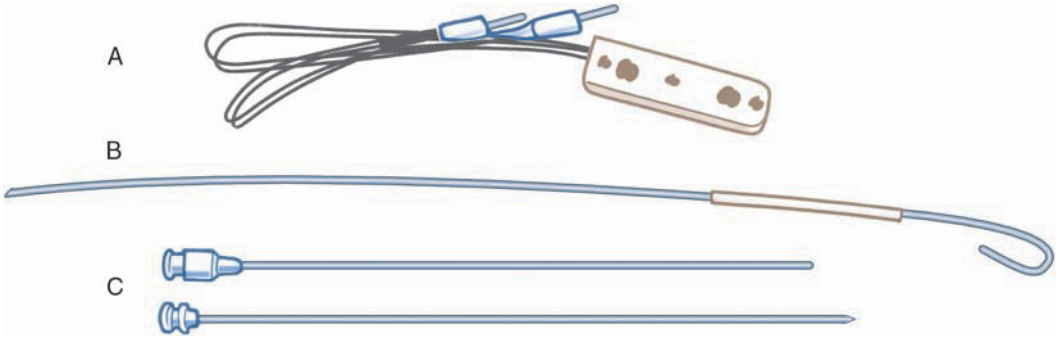

FIGURE 32-1. Equipment required for transthoracic cardiac pacing. **A.** Electrical connector. **B.** Bipolar pacing wire with a sleeve. **C.** Blunt steel cannula with pointed trocar.

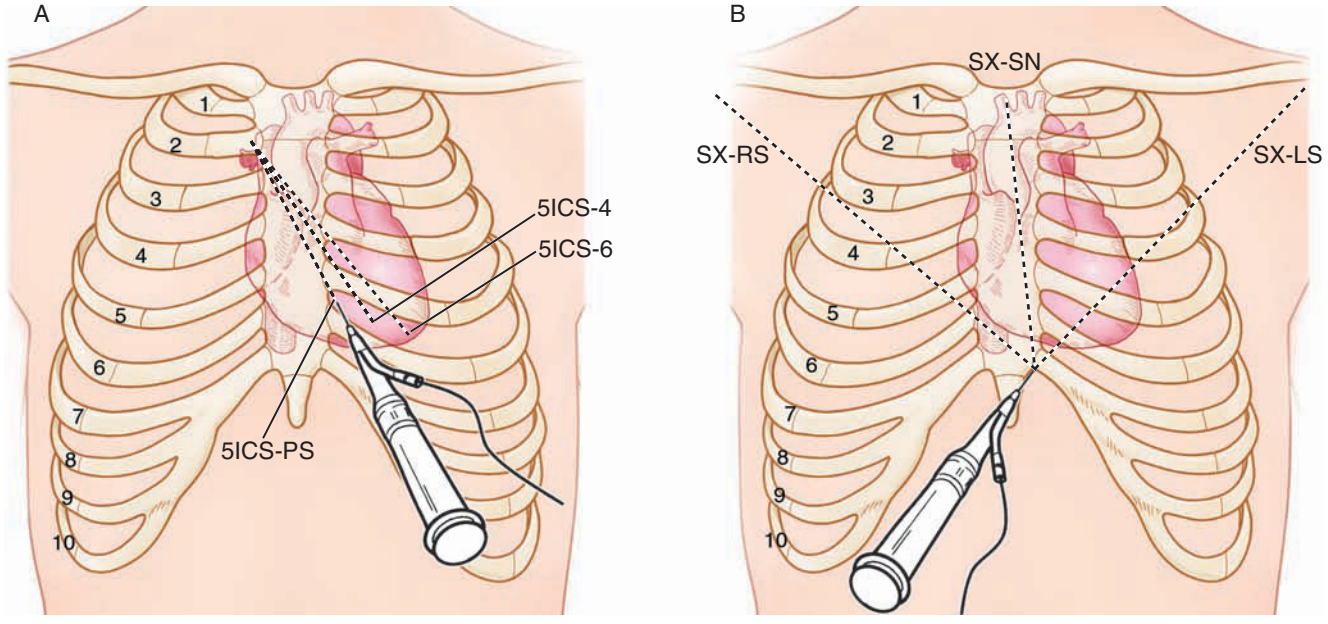

FIGURE 32-2. Placement of a percutaneous transthoracic cardiac pacemaker. **A.** Parasternal approaches. 5ICS-PS, fifth intercostal space immediately to the left of the sternum; 5ICS-4, fifth intercostal space, 4 cm from the midsternal line; 5ICS-6, fifth intercostal space, 6 cm from the midsternal line. **B.** Subxiphoid approaches. SX-RS, subxiphoid—right shoulder; SX-SN, subxiphoid—sternal notch; SX-LS, subxiphoid—left shoulder.

proper positioning. If blood is not aspirated, withdraw the cannula and restart the procedure. Ideally, confirm placement with bedside ultrasound.

Insert the transcutaneous pacing wire. Advance the plastic sheath over the pacing wire until it straightens out and covers the J-shaped end of the pacing wire. Insert the plastic sheath into the cannula hub. Advance the pacing wire through the cannula and into the ventricle. Stop advancing the pacing wire when 4 to 5 cm remains outside the cannula. **No resistance should be felt while the pacing wire is being advanced.** If resistance is felt, the cannula is not within the ventricle. Remove the cannula and pacing wire as a unit and restart the procedure. When it is inside the ventricle, the pacing wire will reform its J shape. Hold the pacing wire securely. Withdraw the cannula over the pacing wire. **Do not release the hold on the proximal end of the pacing wire outside the patient's thorax, so as to prevent it from slipping inside the thorax.**

Insert the proximal end of the pacing wire into the plastic connector. Secure it with the screws in the body of the connector. Connect the positive and negative terminals of the plastic connector to the pacemaker generator. Turn on the pacemaker generator. Set the pacing rate at 70 to 90 beats per minute in an asynchronous mode. Set the current output to the maximum milliampere rate on the pacemaker generator. After myocardial capture of the electrical stimulus is demonstrated (i.e., each pacer spike followed by a QRS complex on the cardiac monitor), lower the current output until 1:1 pacing is lost. Gradually increase the current output to attain stimulation threshold when 1:1 capture is regained. The optimal current output is two to three times the stimulation threshold. Change the mode of the pacemaker to a demand pacemaker with a backup rate of 60 to 70 beats per minute. A complete description of the functioning of the pacemaker generator is reviewed in Chapter 34.

Pacer spikes should be seen on the electrocardiogram (ECG) tracing on the cardiac monitor. If not, check the contact between the pacer wire and electrical connector. Check the batteries in the pacemaker energy source. Pacer spikes not followed by myocardial capture usually indicate inadequate positioning of the pacing electrode. Gently manipulate the transthoracic pacemaker wire to change its position.

ASSESSMENT

The positioning of the pacing wire should be verified by a chest X-ray. Obtain a 12-lead ECG to document capture and to verify the positioning of the pacing wire based on the QRS configuration in the ECG. A left bundle-branch-block configuration will be demonstrated on the ECG if the pacing wire is in the right ventricle. If the pacing wire is in the right atrium or left ventricle, it will still pace the myocardium but the ECG will have a different QRS configuration. If the patient is in AV block, an atrially positioned pacing wire will be ineffective.

AFTERCARE

If the patient survives, secure the pacing wire to the skin with 3-0 nylon suture. A transvenous or permanent pacemaker should be inserted as soon as possible. Consult a Cardiologist immediately and admit the patient to an intensive care unit.

COMPLICATIONS

Analysis of the complications of transthoracic cardiac pacing is greatly limited by the paucity of short-term survivors and the absence of radiographic or pathologic evaluation of nonsurvivors. Complications include laceration of the right atrium, ventricles, coronary arteries, great vessels, vena cava, stomach, liver, and lung. Hemopericardium is a ubiquitous finding in some autopsy studies, and cardiac tamponade has been reported.[17,18] Pneumothorax has been reported and is a particular concern in persons receiving positive-pressure ventilation.[19]

SUMMARY

The technique of transthoracic cardiac pacing has been clinically feasible for more than 50 years, but there is extremely limited literature supporting its regular use. The technique of transthoracic cardiac pacing is simple, can be performed in less than a minute, but carries a high risk for multiple significant complications. There is no clear understanding of the effect of transthoracic cardiac pacing on the outcome of cardiac arrest and the complications associated

with the procedure. Most of the available information comes from animal studies, retrospective analysis, and anecdotal data.

Transthoracic cardiac pacing may be useful in the setting of cardiac arrest with asystole or a pulseless idioventricular rhythm. It may be performed if a transcutaneous cardiac pacing system is not available or not effective. In unstable patients with drug-resistant bradycardia producing cardiovascular collapse or lethal escape rhythms whose clinical condition does not warrant a delay to insert a transvenous pacing catheter, transthoracic cardiac pacing can be initiated promptly. Bedside ultrasound may be useful in guiding and confirming appropriate placement of the transthoracic pacing device.

33 Transvenous Cardiac Pacing

Eric F. Reichman, Myles C. McClelland, and Brian Euerle

INTRODUCTION

Emergency cardiac pacing can be accomplished by several methods. These include epicardial, esophageal, transcutaneous, transthoracic, and transvenous pacing. Emergency cardiac pacing can be a temporizing and lifesaving technique that should be familiar to all Emergency Physicians. It will allow the patient to maintain a cardiac rhythm while providing oxygen and nutrients to the vital organs.

The earliest use of electricity to stimulate the heart can be found in an essay written in the late 1700s.[1] It discusses the use of electric current and artificial ventilation to revive victims of drowning. Transvenous pacing was first attempted on dogs in 1905 by Floresco. The transvenous approach in humans was developed in 1959 using a stiff pacing wire. Semiflexible pacing wires were developed in 1964 and were placed using fluoroscopic guidance. The demand pacemaker was developed in 1966. Catheter technology improved with the semifloating catheter in 1969 and the balloon tip catheter in 1973. The technology and technique have since been developed to allow successful transvenous cardiac pacing in humans. It involves the placement of a pacing wire through the central venous circulation and into direct contact with the myocardium of the right ventricle.

ANATOMY AND PATHOPHYSIOLOGY

The heart is the only muscle of the body that generates its own electric impulses. Its automaticity and subsequent rhythmic contractions propel blood to the tissues of the body. The initial cardiac impulse starts in the right atrium of the heart at the sinoatrial (SA) node. The sympathetic and parasympathetic nervous systems control the rate of impulse generation at the SA node. Once the electric stimulus is generated, it is conducted along the internal conduction pathways of the heart to the muscular atrial and ventricular walls. A delicate balance between electrolyte flux to create action potentials, myocardial integrity to allow impulses to become contractions, and an intact conduction system must be maintained. Conduction system problems are often the result of inadequate blood flow to the heart due to ventricular infarction and coronary artery occlusion. The blood supply to the conduction system of the heart usually originates from the right coronary artery. Occlusion of the right coronary artery can result in arrhythmias and conduction delays.

A transvenous pacing catheter may be introduced through the femoral, internal jugular, or subclavian veins. **In the Emergency Department, the right internal jugular vein and left subclavian vein are the recommended sites (Figure 33-1). These routes allow a more direct and easy access for the pacing catheter to enter the right ventricle.** The right internal jugular vein is preferred, as it allows a relatively straight line of access through the superior vena cava and right atrium into the right ventricle.[2] The left subclavian vein is a good second choice if access to the right internal jugular vein is not accessible. Unfortunately, the left subclavian vein is the site of choice for a permanent pacemaker if required. Thus, many physicians will not use this site. The other routes are technically more difficult to use and often require fluoroscopy for proper placement of the pacing catheter.

The femoral vein is often used in infants and younger children to insert a transvenous cardiac pacing catheter (**Figure 33-2**). Insertion of the pacing catheter via the femoral vein often requires fluoroscopy. The disadvantages of using the femoral vein for vascular access include the potential for deep venous thromboses, infection, restricted mobility, and thrombophlebitis. The infant and young child's relatively large head and short neck make access to the internal jugular vein difficult. The subclavian vein in an infant and a child is situated more posterior to the clavicle than in an adult. This

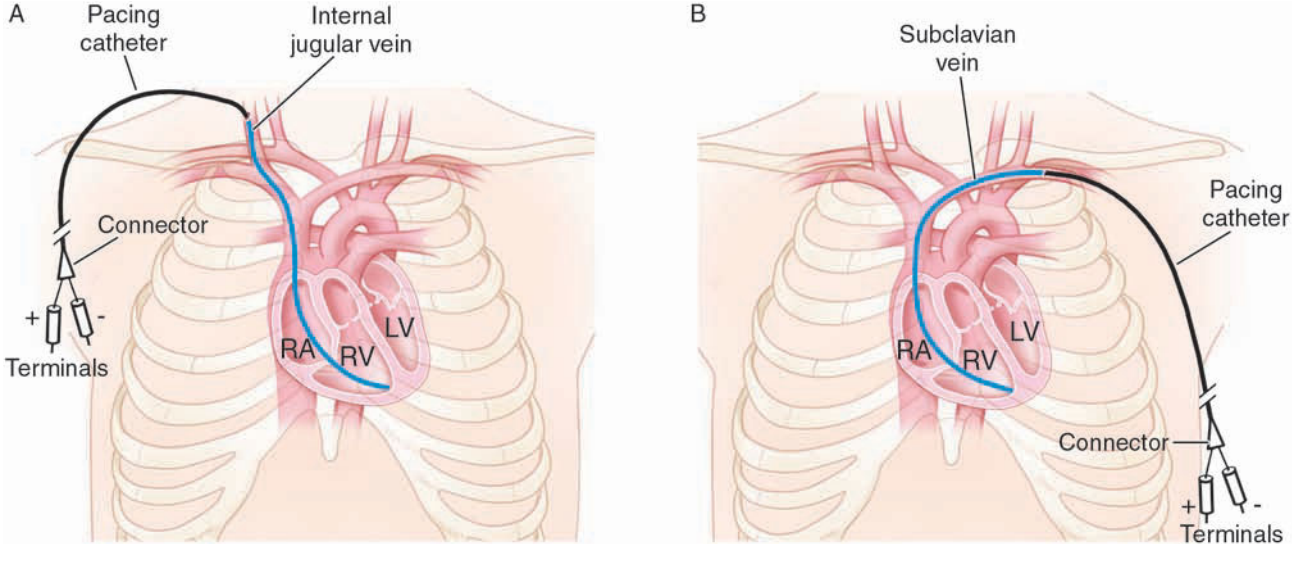

FIGURE 33-1. Common sites for introducing a transvenous pacing catheter. **A.** The right internal jugular vein. **B.** The left subclavian vein.

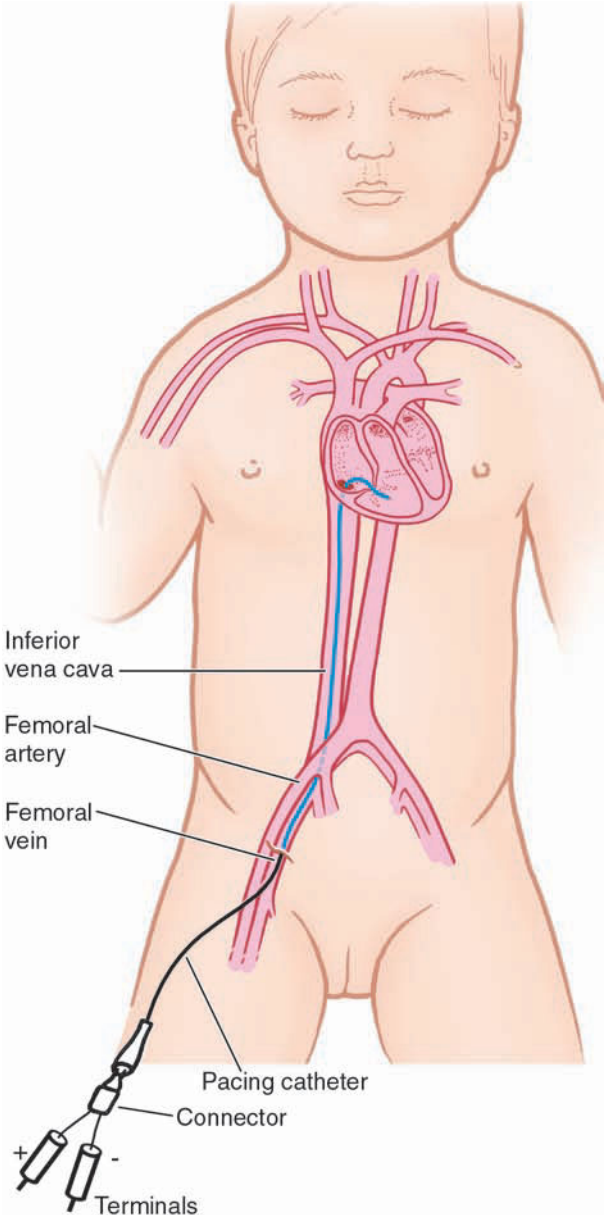

FIGURE 33-2. The femoral vein is used in children to access the central venous circulation and introduce a transvenous pacing catheter.

makes it more difficult to access the subclavian vein while increasing the chance of causing a pneumothorax.

Pacing the left ventricle through a femoral artery approach has been suggested in emergent situations.[3] These instances usually involve the inability to obtain venous access due to scarring, previous procedures, or venous thrombosis. This nonstandard approach has been used successfully in situations when transvenous cardiac pacing was not feasible.[3,4] This technique cannot currently be recommended for routine use, but is a potential alternative technique in the Emergency Physicians armamentarium for use in the most dire of circumstances.

INDICATIONS

The indications for transvenous pacing are the same as for other methods of cardiac pacing. Patients with symptomatic bradycardia unresponsive to drug therapy, conduction delays that may degenerate into complete heart block, atrioventricular dissociation, and atrial or ventricular arrhythmias that require overdrive pacing can benefit from transvenous pacing.[1,2,5,6] Specific bradycardic conditions that may benefit from transvenous cardiac pacing include sinus node dysfunction, sinus arrest, sick sinus syndrome, sinus bradycardia, atrial fibrillation with a slow ventricle response rate, second-degree heart block, and third-degree heart block. Patients with myocardial infarctions and symptomatic bradycardia or new heart blocks require cardiac pacing. Tachyarrhythmic conditions that may benefit from overdrive cardiac pacing include atrial flutter, atrial fibrillation, Wolff–Parkinson–White tachyarrhythmias, supraventricular tachycardias not responsive to drugs or cardioversion, ventricular tachyarrhythmias due to drug toxicity (quinidine or digoxin), and torsades de pointes. Transvenous pacing may be used in patients who do not tolerate or whose heart does not capture with transcutaneous pacing. If a permanent pacemaker is not functioning, a transvenous pacing catheter may be temporarily inserted to pace the myocardium. A more complete discussion on the indications for cardiac pacing is presented in Chapter 31 (transcutaneous cardiac pacing).

CONTRAINDICATIONS

Patients who are hypothermic should not have a transvenous pacing catheter inserted into the heart. These patients have increased irritability of the myocardium and are prone to life-threatening ventricular fibrillation if the pacing wire contacts the heart muscle.[1,2] Digoxin toxicity and other drug ingestions that may increase the irritability of the myocardium are relative contraindications to the placement of a transvenous pacing catheter. Patients who are asystolic for extended periods of time have a low likelihood of successful resuscitation.[2] These patients are not candidates for transvenous pacer placement. Do not insert a pacing catheter through infected skin or areas with any skin lesions (e.g., burns, cellulitis, or dermatides) to prevent possible infections such as endocarditis, myocarditis, or sepsis. Avoid areas that contain subcutaneous devices (e.g., permanent pacer, AICD, port-a-cath, etc.) and choose an alternative site. Do not prophylactically place a transvenous pacing catheter in a patient with a myocardial infarction unless they have a new heart block or symptomatic bradycardia. Patients with bleeding diatheses, anticoagulant therapy, or concurrent thrombolytic therapy should not have a transvenous pacing catheter placed except in truly emergent situations due to the risk of hemorrhage and bleeding complications. Other relative contraindications include the presence of a prosthetic tricuspid valve, coagulopathy, distortion of local and anatomic landmarks, and known abnormal cardiac anatomy.

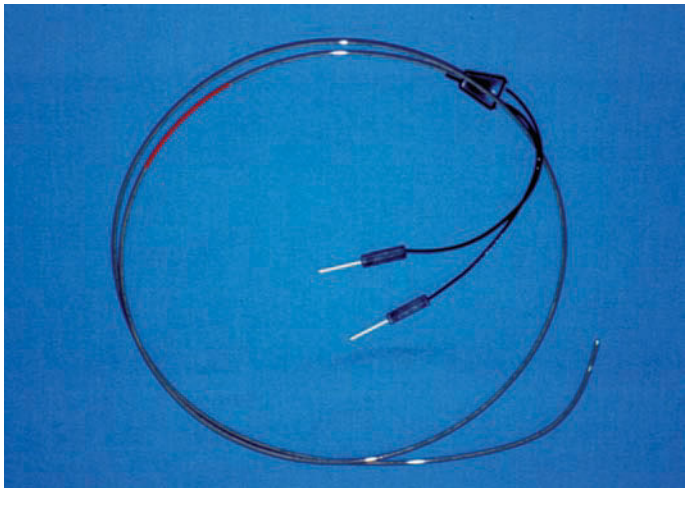

FIGURE 33-3. The flexible transvenous pacing catheter.

EQUIPMENT

- Flexible transvenous cardiac pacing catheter (**Figure 33-3**):
  - 3 or 4 French for infants and children
  - 5 or 6 French for adolescents and adults
- Pacemaker generator (**Figure 33-4**)
- Spare battery for pacemaker
- Sterile drapes
- Sterile gloves and gown
- Face mask with face shield or goggles
- Povidone iodine or chlorhexidine solution
- Cordis or Swan introducer catheter kit, one size larger than the pacing catheter
- Cardiac monitor

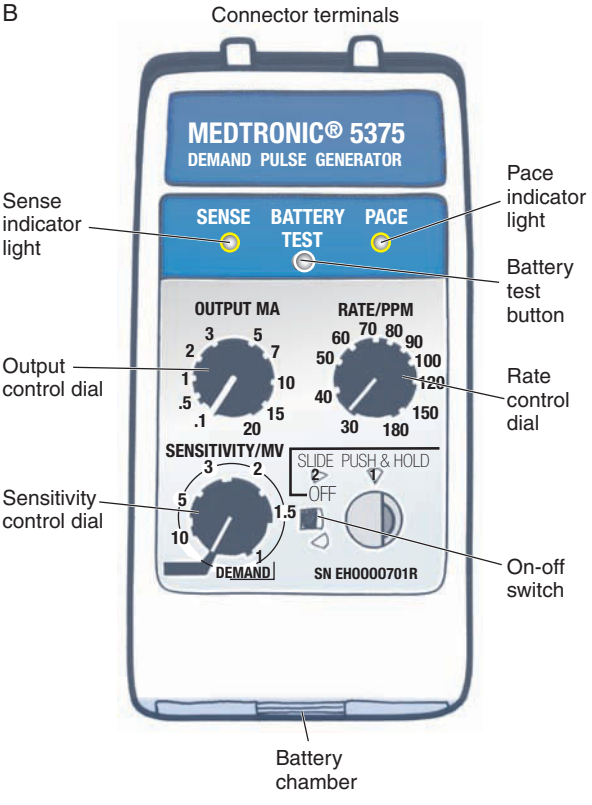

FIGURE 33-4. Examples of pacemaker generators.

- Local anesthetic solution
- 3-0 nylon suture
- Gauze squares
- Skin tape
- Alligator clips and connecting wire
- Towels for shoulder rolls
- Defibrillator
- Airway management equipment
- Resuscitative drugs
- Ultrasound machine with a 3.5 MHz curvilinear or cardiac array probe
- Sterile ultrasound gel
- Sterile ultrasound probe covers

Transvenous cardiac pacing kits are commercially available. They contain the central venous introducer catheter, transvenous pacing wire, and all the required supplies except the pacemaker generator. These single patient use and disposable kits are convenient and worth the expense so that time is not expended gathering multiple kits and supplies in an emergent situation when time may be of the essence.

The pacemaker generator is a simple device (**Figure 33-4**). An example is the Medtronic 5375 demand pulse generator (**Figures 33-4A & B**). Newer models of pacemaker generators (**Figure 33-4C**) have digital displays and other more sophisticated pacing options, but function essentially the same as older models. **The Emergency Physician must be familiar with the pacemaker generator and its use prior to needing it in an emergent situation.** The on/off switch is used to turn the unit on. In the "on" position, a spring-loaded safety prevents the unit from accidentally being turned off. The rate-control dial allows the physician to adjust the number of pacing stimuli per minute. The upper rate limit is often inadequate if overdrive pacing is required. A pacemaker generator with higher rates for overdrive pacing is available. These are rarely kept in the Emergency Department, but are usually available from the hospital catheterization lab. The pace indicator light is illuminated whenever a pacing stimulus is generated. The sense indicator light is illuminated whenever a cardiac impulse is sensed. The battery test button is used to determine if the battery has sufficient voltage to operate the pacemaker generator. Depress the battery test button to check the battery voltage. If both the pacing and sensing indicator lights illuminate simultaneously, the battery has sufficient voltage. The output control dial is used to adjust the amplitude of the stimulus current. The sensitivity control dial is used to suppress the pulse generator. The bottom of the pacemaker has an access panel under which the battery is located. The top of the pacemaker has positive and negative terminals where the electrodes of the pacemaker catheter insert. Numerous pacemaker generators are available, each with its own idiosyncrasies. The above instructions/functions are similar to most models.

The pacemaker wires are enclosed in a catheter and come in a variety of lengths and sizes (**Figure 33-3**). They are typically 100 cm in length with markings at intervals of every 10 cm. They come in both flexible and rigid styles. The rigid catheters are not often used due to the possibility of venous and myocardial perforation. The flexible catheters have a balloon at the tip, which allows the catheter to flow with the blood into the chambers of the heart.

The pacemaker catheter should ideally be inserted under electrocardiographic (ECG) guidance. An insulated wire with an alligator clip at each end is required. One end is attached to the pacemaker wire and the other to the ECG lead. This allows the Emergency Physician to observe the ECG waveforms as they change while the catheter is advanced through the heart.[2,5,7] This technique is known as ECG positioning and requires the patient to have intrinsic cardiac activity.

PATIENT PREPARATION

Explain the risks, benefits, and possible complications to the patient and/or their representatives. If the patient is unable to consent, an appropriate representative may accept for the patient. The patient may also give verbal consent if they are unable to sign but fully understands the risks and benefits of the procedure. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids. **While time is of the essence and this is an emergent procedure, aseptic technique should always be followed.**

Place the patient supine and, if possible, in the Trendelenburg position. Place the patient on continuous pulse oximetry, cardiac monitoring, and supplemental oxygen. Establish peripheral intravenous access. Clean and prep the skin in a sterile fashion with povidone iodine or chlorhexidine at the site chosen to access the central venous system. If the internal jugular vein or the subclavian vein is being used as the site of vascular access, place rolled towels under the patient's shoulders. Turn the patient's head to the opposite side of venous access. Apply sterile drapes to fully cover the patient except the site used for vascular access.

TECHNIQUE

Access the central venous circulation by placing a Swan or Cordis introducer catheter sheath. Some authors recommend using the supraclavicular approach for central venous access.[8] This approach may decrease complications due to well-defined surface landmarks, high success rates of vascular access, minimal interference with other procedures, location away from the pleural dome, avoidance of scarring and thrombosis from previous central venous access attempts, minimization of catheter movement, and having a straight path into the right ventricle. Refer to Chapter 49 for the complete details on inserting central venous catheters.

Prepare the pacing catheter (**Figure 33-5**). Attach the precordial lead V_1 to the pacemaker catheter negative terminal. This is accomplished using an insulated wire with an alligator clip at each

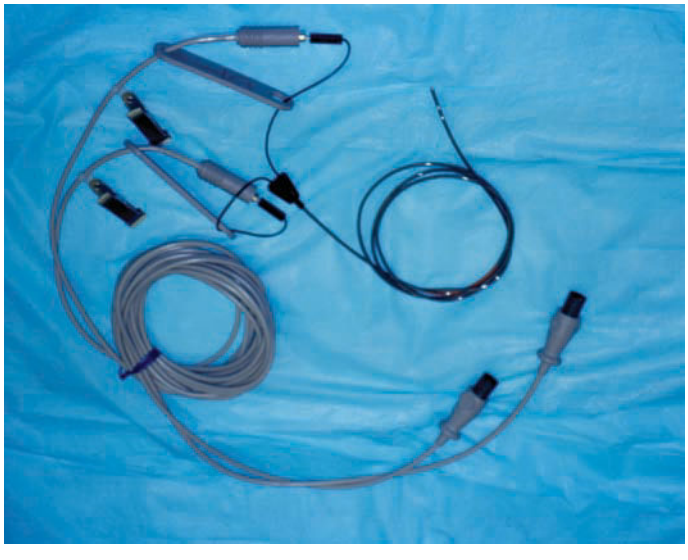

FIGURE 33-5. The negative pacemaker terminal is connected to an insulated wire. The insulated wire will be connected to the ECG lead V_1.

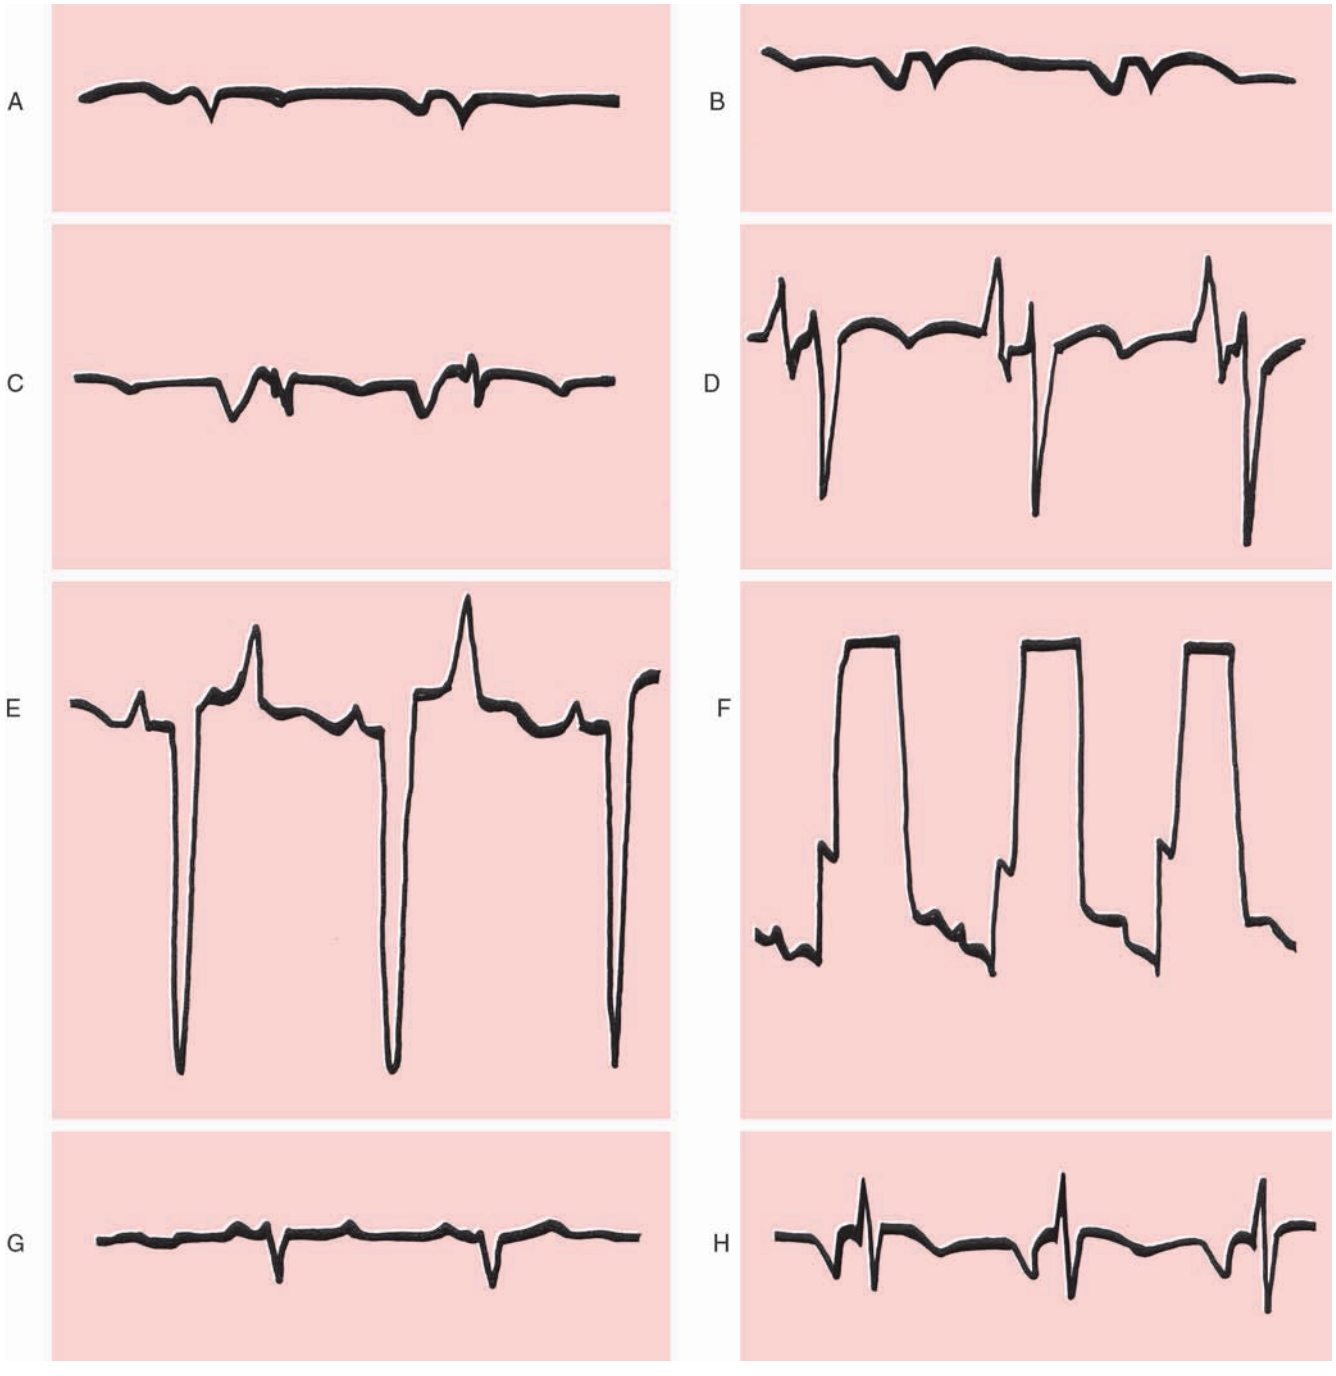

FIGURE 33-6. Typical ECG tracings seen with the transvenous pacing catheter within the different anatomic sites. **A.** The subclavian or internal jugular vein. **B.** The superior vena cava. **C.** The high right atrium. **D.** The low right atrium. **E.** Free-floating in the right ventricle. **F.** Abutting the right ventricular wall. **G.** The inferior vena cava. **H.** The pulmonary artery.

end. Attach one alligator clip to the negative pacemaker wire. Attach the other alligator clip to the V_1 lead of the ECG monitor. Inflate the pacing catheter balloon with 1.5 mL of air in a container of sterile saline to assess the integrity of the balloon. The presence of bubbles in the saline indicates a balloon leak. Turn on the ECG monitor and set it to lead V_1. Touch the tip of the pacing catheter and observe the monitor to confirm that the monitor is recording. A large pressure wave should be seen that soon returns to the baseline.

Insert the pacemaker catheter through the rubber diaphragm of the central venous introducer sheath. Advance the catheter 10 cm. This ensures that the pacing catheter balloon is past the introducer catheter and within the vascular system. Inflate the balloon with 1.5 mL of sterile saline. **Slowly advance the catheter while always observing the ECG monitor (Figure 33-6).** In the subclavian or internal jugular vein, the P wave and the QRS complex are both small in amplitude and inverted (**Figure 33-6A**). In the superior vena cava, the P wave increases in amplitude but is still inverted while the QRS complex is unchanged (**Figure 33-6B**). When the pacing catheter reaches the right atrium, a large P wave with a negative polarity and a small QRS complex will be observed (**Figure 33-6C**). Continue to advance the catheter. As the lower atrium is entered, the P waves become upright and the QRS complex increases in amplitude (**Figure 33-6D**). Continue to advance the catheter into the right ventricle. The QRS complex should appear normal on

FIGURE 33-7. The transvenous pacing catheter connected to the pacemaker generator.

the V_1 lead. When the catheter is floating freely in the right ventricle, the P waves are upright with a large-amplitude QRS complex (**Figure 33-6E**). Stop advancing the catheter once the right ventricle is entered and deflate the balloon. Slowly advance the catheter until ST-segment elevation is observed (**Figure 33-6F**). This indicates that the catheter is abutting the right ventricular wall.

Occasionally, the transvenous pacing catheter may not enter the right ventricle or it may advance past the right ventricle. If the catheter exits the right atrium and enters the inferior vena cava, the amplitude of the P wave and QRS complex will decrease (**Figure 33-6G**). Withdraw the catheter several centimeters until the atrial waveforms are again seen (**Figures 33-6C & D**), then readvance the catheter. If the catheter exits the right ventricle and enters the pulmonary artery, the P wave will become negative and the QRS amplitude will decrease (**Figure 33-6H**). Withdraw the catheter several centimeters until the right ventricle waveforms are again seen (**Figure 33-6E**), then readvance the catheter.

Connect the pacemaker generator to the catheter (**Figure 33-7**). Disconnect the negative terminal of the pacemaker catheter from the ECG lead. Connect the pacemaker catheter terminals on the proximal end of the catheter to the negative and positive terminals of the pacemaker generator. **The positive (+) lead connects to the proximal port on the pacemaker generator. The negative (–) lead connects to the distal port on the pacemaker generator.** Set the pacemaker generator on demand mode with a rate of 70 to 80 beats per minute. Start with 5 mA of energy on the output dial. Turn on the pacemaker. Increase the energy until capture is seen on the monitor. This is signaled by pacing spikes and a wide QRS complex in lead V_1 in a left bundle branch pattern. **Once capture is attained, decrease the pacemaker generator output to just below where pacing stops. This is known as the threshold point. Resume pacing at 2 mA above the threshold point.**[2]

ULTRASOUND-GUIDED TECHNIQUE

It is often difficult to successfully place the tip of the pacing catheter into the apex of the right ventricle. Lead placement can be guided and confirmed with the assistance of ultrasonography.[9] The pacing electrode is easily visible on ultrasound, and its correct position can be confirmed. Aguilera and colleagues reported success in eight of nine patients in whom ultrasound-guided transvenous pacing was attempted in the Emergency Department.[9] In three of these patients, initial misplacement of the electrode was visualized, allowing correct repositioning. They concluded that ultrasound has promising potential use as an adjunct in emergency cardiac pacing. Ultrasound can delineate the right ventricle as well as provide quick and noninvasive confirmation of lead placement. It is useful as an aid to detecting and repositioning misplaced pacer leads. Given the time-sensitive nature of transvenous pacing, consider using ultrasound in conjunction with ECG guidance.

The subxiphoid view is preferred as it allows visualization of the right atrium and right ventricle. It is also a view easily obtained with the patient in the supine position. The subxiphoid view is likely to be the cardiac window with which Emergency Physicians are most familiar and comfortable. The transvenous pacing electrode is a strong reflector of ultrasound waves and will appear as a linear hyperechoic structure.[9] In the subxiphoid view, the electrode can be seen passing through the right ventricle to the apex (**Figure 33-8**). The apical cardiac view is an option. However, obtaining an apical view is more technically difficult and is preferentially performed with the patient in the left lateral decubitus position, which may not be practical. **Care must be taken not to mistake the ventricular septum or wall for the electrode.**

There are limitations in the use of ultrasound. Visualization may be difficult in the obese or those with COPD and resultant expanded lung volumes. Mechanical heart valves may cause significant artifacts that obscure the images. The pacing catheter often lies in multiple echo planes, making visualization more difficult. The lack of catheter visualization may require multiple repositionings of the catheter. Visualization of the catheter may require tilting of the probe, looking at several different angles with the probe, and looking at additional views of the heart. All these maneuvers can result in delays before being able to pace the heart.

Visualize the patient's heart using a subxiphoid view with a 3.5 MHz curvilinear array probe. Instruct an assistant to hold the probe in position while the Emergency Physician performs the procedure. Insert the pacing catheter as described above using the

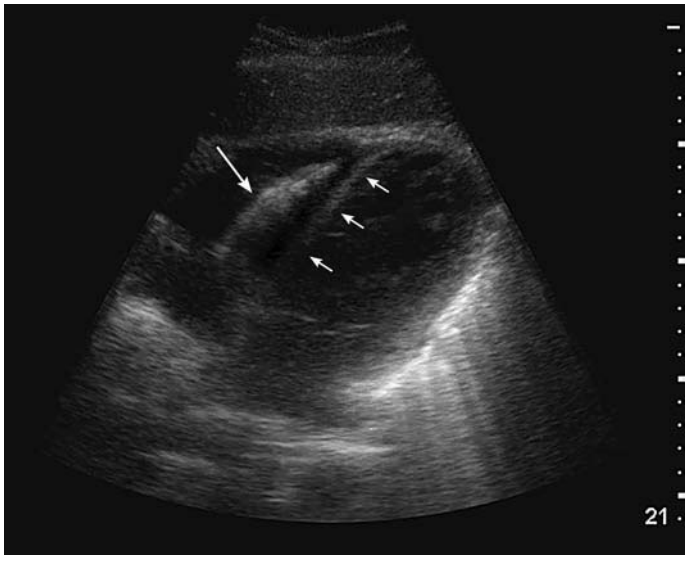

FIGURE 33-8. Subxiphoid cardiac ultrasound image. The transvenous pacing electrode (*large arrow*) is seen as a linear hyperechoic structure passing through the right ventricle to its apex. The interventricular septum is denoted by the *small arrows*.

ECG-guided technique. Visualize the pacing catheter using ultrasonography after it enters the right atrium and then as it enters the right ventricle as also noted by the changing ECG waveforms. Continue to advance the pacing catheter under ultrasound guidance until its tip is lodged in the apex of the right ventricle (**Figure 33-8**). This may require manipulation of the pacing catheter and/or ultrasound probe to maintain visualization. Continue the remainder of the procedure as noted in the previous section. Ventricular capture is noted as cardiac contractions on the ultrasound monitor that are at the same rate as the pacemaker generator setting.

ALTERNATIVE TECHNIQUE

Blind transvenous catheter placement is an alternative to the above method. The pacing catheter is inserted "blindly" and without ECG guidance. This technique is often used when alligator clips are not available to connect the pacing catheter terminals to the ECG monitor. A flexible catheter should always be used. **Never place a rigid catheter blindly due to the risk of myocardial perforation.**

Prepare the catheter. Test the balloon as described previously. Make sure the pacemaker generator is off. Connect the pacemaker catheter terminals to the pacemaker generator. Insert the pacemaker catheter through the rubber diaphragm of the central venous introducer sheath. Advance the catheter 10 cm. Inflate the balloon with 1.5 mL of sterile saline.

Turn on the pacemaker. **Set the pacemaker on demand mode with a rate twice the patient's native heart rate.** This usually ranges from 80 to 120 beats per minute. Set the output dial to 1.5 to 2.0 mA.

Advance the catheter while observing the sensing indicator light. When the catheter enters the right ventricle, the sensing indicator will illuminate with every other native heartbeat. Stop advancing the catheter. Deflate the balloon. Increase the output dial to 10 mA. Slowly advance the catheter until ventricular capture occurs on the cardiac monitor. **Electrical capture is indicated when the ECG monitor attached to the patient's skin by electrodes shows pacer spikes and the development of wide QRS complexes. Do not advance the catheter more than 10 cm past the point where the sensing indicator began to illuminate.** If ventricular capture is not successful within 10 cm, withdraw the catheter and rotate it 90°. Readvance the catheter up to 10 cm. The pacemaker generator output may be set at 20 mA and the pacing catheter readvanced. Continue to repeat the process until ventricular capture is successful. Once this occurs, slowly decrease the ventricular rate to 70 beats per minute. Decrease the pacemaker generator output to 2 mA above the threshold point.[2]

This blind procedure can be modified to be used with ultrasound. Visualize the pacing catheter after it enters the right ventricle. Use ultrasound to help guide the tip of the pacing catheter into the apex of the right ventricle or to confirm proper positioning of the pacing catheter (**Figure 33-8**).

ASSESSMENT OF SUCCESSFUL PACING

The Emergency Physician must assess the patient for both electrical capture and associated mechanical capture when considering whether or not the procedure was successful. Successful capture is usually characterized by a wide QRS complex, since it is ventricular in origin, and a broad T wave. It is easy to mistake the wide, slurred afterpotential following an external pacing spike for electrical capture. **Electrical capture is best judged by the presence of a consistent ST segment and T wave after each generated pacer spike (Figure 31-6C).** Paced beats below the patient's intrinsic cardiac rate may not produce an associated QRS complex (**Figure 31-6B**), and electrical capture is not achieved. In this situation, the pacing rate must be increased to achieve capture.

Once electrical capture is achieved, mechanical capture must be ensured by either a palpable pulse rate or arterial catheter blood pressure monitoring. The patient will have a pulse rate that is exactly equal to that of the paced rhythm on the cardiac monitor if mechanical capture is achieved. Assess the pulse using palpation of the carotid or femoral artery to avoid confusion with skeletal muscle contractions generated by the pacing current. If the palpated pulse rate is less than that of the paced rate, mechanical capture has not been achieved. Increase the threshold current. Mechanical capture is also achieved when the invasive arterial blood pressure line demonstrates a pulse rate that is exactly equal to that of the paced rhythm on the cardiac monitor.

Ultrasound can confirm electrical and mechanical capture. Use ultrasound to determine the ventricular contraction rate. The patient will have a heart rate that is exactly equal to that of the set paced rate if mechanical capture is achieved. Refer to Chapter 29 for the complete details of cardiac ultrasonography.

AFTERCARE

Secure the pacing catheter by suturing it to the chest wall. Infiltrate subcutaneously with 2 mL of local anesthetic solution 1 cm from where the catheter exits the central venous sheath. Using 3-0 nylon, secure the catheter to the skin. Apply antibacterial ointment to the site where the pacing catheter exits the central venous sheath. Apply an adhesive dressing, such as Tegaderm, over the sheath and catheter. Obtain an ECG. It will show the characteristic left bundle branch block pattern. Obtain a postprocedural chest radiograph to assess the catheter position and to rule out an iatrogenic pneumothorax and/or hemothorax. Admit the patient to an intensive care unit. Consult a Cardiologist for possible permanent pacemaker placement.

The most important assessment in the aftercare period is to ensure continuous electrical and mechanical capture. This should be accomplished by frequent checks of the cardiac monitor, palpation of a pulse, and measurement of a blood pressure. This is more easily established using an arterial line.

COMPLICATIONS

Perforation of the ventricular septum, the atria, or the free wall of the ventricle may occur during catheter placement.[10] This is more commonly seen with the rigid catheters, and in elderly patients with kyphoscoliosis where right heart catheterization can be more difficult.[11] Septal perforation should be suspected if the pattern on the ECG changes from a left to a right bundle branch block.[2,12] Septal perforation should also be suspected if there is an increase in the pacing threshold. Ventricular perforation can present as a failure to capture or as cardiac tamponade. A friction rub may be audible on cardiac auscultation if a perforation is present. Perforation of the inferior wall could stimulate and pace the diaphragm.[2,12] The treatment for these complications is to withdraw and reposition the pacing catheter. The patient must then be evaluated and observed for the possibility of cardiac tamponade.

Multiple attempts to place the tip of the pacing catheter in the apex of the right ventricle can result in complications. Movement of the catheter forward and backward can form a loop within the cardiac chambers. The catheter tip can advance through the loop and result in a knot being formed in the pacing catheter. This requires an Interventional Cardiologist to unknot and remove the catheter in the cardiac catheterization laboratory under fluoroscopic guidance.

Advancement of the pacing catheter through a patent foramen ovale will result in left ventricular pacing.[13] This is recognized as a right bundle branch pattern on the ECG. Ultrasonography can be

used to visualize the pacing catheter in the left ventricle or the lack of it in the right ventricle. Radiographic or angiography studies will be needed to determine if the tip of the catheter passed through the foramen or perforated the interatrial or interventricular septum.

Cardiac arrhythmias may occur during insertion of the pacing catheter. Ventricular arrhythmias can occur during the procedure and even after the procedure is completed. Immediately withdraw the catheter a few centimeters and observe the rhythm. If that resolves, readvance the catheter. A defibrillator and cardiac resuscitation drugs must be available to facilitate immediate treatment of any rhythm disturbance.[2,12]

In transvenous pacing, as with any procedure, infection can be a delayed complication. **Always use strict aseptic techniques when inserting the central venous introducer sheath and the transvenous pacing catheter.** There is currently no clinical evidence to suggest that the use of prophylactic antibiotics decreases infections or infectious complications. The use of prophylactic antibiotics cannot be currently recommended. The most common organisms are skin flora. The types of infection can range from cellulitis at the puncture site to myocarditis and florid sepsis.[2,5,12] Antibiotic therapy should be started and the catheter removed and cultured. If the pacing catheter is absolutely required, a new puncture site should be selected and a new pacing catheter inserted.

The pacing catheter balloon can be a source of complications.[14,15] Air embolism has been reported. This can be prevented by assessing the balloon for leaks prior to inserting the catheter. Do not overinflate the balloon. An air embolism or a piece of ruptured balloon may obstruct part of the pulmonary circulation. Do not inflate the balloon after it is inserted more than 10 to 15 cm into the ventricle. If the balloon is inflated when the catheter tip is in a branch of the pulmonary artery, the vessel may rupture. Forward and backward movement of the pacing catheter with the balloon inflated may result in rupture of the chordae tendineae with subsequent tricuspid regurgitation.

The pacing circuit (i.e., catheter, wires, and pacemaker) can also be a source of complications. The catheter may become dislodged or fractured. The pacemaker may fail due to battery drainage, generator failure, or electrical interference.

Anatomic variations may be present and not known to the patient or the Emergency Physician. These include persistent left-sided superior vena cava, congenital lack of a vein, or congenital duplication of a vein.[16] Anatomic variations can increase the technical difficulty of the procedure. It might be necessary to use a femoral approach if the internal jugular or subclavian vein approaches are unsuccessful, regardless of the reason.[16]

Complications related to obtaining central venous access are discussed in Chapter 49. They include air embolism, infection, sepsis, cellulitis, pneumothorax, improper placement, arterial puncture, venous thrombosis, venous thrombophlebitis, and guidewire complications. Complications may be decreased by using the supraclavicular approach rather than the subclavian or internal jugular approaches.[8]

SUMMARY

Placement of a transvenous cardiac pacing catheter can be a lifesaving procedure. It is a safe method to electrically stimulate the heart. It is indicated when an unstable rhythm of the heart is refractory to medications and transcutaneous pacing. Proper placement of the pacing catheter is cardinal to its functioning. Recognition of the ECG changes that occur in the different anatomic areas helps to guide its placement. One must also be aware of the potential complications and their management. This procedure should be mastered by all Emergency Physicians caring for critically ill and/or injured patients.

34 Pacemaker Assessment

Nnaemeka G. Okafor

INTRODUCTION

Pacemakers are common among Emergency Department patients. Patients may present due to symptoms referable to pacemaker malfunction or symptoms unrelated to the pacemaker, and its presence may modify the investigation and therapeutic approach. It is important for the Emergency Physician to understand the workings of a pacemaker, the problems that may be encountered, the etiologies of the problems, and the assessment of a patient with a pacemaker.

There are numerous indications for the implantation of a cardiac pacemaker.[1–8] However, a detailed discussion regarding the indications for permanent pacemaker insertion is beyond the scope of this chapter.[1,6,7] The most common indication for permanent pacemaker placement is symptomatic bradycardia. Mortality rates can be decreased in these patients with pacing. A permanent pacemaker is inserted prophylactically when intrinsic cardiac rhythms can degenerate to higher-degree blocks or in patients who may develop symptoms in the near future even though the initial presentation was asymptomatic. An example would be the Mobitz type 2 second-degree atrioventricular (AV) block. In addressing the treatment modalities for cardiac rhythm disturbances, the decision to implant a pacemaker can be difficult and must be reached by a careful review of each patient on an individual basis.

The pacemaker unit is implanted by a Cardiologist in the cardiac catheterization laboratory. The pacemaker unit consists of the pacemaker generator, the pacemaker wires (also known as electrodes or leads), and the terminal electrodes. The square or rectangular pacemaker generator is implanted subcutaneously in the left or right upper chest. It is responsible for the functioning of the unit and contains the battery that powers it. **A reed switch in the pacemaker generator can be used to inactivate its sensing mechanism and cause it to perform in an asynchronous mode.** The pacemaker wires are embedded in plastic catheters and attached to the pacemaker generator. The wires are inserted through the subclavian vein or, less commonly, through the cephalic vein and into the right side of the heart. The terminal electrodes are at the distal end of the pacing wires and are designated as unipolar or bipolar. The terminal electrodes are placed under fluoroscopic guidance in the right ventricle for single chamber pacing or the right atrium and right ventricle for dual chamber pacing. After insertion, the unit is programmed and tested.

The North American Society for Pacing and Electrophysiology and the British Pacing and Electrophysiology Group have accepted a five-letter pacemaker code, which is also followed by the pacemaker industry (**Table 34-1**). The code is generic in nature. The character position is labeled in Roman numerals I through V. The first letter designates the chamber(s) in which pacing occurs. It can be designated as none (0), atrial (A), ventricular (V), or both atrial and ventricular (D or dual). The second letter designates which cardiac chamber(s) the pacemaker uses to sense intrinsic electrical cardiac activity. It can be designated as none (0), atrial (A), ventricular (V), or both atrial and ventricular (D or dual). The third letter designates how the pacemaker responds to sensed intrinsic electrical activity. A sensed event may inhibit (I), trigger (T), both inhibit and trigger (D), or cause no response (O) from the pacemaker generator. To have a designation other than O, the pacemaker must be a dual-chamber system. The fourth letter reflects the programmability and rate modulation of the unit. The fifth letter designates the antitachyarrhythmia function(s) of the pacemaker. The fourth and fifth letters are rarely used, as these functions are not often required.

TABLE 34-1 The Generic and Standard Pacemaker Codes

Position	I	II	III	IV	V
Interpretation	Chamber(s) paced	Chamber(s) sensed	Response to sensing	Programmability rate modulation	Antitachyarrhythmia function(s)
Variable	0	0	0	0	0
	A	A	T	P^1	P^2
	V	V	I	M	S
	D (A + V)	D (A + V)	D (T + I)	C	D (P + S)
				R	

Key: A, atria; C, communicating; D, dual; I, inhibited; M, multiprogrammable; 0, none; P^1, simple programmable; P^2, pacing; R, rate modulation; S, shock; T, triggered; V, ventricle.

The code does not describe the characteristics, specific functions, or unique functions that are specific to each pacemaker unit or the manufacturer of the unit. The most common mode for a pacemaker is VVI. The reader is referred to other references for a more complete discussion of pacemaker modes.[1,6,7]

EVALUATION OF PACEMAKER FUNCTION

Pacemaker patients who present to the Emergency Department with a complaint that may be associated with their pacemaker require a thorough evaluation. Place the patient on the pulse oximeter and cardiac monitor and apply a noninvasive blood pressure cuff. Provide supplemental oxygen via a nasal cannula or face mask. A history and physical examination should be performed while simultaneously obtaining a 12-lead electrocardiogram (ECG). Obtain posteroanterior and lateral chest radiographs if the patient is stable. If not, a portable anteroposterior chest radiograph will suffice. Perform a magnet examination of the pacemaker. **A Cardiologist should always be consulted regarding a patient with an actual or a potential pacemaker problem.**

HISTORY AND PHYSICAL EXAMINATION

The initial evaluation begins with a complete history. Palpitations, dizziness, near syncope, syncope, or any symptom that may resemble those prior to pacemaker implantation may reflect a potential pacemaker malfunction. In patients who have had their pacemaker placed recently, the complaints related to potential pacemaker infection should also be explored. Determine if the patient is taking medications that can raise the myocardial threshold to pacing. Traumatic injury to the torso can cause the leads to displace or fracture. Direct trauma over the pacemaker generator can render it inoperable.

Ask the patient if they have a pacemaker card. This is a business card-size piece of paper that is given to the patient after pacemaker implantation to identify the pacemaker type, manufacturer of the unit, programmed rate, the five-letter code programmed in the pacemaker, and the manufacturer's phone number. The patient should be questioned regarding any known changes in the pacemaker settings since receiving the pacemaker card.

Perform a thorough examination of the patient. Observe the vital signs for bradycardia, fever, hypertension, hypotension, or tachycardia. Evaluate the veins of the head and neck for venous engorgement suggesting a central venous thrombosis or a superior vena cava syndrome. Edema of the ipsilateral upper extremity indicates thrombosis and possible occlusion of the subclavian vein. Identify the location of the pacemaker pocket and implantation scar on the skin. Note if the pacemaker generator has moved from its original position. This can cause a partial or complete disconnection of the pacemaker wires from the generator. Inspect the pacemaker pocket for signs of infection, including a discharge, edema, skin erosion, erythema, redness, tenderness, and/or warmth.

ELECTROCARDIOGRAM

Obtain a 12-lead ECG. This recording will disclose whether the patient is presently being paced and in what manner (e.g., ventricular or atrioventricular pacing). If not, the underlying rhythm and PR interval of an intrinsic cardiac beat can be readily established (**Figure 34-1A**). Bipolar spikes tend to be smaller, and examination of various leads of the ECG tracing may clarify the presence or absence of capture. A paced beat occurs when ventricular depolarization is secondary to pacer stimulation (**Figure 34-1B**). The pacer spike is seen immediately preceding the QRS complex. A fusion or pseudofusion beat can occur due to pacemaker firing on an intrinsically occurring P wave or QRS complex. A fusion beat is a QRS complex that has been formed by depolarization of the myocardium that was initiated by both the pacemaker spike and the patient's intrinsic electrical activity (**Figure 34-1C**). The QRS configuration of the fusion beat is different from the paced QRS morphology and the intrinsic cardiac QRS morphology. It is a hybrid of the paced and intrinsic QRS complex morphology. A pseudofusion beat is a QRS complex that is formed by the depolarization of the myocardium initiated by the patient's intrinsic electrical activity, and a pacemaker spike is present distorting the terminal QRS complex. The morphology is similar to that of the intrinsic QRS complex (**Figure 34-1D**). It is often due to the pacemaker firing during the refractory period of an intrinsic P wave or during the beginning of the QRS complex before intracardiac voltage increases to activate the sensing circuit and inhibit the pacemaker. Pseudofusion beats can be normal occurrences in pacemaker patients.

A properly functioning pacemaker will sense intrinsic cardiac electrical activity. If the intrinsic cardiac activity is below the programmed rate, a pacemaker spike will be seen followed by a QRS complex in a single-chamber or ventricular pacemaker (**Figure 34-2**). If the patient has a dual-chamber pacemaker, a

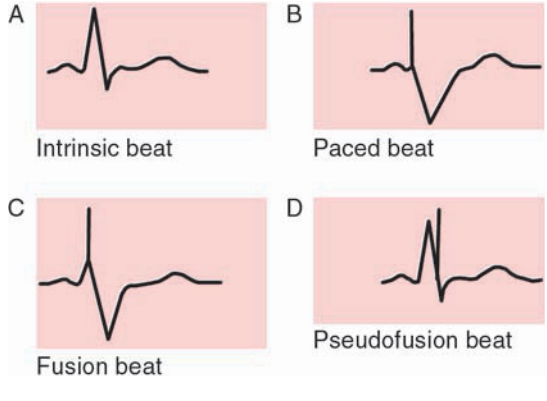

FIGURE 34-1. Schematic of typical electrocardiographic beats.

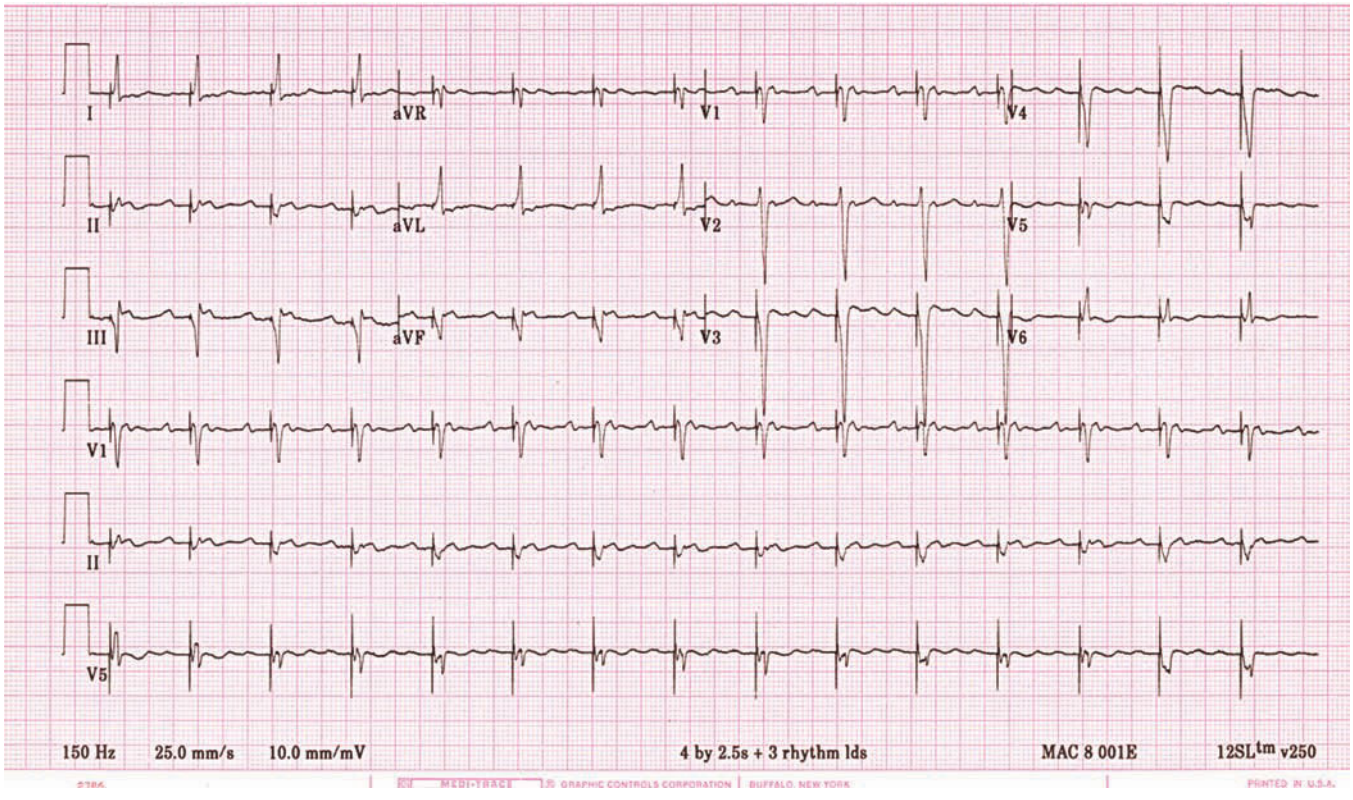

FIGURE 34-2. A 12-lead electrocardiogram of a single-chamber or ventricular pacemaker.

pacemaker spike will be followed by a P wave; then a second pacemaker spike will be seen followed by a QRS complex (**Figures 34-3 & 34-4**). If the intrinsic cardiac electric activity is above the programmed rate, no pacemaker spike should be seen on the ECG. Since the pacemaker wire is usually implanted in the right ventricle, a typical paced QRS complex will have a left bundle branch pattern (**Figures 34-1 to 34-4**). Occasionally, the pacing wire will be implanted in the left ventricle and the QRS complex will have a right bundle branch pattern.

Examine the current ECG and determine the electrical axis of the pacemaker spike, the electrical axis of the QRS complex, and the morphology of the QRS complex. These must be compared to the same features on previously obtained ECGs. A change in the axis of the pacemaker spike may be seen in cases of lead migration. A change in the ECG morphology from a left bundle branch pattern to a right bundle branch pattern suggests that the lead has perforated the interventricular septum and is now within the left ventricle.

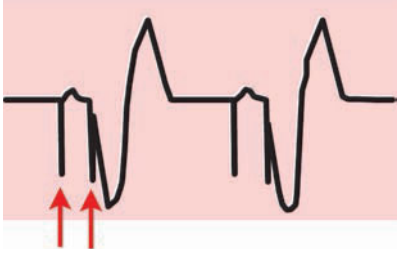

FIGURE 34-3. Schematic of an electrocardiographic monitor strip of a dual-chamber pacemaker. Atrial (*first arrow*) and ventricular (*second arrow*) pacing spikes are clearly visible.

MAGNET EXAMINATION

A magnet may be used to assess battery depletion, failure of a component of the system, or the possibility of oversensing. It can also be used in an attempt to terminate pacemaker-mediated tachycardia (PMT, discussed further on in this chapter). A doughnut-shaped magnet is required for this procedure. A standard or generic magnet may be used. Occasionally, but rarely, a brand-specific magnet may be required to evaluate a pacemaker. **A transcutaneous pacemaker generator, defibrillator, the required cables and skin electrodes, and ACLS resuscitation medications must be available in case of an emergency during the magnet examination.**

To obtain the magnet rate, place a standard magnet over the pacemaker generator while simultaneously obtaining a 12-lead ECG and rhythm strip. **The magnetic field causes the reed switch to close, bypass the sensing amplifier, and temporarily convert the pacemaker into the asynchronous (VOO or DOO) mode (Figure 34-5). This essentially turns off the sensing mode and the pacemaker fires at the programmed rate.** The magnet rate may be slower or faster than the program rate and depends on the model of the pacemaker. Pacemaker spikes occurring during the refractory period of an intrinsic QRS complex will not be captured (**Figure 34-5B**). Theoretically, a pacing spike occurring on the T wave could induce ventricular arrhythmias, but this is rarely a practical problem.

The application of the magnet over the pacemaker generator can have a variety of results. If it is working properly, the pacemaker will fire at the programmed rate. This indicates that the failure to pace the myocardium in a patient with bradycardia is due to oversensing. The unit may be sensing a large T wave as a QRS complex. Alternatively, it may be sensing a normal T wave as a QRS complex if the QRS complexes are small in amplitude. If a patient's bradycardia is corrected, tape the magnet in place over the pacemaker generator.

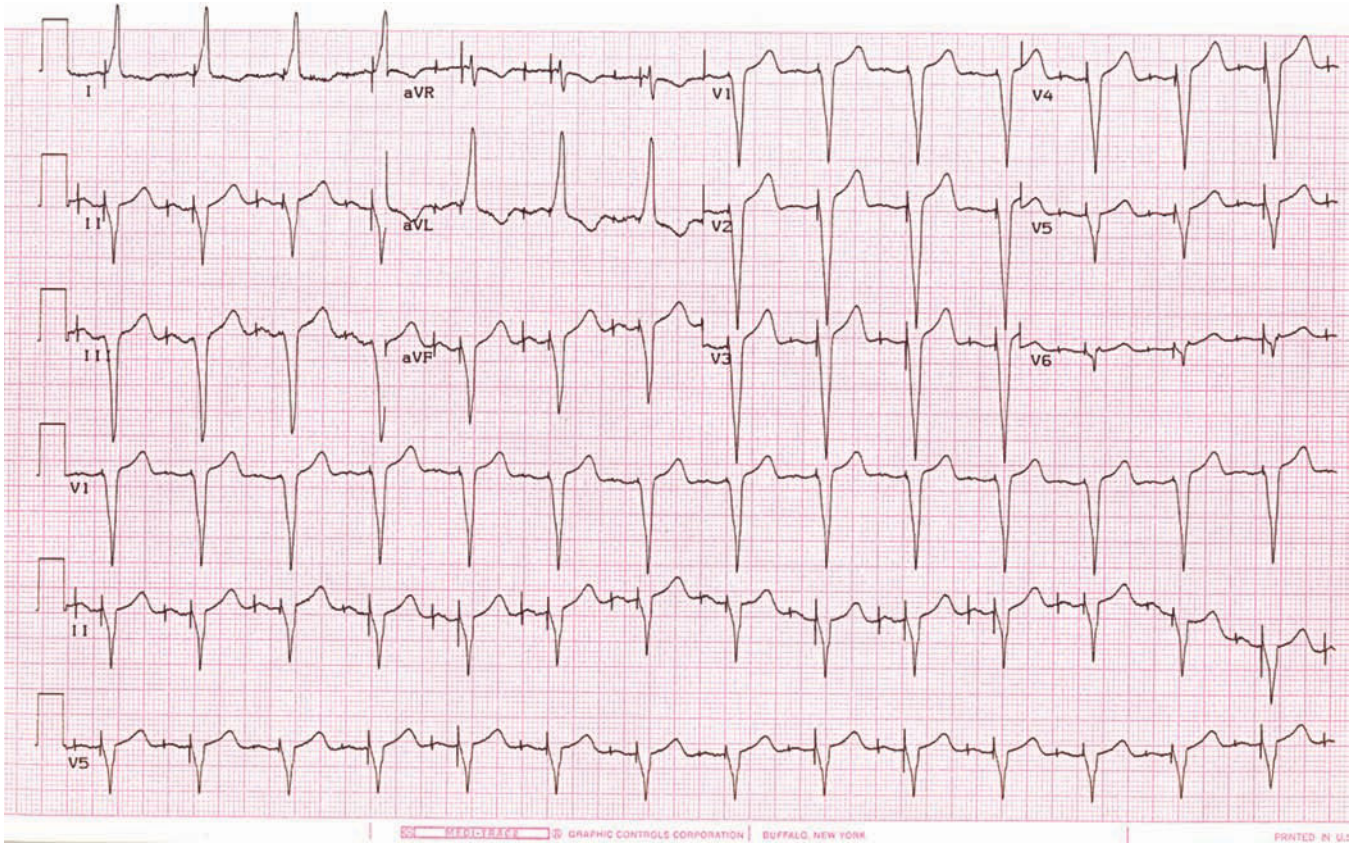

FIGURE 34-4. A 12-lead electrocardiogram of a dual-chamber or atrioventricular sequential pacemaker.

If the generator is pacing intermittently, the magnet may not be directly over the pacemaker generator. Reposition the magnet and observe the results. If no pacemaker spikes are seen on the ECG, a component of the system (i.e., generator, battery, or leads) has failed. If the pacemaker spikes occur at less than the programmed rate, the battery may be depleted or the set rate has been changed.

CHEST RADIOGRAPHY

Obtain overpenetrated posteroanterior and lateral chest radiographs. This is helpful in locating the pacemaker generator and lead positions. Look for a loose connection where the lead connects to the pacemaker generator. Manipulation of the pulse generator within the pocket may relieve or reproduce the patient's problem. A pneumothorax and/or hemothorax may be detected in patients whose pacemakers have been recently implanted.

The pacemaker lead may have become dislodged from its implantation site. This is extremely uncommon with current systems, as they have safety mechanisms to prevent lead dislodgement. Ensure that the distal end of the pacing wire is within the cardiac silhouette and against the myocardium. It may be free-floating within the ventricle or may have perforated the ventricular wall. Previous chest radiographs should be obtained and compared to the current radiographs to help determine if the leads have been displaced.

Lead fractures can occur anywhere along the length of the pacing wire. They most often occur at stress points adjacent to the pacemaker or just under the clavicle as the pacing wire enters the subclavian vein. The lead also has a J-shaped retention wire to help maintain its shape. The tip of the retention wire may occasionally protrude from the plastic-coated lead. This protruding wire has the potential to puncture the right atrium or superior vena cava and cause a hemorrhagic pericardial effusion that may result in cardiac tamponade.

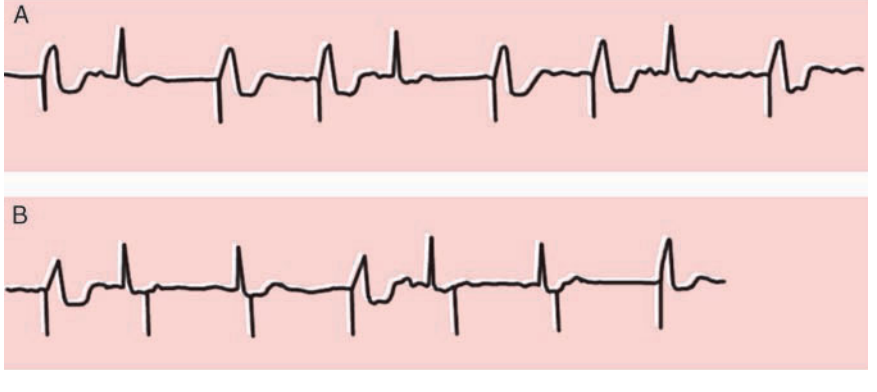

FIGURE 34-5. Schematic of a pacemaker's electrocardiographic monitor strip. **A.** Pacemaker activity without a magnet applied. **B.** Pacemaker activity with a magnet applied.

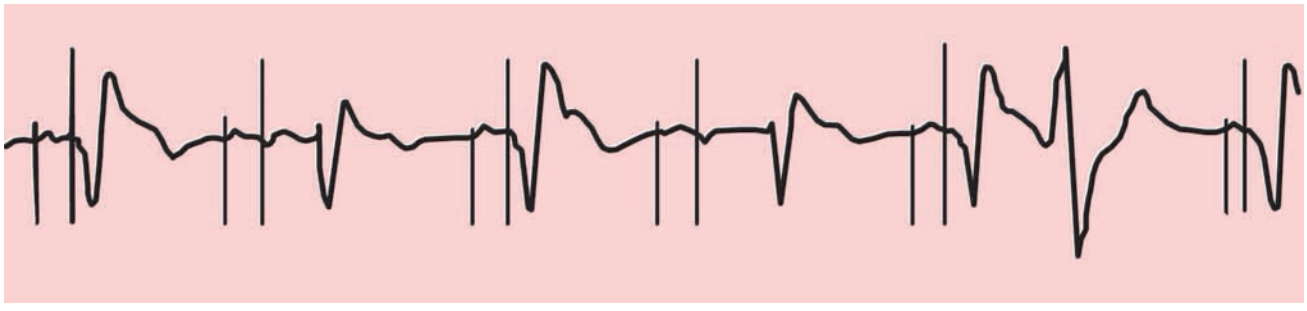

FIGURE 34-6. Schematic of an electrocardiographic monitor strip of an AV sequential pacemaker demonstrating lack of capture or intermittent capture.

PACEMAKER INTERROGATION

Recent pacemakers contain crucial information such as the range of heart rate, percentage of pacing, intracardiac ECG recordings as well as arrhythmia logs.[9] The pacemaker can be interrogated to obtain generator life, lead integrity, false discharges, undersensing, and oversensing. The device interrogation by the industry representative or a cardiology technician is a vital part of the Emergency Department evaluation of a patient presenting with symptoms that might be attributed to the pacemaker. The interrogator, in consultation with the patient's Cardiologist, may have the capability of changing the threshold setting on the device to resolve certain problems and negating the need for admission.[10]

ELECTROCARDIOGRAPHIC ABNORMALITIES

FAILURE TO PACE

Failure to pace is a result of either pacemaker output failure (i.e., lack of a pacer spike) or failure to capture (i.e., lack of a myocardium stimulation after a pacer spike). **Failure to pace is noted by a lack of the pacemaker spike on the ECG and the failure to deliver a stimulus to the myocardium when there is a pause in the intrinsic cardiac electrical activity.** The pacer-dependent patient may complain of chest pain, dizziness, lightheadedness, weakness, near-syncope, syncope, or other signs of hypoperfusion.

The failure of pacemaker output is detected by the lack of pacing activity (i.e., pacer spikes) on the ECG in a patient with a heart rate lower than the programmed rate. It can be the result of oversensing or an inherent problem with the device. Total or nearly total battery failure, complete inhibition of a demand pacemaker by skeletal muscle contraction or electrical magnetic interference, oversensing, insulation failure, lead fracture, or an improper connection between the electrode and the pulse generator can all cause total lack of pacemaker stimulus. The incorrect diagnosis of a failure to pace and a lack of pacemaker output can be made if the patient's pacemaker spike is very small. The evaluation of multiple leads of the ECG tracing usually prevents this misdiagnosis.

Oversensing is the inappropriate inhibition of the pacemaker due to its sensing of signals that it should otherwise ignore. For instance, P or T waves or skeletal muscle activity may be misinterpreted as QRS complexes resulting in the inhibition of pacemaker function. Oversensing has decreased in prevalence due to the use of bipolar pacing devices.[9] Oversensing can be detected by placing a magnet over the pacemaker. If it is working properly, the pacemaker will fire at the programmed rate. This indicates that the failure to pace the myocardium in a patient with bradycardia is due to oversensing. The unit may be sensing a large T wave as a QRS complex. Alternatively, it may be sensing a normal T wave as a QRS complex if the QRS complexes are small in amplitude. If a patient's bradycardia is corrected, tape the magnet in place over the pacemaker generator. If the generator is pacing intermittently, the magnet may not be directly over the pacemaker generator. Reposition the magnet and observe the results. If no pacemaker spikes are seen on the ECG, a component of the system (i.e., generator, battery, or leads) has failed. If the pacemaker spikes occur at less than the programmed rate, the battery may be depleted or the set rate has been changed.

FAILURE TO CAPTURE (LACK OF CAPTURE OR INTERMITTENT CAPTURE)

Failure to capture is detected by the lack of a QRS complex after an appropriately timed and placed pacemaker spike on the ECG (Figure 34-6). It occurs when the generated pacing impulse is incapable of effectively depolarizing the myocardium. Lack of capture or intermittent capture could be as a result of the inadequate energy generation by the pacemaker (i.e., battery failure), increased resistance at the electrode–myocardium interface (i.e., lead fracture or displacement), poor electrode positioning, prolongation of the refractory state of the myocardium (e.g., myocardial infarction, electrolyte abnormalities, supratherapeutic levels of antidysrhythmic drugs), or perforation of the myocardium by the electrode.[10] For patients with failure to capture as a result of high antidysrhythmic drug levels, isoproterenol has been shown to be an effective therapy.[10,11]

Failure to capture during the postimplantation period could result from an elevated voltage threshold for pacing due to tissue changes at the electrode–myocardium interface.[10,11] The occurrence of postimplantation failure to capture typically occurs in the first few weeks after implantation. However, its incidence has decreased because of recent advances in steroid-eluting leads.[10,11]

A poor threshold may be present from the time of implantation. A chronic rise in threshold can be related to fibrosis around the tip of the lead, causing lack of capture or intermittent capture. Severe metabolic abnormalities and drugs can increase the pacing threshold. A myocardial infarction involving the myocardium at the tip of the pacer leads will cause a rise in the pacing threshold. Lead fracture and poor connections between the electrode and generator can present as lack of capture or intermittent capture. The pacemaker generator battery may fail and present with too low a voltage to capture the heart but enough voltage to generate a pacemaker spike. Insulation breaks in the pacemaker lead allow parallel electrical circuits to occur in the system and may cause various pacemaker abnormalities.

RATE CHANGE

Rate change is defined as a stable change in the pacemaker's rate of firing compared to the pacemaker's rate at the time of implantation. Minor chronic changes in the pacemaker rate of one or two beats per minute can occur in some patients. The most common cause for a marked drop in the paced rate is battery depletion.

FIGURE 34-7. Schematic of an electrocardiographic monitor strip demonstrating intermittent or erratic prolongation of the pacing spike interval.

FIGURE 34-8. Schematic of an electrocardiographic monitor strip demonstrating lack of appropriate sensing or failure to sense.

This is a sign that the elective battery replacement time is nearing. Inappropriate sensing of the preceding T wave as a QRS complex can also result in a paced rate several beats per minute slower than the programmed rate.

INTERMITTENT OR ERRATIC PROLONGATION OF THE PACING SPIKE INTERVAL

A prolongation of the pacing spike interval can be due to inappropriate sensing of the T wave, pacemaker afterpotential, or skeletal muscle activity (**Figure 34-7**). Intermittent fracture of leads, poor electrode–generator connection, breaks in the insulation of the leads, external electromagnetic interference, or radiofrequency interference can also cause this malfunction.

FAILURE TO SENSE OR UNDERSENSING

Failure to sense is a result of the inability of the pacemaker to sense the native cardiac activity. It is recognized by noting pacemaker spikes on the ECG despite the patient's intrinsic cardiac rate being higher than the pacemaker's programmed rate (Figure 34-8). Patients with an undersensing pacemaker might present with weakness, lightheadedness and syncope due to alterations in rhythm due to competition with the native cardiac rhythm. The pacemaker does not sense the preceding QRS complex appropriately and fires. Causes of undersensing include conditions that alter the nature of cardiac signals such as new bundle branch blocks, myocardial ischemia, premature ventricular contractions (PVCs), or premature atrial contractions.[10] Other etiologies of failure to sense include poor electrode position, lead dislodgement, reed switch malfunction, breaks in the lead insulation, battery failure, and inappropriate programming of the sensitivity of the pulse generator. However, many of these etiologies can also result in failure to capture. Low-amplitude QRS complexes or broad QRS complexes with a low slow rate, as in a bundle branch block, may be responsible for pacemaker sensing problems.

PACEMAKER-MEDIATED TACHYCARDIA

Pacemaker-mediated tachycardia (PMT) is a paced rhythm in which the pacemaker is firing at a very high rate (Figure 34-9). PMT can occur only when the pacemaker is programmed to an atrial synchronized pacing mode (e.g., DDD). PMT is a reentry dysrhythmia commonly precipitated by a PVC in a patient with a dual-chamber pacemaker. If the PVC is conveyed in a retrograde fashion through the AV node, it may be sensed as a retrograde P wave. The sensed retrograde P wave is considered by the pacemaker as atrial activity and the pacemaker initiates ventricular pacing.[10,12] This continues via an endless loop involving the pacemaker. Modern pacemakers have algorithms to prevent and terminate PMT. Management includes the application of a magnet, Valsalva maneuvers, transcutaneous pacing, and various isometric pectoral exercises. Other methods to terminate this rhythm include a precordial thump, reprogramming the pacemaker, and cutting the leads as they exit the pacemaker generator. Consult a Cardiologist prior to performing any of these maneuvers.

COMPLICATIONS OF CARDIAC PACING UNRELATED TO ELECTROCARDIOGRAPHIC ABNORMALITIES

IMPLANTATION-RELATED COMPLICATIONS

Complications may occur from the implantation procedure. Discomfort and ecchymosis at the incision site or the pacemaker pocket are common in the first few days. Dehiscence of the incision can occur, especially if a large hematoma in the pocket puts excessive stress or pressure on the incision. Nonsteroidal anti-inflammatory drugs, excluding aspirin, are adequate and appropriate to alleviate the discomfort. Assure the patient that the discomfort and ecchymosis will resolve spontaneously. The patient should not be taking aspirin in the immediate postimplantation period unless authorized and/or prescribed by the Cardiologist. The pacemaker can migrate, cause pressure on the overlying skin, and result in skin erosions that require pacemaker relocation and wound debridement.

The most common insertion site for the pacemaker wires is through the subclavian vein using a blind insertion technique. Complications include air embolism, arteriovenous fistula formation, brachial plexus injury, hemothorax, pneumothorax, subclavian artery puncture, subcutaneous emphysema, and thoracic duct injury. Refer to Chapter 49 for complete details on complications related to the placement of a central venous line.

A hematoma may form at the site of the subcutaneous pacemaker generator. This can be due to anticoagulation therapy, aspirin therapy, or an injury to a subcutaneous artery or vein. A hematoma can be managed with the application of dry, warm compresses to the area and oral analgesics. The Cardiologist may evacuate the hematoma if it continues to expand and threatens to compromise the incision site. Otherwise, a hematoma is self-limited and resolves spontaneously. **Do not attempt to aspirate a hematoma.** This is usually unsuccessful, can introduce an infection, may damage the pacemaker or leads, and does not address the etiology of the bleeding.

The ventricular wall may be perforated during the implantation of the pacemaker lead or postimplantation. The patient may be asymptomatic, complain of chest pain and/or dyspnea, or have signs and symptoms of cardiac tamponade. Other signs suggestive of ventricular perforation include diaphragmatic contraction or hiccups at a rate equal to the pacemaker rate, a friction rub, intercostal muscle contractions at a rate equal to the pacemaker rate, pericardial

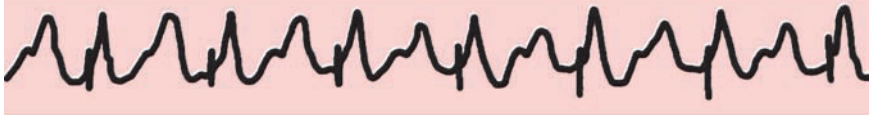

FIGURE 34-9. Schematic of an electrocardiographic monitor strip demonstrating pacemaker-mediated tachycardia.

effusions, pericarditis, or a right bundle branch pattern on the ECG. The evaluation may include chest radiography, echocardiography, and/or pacemaker interrogation and evaluation.

PACEMAKER SYNDROME

The pacemaker syndrome is defined as adverse hemodynamic effects that cause the patient to become symptomatic or limit their ability to be fully functional even though the pacemaker system is functioning normally. Patients may complain of anxiety, apprehension, dizziness, fatigue, pulsations in the neck, or shortness of breath. Ventricular pacing can cause a lack of atrioventricular synchrony, leading to decreased left ventricular filling and subsequent decreased cardiac output. Syncope and near-syncope are thought to be associated with a vagal reflex initiated by elevated right and/or left atrial pressures caused by dissociation of the atrial and ventricular contractions. The high wedge pressure can result in shortness of breath. Patients with the pacemaker syndrome most commonly have documented one-to-one ventricular-to-atrial conduction during ventricular pacing. Patients with retrograde AV conduction are more symptomatic. However, a pacemaker syndrome can occur in the absence of retrograde atrioventricular conduction. Provide supportive care until the pacer can be upgraded to one that restores AV synchrony, such as changing a single-chamber pacer to a dual-chamber pacer.

RUNAWAY PACEMAKER

The runaway pacemaker is a rare medical emergency in which rapid pacer discharges occur above its preset upper limit. Ventricular tachycardia or fibrillation may be induced. The cause is a malfunction in the pacemaker pulse generator, unlike PMT, which is caused by an external re-entrant loop.[10,11,13] Runaway pacemaker can be differentiated from PMT by the response to the application of a magnet. PMT will usually stop temporarily by inducing asynchronous pacing with a magnet. However, magnet application generally has little or no affect on a runaway pacemaker.[12] Treatment requires emergent pacemaker interrogation and reprogramming. If this fails, emergent surgical intervention to disconnect or cut the leads in the pacemaker pocket is necessary. Fortunately, all modern pacemakers are programmed to prevent discharges at rates above a set limit, usually 180 beats per minute.[13]

INFECTION

Infection often occurs shortly after implantation and is usually localized to the pacemaker pocket area. However, endocarditis has also been reported in association with pacemakers. Infection may present as localized erythema and tenderness, localized inflammation, purulent discharge from the skin incision, skin erosion, sepsis, and/or bacteremia. *Staphylococcus aureus* is responsible for many acute infections while *Staphylococcus epidermidis* is a frequent culprit of late or chronic infection.[14] The pacemaker generator and leads usually have to be removed to eradicate an infection. In some instances, the infection has been treated successfully with vancomycin or other parenteral antibiotics and the pacemaker did not require removal.

The pacemaker electrode becomes endothelialized in a few weeks postimplantation. Patients generally do not require prophylactic antibiotics when they undergo a procedure that is likely to produce transient bacteremia. Prophylactic antibiotics are required only in the first few weeks after permanent pacemaker implantation.

STIMULATION OF THE DIAPHRAGM AND PECTORAL MUSCLE

Stimulation of the diaphragm may be caused by perforation of the right ventricular wall by the pacing wire and can occur with very few complications. Diaphragmatic stimulation can also occur without perforation of the right ventricular wall. Decreasing the pulse width and/or voltage output can minimize the stimulation until the defective component can be replaced.

Pectoral muscle stimulation is less common with the currently available bipolar pacemakers. An insulation break or a defect in the pacing wire before it enters the subclavian vein will allow the current to flow in the area of the pacemaker generator and cause skeletal muscle stimulation. This can also be seen with current leakage from the connector of the pacing wires or sealing plugs. In rare instances, erosion of the protective coating of the pacemaker generator can cause this phenomenon. Decreasing the pulse width and/or voltage output can minimize the stimulation until the defective component can be replaced.

THROMBOSIS

Thrombosis of the vein (e.g., subclavian or cephalic) containing the pacemaker lead occurs commonly, but rarely causes clinical symptoms. Patients with symptomatic thrombosis and occlusion of the subclavian vein may present with ipsilateral edema and pain in the upper extremity. Occlusion of the superior vena cava can result in a superior vena cava syndrome. Thrombus formation in the right atrium and/or right ventricle can result in pulmonary emboli and hemodynamic compromise. Fortunately, these events are extremely rare.

ALLERGIC REACTIONS

Allergic reactions to the metal components of the pacemaker have been noted in the past. Current pacemaker generators and leads are coated with a substance to prevent the body from being exposed to the metal. Allergic reactions to the pacemaker covering are very rare but have been reported.

SUMMARY

Routine follow-up of patients with pacemakers in the pacemaker clinic helps to identify pacemaker malfunction earlier and often before problems occur. Patients presenting to the Emergency Department with symptoms referable to pacemaker malfunction should have a history and physical examination, chest radiograph, routine ECG, and ECG recording with a magnet over the pacemaker. This helps to identify patients with pacemaker malfunction who require detailed pacemaker interrogation. A Cardiologist should be consulted on every patient who presents with an actual or a potential pacemaker problem.

35 Automatic Implantable Cardioverter-Defibrillator Assessment

Carlos J. Roldan

INTRODUCTION

The introduction of implantable cardioverter-defibrillator (ICD) technology has revolutionized the fields of cardiology and electrophysiology. More than 100,000 such devices are implanted annually in the United States alone. ICDs allow life-threatening ventricular tachycardia and ventricular fibrillation to be safely controlled and benefit patients at risk for sudden cardiac death. Multiple

studies (e.g., CABG patch, MADIT, MADIT II, MUSTT, DINAMIT, AMIOVIRT, COMPANION, SCD-HEFT) have examined the prophylactic indication for ICD therapy in high-risk groups.[1–7] The ICD is becoming a more common therapeutic option for the young population with a diagnosis of Brugada syndrome, prolonged QT syndrome, and hereditary cardiomyopathies to name a few.

The Emergency Department is often the initial contact point for these patients. Now more than ever Emergency Physicians must be familiar with the problems that can be encountered by a patient with an ICD. This chapter describes technical aspects, basic interrogation of the device, and a general approach to a patient who presents to the Emergency Department with an ICD.

TECHNICAL CONSIDERATIONS

The ICD has four main functions. It recognizes and records local atrial and ventricular electrogram signals. It then classifies the sensed signals according to programmable heart rate zones. The ICD provides therapy (i.e., a shock) to terminate ventricular tachycardia or ventricular fibrillation. It has a pacing capability for bradycardia and/or cardiac resynchronization therapy. When detection criteria are satisfied, therapy to terminate the arrhythmia is initiated with high-energy shock of up to 40 Joules (J).

ICD technology has progressed exponentially since its introduction by Mirowski and colleagues in the early 1980s.[8] The ICD system is comprised of a pulse generator, a battery, and a lead system. The lead system is required for sensing, pacing, and the delivery of therapy. Earlier systems required that the pulse generators be placed abdominally due to their large size (**Figure 35-1**). Defibrillation was delivered via two epicardial patches positioned anteriorly and posteriorly. Occasionally, a transvenous spring electrode in the superior vena cava was utilized with an epicardial patch. Sensing was achieved through separate epicardial screw-in electrodes. Initial lead placement required either a sternotomy, lateral thoracotomy, or a subxiphoid approach, making early implants quite cumbersome.[9]

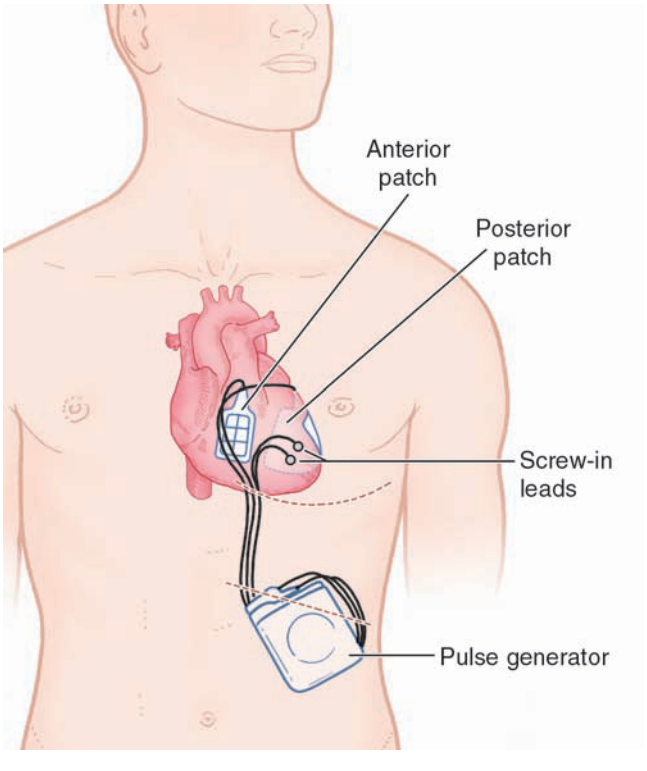

FIGURE 35-1. Abdominal placement of the ICD generator. Initial implants required a thoracotomy to position the epicardial patches needed for defibrillation as well as the screw-in sensing leads. The leads were tunneled abdominally to the ICD generator.

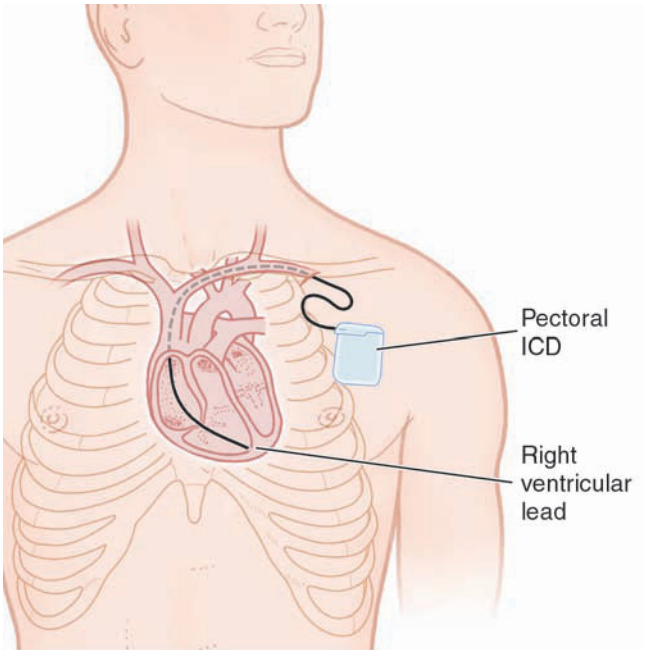

FIGURE 35-2. The current nonthoracotomy system. The development of smaller generators and biphasic waveforms for defibrillation allowed for transvenous positioning of the ICD leads and a pectorally located generator.

The smaller size of the newer devices allows for superficial implantation of the pulse generator in the anterior chest wall, similar to a pacemaker (**Figure 35-2**). The current ICD systems are comprised of three main parts. The pulse generator is programmable and capable of analyzing and recording the patient's heart and rhythm. The ICD generator houses the batteries, high-voltage capacitors, and microprocessors necessary to process sensed intrinsic cardiac electrical activity. In essence, the generator is a minicomputer within a hermetically sealed titanium can (aka case) capable of generating shocks. Typical ICDs contain lithium silver vanadium oxide cells that store between 2 and 7 Volts (V).[12] The high voltages necessary for defibrillation are generated with the aid of high-voltage capacitors that are able to generate 700 to 800 V of defibrillation energy in under 20 seconds. The lead system or wires are inserted into the right ventricle for single chamber devices or both the right atrium and right ventricle for dual chamber devices. The leads are required for sensing, pacing, and the delivery of therapy. The final component is the battery to power ICD system.

ICD implantation has evolved quite rapidly due to advancements in lead technology, generator technology, and the development of biphasic defibrillation waveforms, which lowered the energy requirements necessary for successful defibrillation.[10] The creation of a (bipolar) lead combining pacing and sensing capabilities with a high-voltage electrode coil allowed for nonthoracotomy system implants, which reduced surgical morbidity and mortality.[11] The leads were now positioned transvenously via the subclavian vein and fixed to the inside of the right ventricle. However, the leads still had to be tunneled subcutaneously to the abdomen, as the generators remained fairly large. Technology has advanced the development of more compact generators. The smallest commercially available devices today are under 40 cm^3 and weigh well under 100 grams. Smaller generators allow for subcutaneous pectoral implantation and simplification of the implantation process (**Figure 35-2**).[12]

Current ICDs allow extensive programmability for tiered antitachycardia pacing (ATP), tiered high voltage therapies, single or dual chamber bradycardia pacing, supraventricular tachycardia (SVT) discrimination algorithms, and detailed diagnostics of tachycardic and bradycardic episodes. Implantable loop recorders and home monitoring (HM) functions extend the technical capabilities for automatic detection of arrhythmias that may not be symptomatic. It also allows for a fully automatic and wireless data transmission, including episode counters.[9,10] This allows alterations in device programming or medication dose modifications in the outpatient setting, thus avoiding hospitalization.[13,14]

ATP may be enabled to manage ventricular tachycardia. ATP commonly consists of a burst of pacing (i.e., 6 to 10 beats) at a rate faster than the ventricular tachycardia rate. ATP may be felt by the patient. It is painless and often terminates the ventricular tachycardia before the patient becomes symptomatic. ATP is the initial preferred treatment, even for fast ventricular tachycardias, with shocks programmed as a backup if ATP fails.[15] In addition, current ICDs have an antibradycardia function that works like a pacemaker. If the heart rate falls below the programmed rate, the ICD will provide a pacing function with significantly less forceful shocks.

Exercise testing should be performed with the realization that increasing the heart rate above the programmed ventricular tachycardia and ventricular fibrillation detection rate is likely to elicit therapy (i.e., a shock) from the ICD. **Consult the patient's Electrophysiologist before any exercise or stress testing.** Determine the programmed the ICD arrhythmia detection rate. During the exercise or stress test, if the programmed rate is approached, stop the test to avoid the delivery of inappropriate therapy (i.e., a shock).

ROUTINE ICD FOLLOW-UP

A systematic follow-up procedure to assess the integrity of the ICD system is recommended every 1 to 6 months depending upon the device, battery status, and arrhythmia frequency (**Table 35-1**). The device should be interrogated with the appropriate system analyzer to assure battery voltage, lead and electrode integrity, and capacitor charge times. System integrity test results can reveal malfunctions that may compromise the device's ability to treat an arrhythmia effectively.[16,17] Once the system's integrity has been verified, each recorded arrhythmic episode should be analyzed to determine the appropriateness and effectiveness of therapies. This is achieved by examining the stored diagnostic information contained within the ICD, which may include intracardiac electrograms, arrhythmic interval values, classification markers for each interval, episode plots, textual episode descriptions, energy, charge time and impedance values for shocks, and device classifications of therapy success. This diagnostic information can be extremely valuable to determine whether programming changes should be made.[18]

TABLE 35-1 The ICD Follow-Up Checklist

- Detailed history of shocks, palpitations, light-headedness, syncope, chest pain, and dyspnea, or symptoms of congestive heart failure
- Note any changes in medications (i.e., antiarrhythmic therapy)
- Physical examination (examine incision site for any indication of infection)
- Interrogate device with appropriate system analyzer
- Check lead parameter including pacing thresholds and lead impedances (sensing is established by examining intracardiac R waves)
- Determine capacitor reformation times
- Check battery voltage (longevity is typically 5–10 years dependent on use)
- Measure impedance of the high-voltage coil (In older ICDs, this may require the administration of a subthreshold shock)
- Analyze arrhythmia counters. Examine corresponding intracardiac electrograms to determine appropriateness of therapy
- Make the necessary program changes. These include adjusting the tachycardia zones, changing the detection cutoff rates, turning on special features to aid tachycardia discrimination (stability, sudden-onset criteria, and electrogram width), and adjusting the sensitivities
- Confirm changes and reinterrogate device

BATTERY AND CAPACITORS

Battery longevity is significantly different among manufacturers. Battery voltages and capacitor charge times must be noted. Capacitors with smaller or larger capacities and changes in the initial shock polarity have not significantly improved defibrillation efficacy.[19] A variation in the number and position of electrodes can significantly influence the defibrillation threshold.[19] Generator replacement is usually recommended when voltages fall below the elective replacement indicator (ERI), which is approximately 2.6 V. When battery voltage falls below 2.2 V, the battery has reached its end of life (EOL). This signifies a more urgent need for battery replacement. The need to replace a generator is also dependent on capacitor charge times. Two consecutive charge times greater than 16 seconds is considered prolonged and may warrant urgent replacement regardless of the battery voltage. Automatic capacitor reformation is usually set to every 6 months to replenish their charge. This function can be programmed at preset time intervals. More frequent reformation is required and performed as the device reaches the battery EOL.

LEAD INTEGRITY

With the growing number of prophylactic ICD implantations and generator replacements, concern about the long-term reliability of chronically implanted leads increases. ICD lead failure can be caused by an insulation defect or conductor disruption. Lead failure can affect the high voltage lead or the pace–sense circuit of the lead. Newer ICDs provide lead-impedance monitoring for early detection of lead failure. An abnormal impedance indicates conductor fracture or insulation defect. An audible signal (Patient Alert™) notifies the patient who should then immediately contact their Cardiologist or present to the Emergency Department. Retrospective data from single centers suggest a potential clinical benefit of Patient Alert™ for ICD lead failure detection.[20]

Various parameters are checked to ensure lead integrity, including pacing thresholds, lead impedance, and the size of intracardiac R waves. At the time of implantation, a pacing threshold of ≤1.0 V at a pulse width of 0.5 milliseconds is desired. An acute rise in threshold may be seen initially; it generally falls with time. Chronic thresholds range between 0.5 and 2.0 V. Epicardial leads generally exhibit higher thresholds. Any change in thresholds must be compared with prior trends to assess its significance. Pacing thresholds may also change with the administration of antiarrhythmic drug therapy. Potential complications of ICD lead failure include oversensing of electrical noise, undersensing of ventricular tachyarrhythmias, inappropriate therapy, and lethal antiarrhythmic therapy.[21]

Current devices measure lead impedance only once a day. It is unlikely that such discrete measurements will reveal abnormal impedance if lead failure causes sporadic dysfunction. Thus, multiple impedance measurements per day may be necessary to enhance the sensitivity of the Patient Alert™.[22] Lead impedances will vary based on the type of lead. The high voltage impedance measurement differs between devices.[23] Normal impedances range from 300 to 1200 Ohms (Ω). A sudden change in impedance may signal a problem with lead integrity. A high impedance reading suggests the possibility of lead or patch fracture. A low impedance indicates a problem with the insulation. The impedance of the high-voltage coil must also be evaluated. Epicardial and active can systems

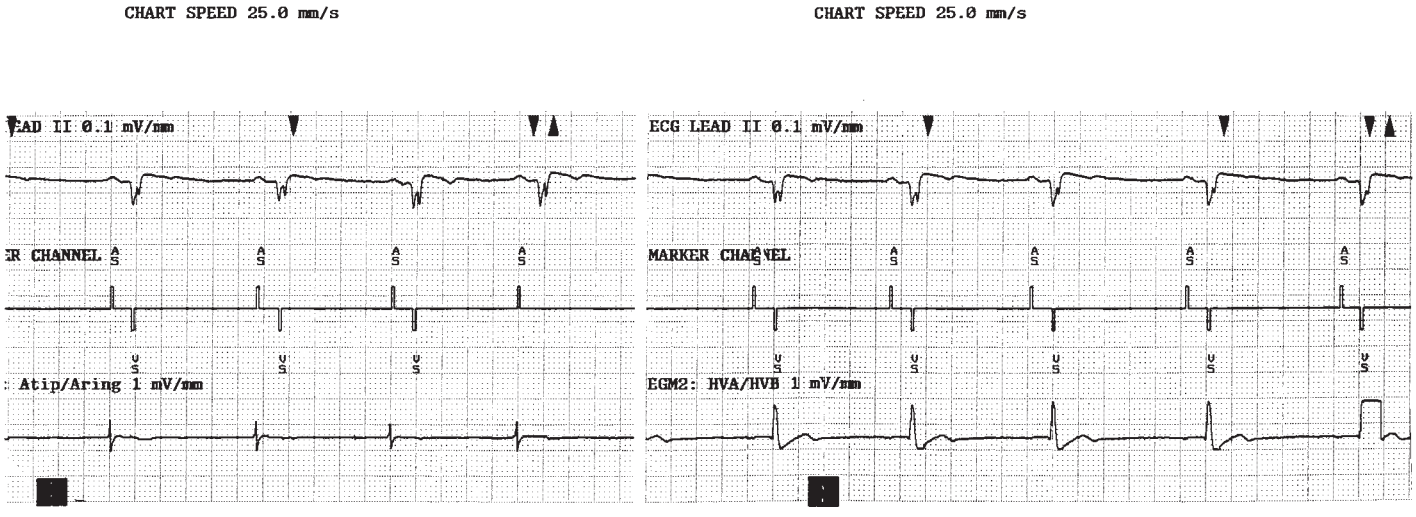

FIGURE 35-3. The intracardiac electrogram as recorded by the ICD. Printouts were obtained from a Medtronic Gem II DR dual-chamber ICD. The first line shows an ECG rhythm strip (lead II). The marker channel directly under the rhythm strip indicates behavior (sensing/pacing) in each chamber. The third line represents the intracardiac electrogram from the atrium (*left*) and ventricle (*right*). Measured in millivolts per millimeter, larger signals imply better sensing.

demonstrate lower impedance values compared to endocardial systems due to their larger surface area. Normal values generally range between 20 and 80 Ω. High impedance values, as with the pace/sense leads, usually indicate a fracture in the defibrillation system. Any stark changes in impedance levels may suggest a patch problem. This includes crinkling, seroma formation, or migration. Any impedance change in an endocardial system may indicate lead dislodgement.

R-wave amplitude is a direct measure of intracardiac electrogram activity and determines the device's ability to sense. At implantation, an R wave of ≤5 mV is desired to ensure adequate detection of ventricular fibrillation. The most common explanations for a decrease in R-wave amplitude after an implant are lead dislodgment or local factors such as edema or fibrosis. This change may be associated with an increase in lead impedance and pacing thresholds.

ANALYZING APPROPRIATENESS OF THERAPY

Current ICDs have simultaneous marker channels with real-time intracardiac electrograms (**Figure 35-3**). It is important to document intracardiac activity during sinus rhythm. These electrograms can be used as a basis of comparison with tachycardia events. The signals should be examined for evidence of noise, which may be an indicator of sensing problems, a connector issue, or a faulty adaptor. In the event of noise detection, electrograms must be examined during various maneuvers including deep breathing, arm maneuvers, and bending. Intracardiac electrograms should be examined for T-wave oversensing or detection of pacemaker spikes as ventricular signals. In dual-chamber devices, oversensing by the atrial lead should be ruled out. Wide variations in electrogram size may suggest that the lead is not stable or well fixed.

THE ICD IN THE EMERGENCY DEPARTMENT

A patient with an implantable defibrillator may present to the Emergency Department for various reasons. Manufacturers offer 24 hour technical support. They also maintain a registry of devices implanted and evaluations performed. A staff of field engineers are often available for help with the assessment, interrogation, and management of ICD function. The US Food and Drug Administration (FDA) is responsible for assessing both the premarket and postmarket safety and effectiveness of medical devices marketed in the United States. They require manufacturers to submit annual reports detailing the number of device implants and malfunctions that have occurred.[24]

Individuals with recently implanted devices may be quite anxious and may seek medical attention even after a single ICD discharge. Patients may also present after multiple ICD discharges or in full cardiac arrest, requiring cardiopulmonary resuscitation (CPR). The warmth, local redness, and pain associated with a potential infection of the ICD pocket may prompt the individual to seek medical attention. Questions regarding interactions between ICDs and electromagnetic interference (EMI) will arise more frequently. These clinical situations are discussed in more detail below.

Patients with ICDs must be placed on continuous telemetry. Perform a detailed and complete history and physical examination. The patient should be questioned regarding the number of shocks received, symptomatic palpitations, presyncope, symptoms of congestive heart failure, or symptoms consistent with angina. The pocket site must be examined for evidence of local infection, including warmth, tenderness, and discharge. Upper extremity or neck swelling ipsilateral to the inserted endocardial lead suggests the possibility of a subclavian vein or superior vena cava thrombosis.[25] Bilateral head edema and neck vein swelling suggest the possibility of a superior vena cava thrombosis or a superior vena cava syndrome. It is important to document any changes in medications or whether antiarrhythmic therapy has recently commenced. Routine blood work should be obtained, including a complete blood count, serum electrolytes, magnesium level, renal function indices, and quantitative levels of measurable medications.

The ICD model should be identified. Patients are generally given identification cards that list the manufacturer, lead system, generator model, and a 24 hour emergency contact number. Often this information is not available. However, in an emergency situation, an overpenetrated chest radiograph showing the generator will demonstrate the radiopaque identifier of the manufacturer.

The chest radiograph may be of diagnostic importance. It is not only important for device identification but can also give useful information about lead integrity. In a recent implant, a chest radiograph is routinely performed to assure lead positioning, slack in the lead, and to rule out other thoracic pathology. In patients with

epicardial patches, the chest radiograph is an excellent tool for demonstrating patch crinkling, fracture, or migration. With endocardial systems, the lead can again be assessed for fractures or discontinuities. Fractures can occur anywhere along the lead. They are most commonly seen near the junction of the first rib and the clavicle, a condition referred to as "subclavian crush."

If the patient presents with a ventricular arrhythmia and is hemodynamically stable, attempts should be made to obtain a 12-lead electrocardiogram (ECG) before any interventions are made to terminate the arrhythmia. Often this may be difficult due to concomitant discharges from the device, an anxious staff, and an anxious patient. Antiarrhythmic medications such as amiodarone, procainamide, and β-blockers may have to be considered in the event of recurrent ventricular tachycardia. Despite the absence of clinical trials examining the efficacy of lidocaine, it is generally considered the treatment of choice in the setting of an acute myocardial infarction or acute ischemia if the patient is experiencing a ventricular arrhythmia.

EMERGENCY DEACTIVATION (MAGNET BEHAVIOR)

The ability of an ICD to identify and treat tachyarrhythmias can be temporarily disabled with the use of a magnet. This situation may arise in the setting of multiple ICD discharges where the shocks are not tolerated or prior to a surgical procedure where electrocautery is necessary. Emergency deactivation with a magnet can result in serious complications such as causing a battery indicator to switch to "end of life" and the loss of some antitachycardia therapies.[26] **The application of a donut-shaped magnet overlying the ICD pulse generator forms a magnetic field that trips a reed switch in the ICD generator circuit.** This results in a suspension of tachycardia detection and therapy delivery. Generally, a single magnet will suffice. In obese patients or in the presence of pockets with significant edema, two or more magnets may be required to achieve deactivation.[27] **The patient must be fully monitored, a cardioverter-defibrillator unit must be readily available, and Advanced Cardiac Life Support (ACLS) medications must be readily available if an ICD is to be deactivated.**

The magnet response of an ICD varies subtly from manufacturer to manufacturer. In Medtronic devices, the application of a magnet temporarily disables tachycardia detection and therapy with no effect on bradycardia pacing. Removal of the magnet will resume arrhythmia detection. When activated, newer Medtronic ICDs (Gem II DR, patient alert function) will elicit a continuous beep lasting for 15 seconds if a magnet is placed directly over the ICD. A magnet applied over Guidant (CPI) ICDs also inhibits tachycardia therapy with no effect on bradycardic pacing. These devices will generate beeping tones, which change to a continuous tone. The constant tone indicates that the device is off and will not deliver tachycardia therapy. The device can be turned back on by reapplying the magnet over the ICD for 30 seconds. Tones will now change from continuous to beeping synchronous with R waves, signifying that the device is on again. Newer-generation Guidant ICDs (Prism II) have a built-in electrocautery feature that can be activated by use of the Guidant programmer. This will suspend tachyarrhythmia therapies and pace in the DOO mode. Regular functioning of the ICD is restored by turning this feature off.

ICD DISCHARGES

Patients who experience a shock but feel unwell after the event or who receive more than one symptomatic ICD therapy within a short period of time (i.e., minutes to hours) require emergent evaluation.[27,28] Most ICDs have a limit to the number of shocks it can generate before it stops producing shocks. This number is usually five to seven shocks. However, if the patient's cardiac rhythm reverts to normal sinus rhythm, the ICD can reset and start shocking the patient again to the set maximum number of shocks. Multiple ICD discharges or shocks in a short period of time can cause severe battery depletion. Ongoing arrhythmias not adequately treated by the device, myocardial infarction, electrolytes imbalances, and ICD malfunction are all possible etiologies that warrant medical attention.

Emergency Department patients presenting with multiple ICD discharges require immediate attention. From a psychological perspective, multiple discharges are usually not well tolerated and can be emotionally devastating to the patient.[25] Myocardial injury and transient reduction in left ventricular function can occur as a result of multiple shocks.[28] This has been associated with a poorer long-term prognosis. Multiple discharges can lead to premature depletion of battery life.

ESTABLISHING THE ETIOLOGY

It is important to establish the etiology of the shocks in order to administer proper and prompt management (**Table 35-2**). It is of the utmost importance to determine whether the shocks are appropriate for ventricular tachycardia or fibrillation, inappropriate therapy, or phantom shocks.[49] More than one-third of patients with a history of ventricular tachycardia or ventricular fibrillation receive a shock within 2 years of the ICD implantation.[29] Recurrent ventricular tachyarrhythmia is a common cause of repeated ICD firing. Ineffective termination of a tachyarrhythmia in this situation can be the result of an increase in defibrillation thresholds secondary to concomitant antiarrhythmic drug therapy and lead migration or lead dislodgement. Inefficient termination can occur if inappropriately low amounts of energy are programmed for the initially administered shock. Shocks may also be the result of inappropriate detection of SVTs, the most frequent of which include sinus tachycardia and atrial fibrillation.[30] The administration of a low-energy shock may convert a benign SVT into an unstable ventricular arrhythmia resulting in an ICD proarrhythmia. The introduction of an atrial lead in dual-chamber devices has aided in the discrimination process between SVTs and ventricular tachyarrhythmias. Rapid SVTs are particularly a problem in children and athletic individuals in whom exercise or reductions in

TABLE 35-2 Causes of Frequent ICD Discharges

Appropriate
Sustained ventricular tachyarrhythmias
Recurring episodes, each one terminated by a shock
One shock needed to terminate each episode of sustained ventricular tachyarrhythmia
Nonsustained ventricular tachyarrhythmias
Inappropriate
Supraventricular tachyarrhythmia that satisfies detection criteria
Atrial fibrillation
Sinus tachycardia
Paroxysmal SVT
Oversensing of signals
Sensing lead failure (migration or dislodgement)
Environmental electrical noise
Double and triple counting of pacing artifacts
P-wave oversensing
T-wave oversensing
Electromagnetic interference
Increase in defibrillation thresholds (antiarrhythmic drug therapy)
Phantom (absence of both arrhythmia and ICD discharge)
Random component failure

FIGURE 35-4. Inappropriate ICD discharge. Intracardiac electrogram of a patient with a Ventak Mini III presenting with repetitive ICD discharges. Examination of the intracardiac electrograms (line 2) demonstrates noise sensed as ventricular fibrillation (FS) resulting in an inappropriate shock (CD). Noise was traced to an insulation break in the ICD lead. Lead replacement corrected the problem.

medications that slow the heart rate, such as β-blockers, are commonly encountered causes of inadequate shocks from sinus or SVT. Inappropriate ICD firing can occur because of the erroneous detection of noise or interference that can be the result of insulation breakdown or a loose set screw (**Figure 35-4**). Oversensing of T waves, pacing artifacts, R waves, and electromagnetic interference may also lead to inappropriate detection and discharge. Patients who have received painful shocks occasionally suffer from phantom shocks, which are the perception of a shock in the absence of any arrhythmia or therapy from the ICD.[49] Finally, random component failure should be considered if all other causes have been ruled out.

APPROACH TO THE PATIENT WITH MULTIPLE ICD DISCHARGES

These patients must be under constant ECG monitoring. Apply defibrillator pads in anticipation of the development of an unstable cardiac arrhythmia. In devices with limited stored diagnostic capabilities, this may be the only means of establishing a shock-rhythm correlation. Sedation is reasonable in extremely anxious patients. Once the patient is stabilized, obtain an electrophysiology consultation for assistance in interrogating the ICD. The device should be interrogated and stored electrograms obtained for analysis.[31] For instance, it is often useful to inquire about the pattern of ICD discharge. Consecutive shocks occurring within a few seconds suggest an inappropriate discharge for SVT, oversensing, or device failure. On the other hand, isolated shocks occurring every few minutes may be indicative of recurrent ventricular tachycardia. Progressive dyspnea on exertion, shortness of breath, orthopnea, or paroxysmal nocturnal dyspnea suggests new onset or worsening heart failure, which can precipitate ventricular arrhythmias. Potential reversible causes, such as electrolyte abnormalities, need to be identified and promptly corrected.

Careful examination of the 12-lead ECG is crucial. Specific ST-segment changes may imply an acute coronary syndrome and determine the need for primary intervention or thrombolytic therapy. An ECG obtained during an actual shock may establish whether the culprit arrhythmia is a supraventricular or ventricular tachycardia.

If the discharges are inappropriate, the ICD should be emergently deactivated, as previously described. Supraventricular tachyarrhythmias should be managed with intravenous drug therapy, such as adenosine, diltiazem, or verapamil. In the situation where discharges are secondary to rapid atrial fibrillation, attempts must be made to control the patient's ventricular response with atrioventricular (AV) nodal blocking agents such as diltiazem, verapamil, β-blockers, and digoxin. Chemical cardioversion or electrical cardioversion may be attempted in the event of hemodynamic instability. Shocks secondary to prolonged episodes of nonsustained ventricular tachycardia can be prevented by adjusting initial detection parameters coupled with the addition of antiarrhythmic drug therapy.

Patients with an ICD can develop "electrical storm." Patients in electrical storm require immediate attention. This condition involves recurrent, hemodynamically unstable ventricular tachycardia or fibrillation occurring two or more times in a 24-hour period.[32] Potential triggers can be found in approximately 66% of patients and include new or worsened heart failure, changes in antiarrhythmic medication, psychological stress, and hypokalemia. In most patients, electrical storm consists of monomorphic ventricular tachycardia indicating the presence of a reentry mechanism. Ventricular fibrillation is rare and may be indicative of acute ischemia. The key intervention in electrical storm is reduction of the elevated sympathetic tone by intravenous β-blockers, benzodiazepines, and amiodarone.[33]

An Electrophysiologist should be promptly consulted and the patient stabilized prior to transfer to the intensive care unit (ICU). Defibrillator pads should be applied in anticipation of the development of unstable cardiac arrhythmias. Potential reversible causes, such as electrolyte abnormalities, need to be identified and promptly corrected. If torsades de pointes is established, the treatment of choice is magnesium and/or temporary cardiac pacing. Thrombolysis or urgent catheterization/intervention may be needed in the setting of an acute myocardial infarction. If analysis of stored electrograms demonstrates ineffective discharges, the ICD should be deactivated. Attempts to terminate the arrhythmia in the hemodynamically stable patient via ATP is a useful option. Intravenous antiarrhythmic drugs are a necessary adjunct in these situations. The administration of amiodarone in combination with β-blocker therapy has been shown to be successful in the management of electrical storm.[34] Often a combination of antiarrhythmic drugs will be required. Bretylium should be reserved until other antiarrhythmic agents have failed.

ICDs AND CARDIAC RESUSCITATION

Patients who have an ongoing arrhythmia when evaluated emergently should be managed according to ACLS guidelines regardless of the presence of an ICD. Although in the vast majority of instances ICD function will be found to be appropriate, this cannot

be assumed.[18] ACLS guidelines should be followed and the device considered inactive.[35,36] If the clinical situation permits and an ICD programmer is readily available, the device should be deactivated. This will prevent the reinduction of ventricular fibrillation or tachycardia due to concomitant ICD discharges that may occur during CPR. **There is often some hesitation to initiate resuscitative measures in patients with an ICD for fear of getting shocked. This fear is understandable but unwarranted.** Although a mild electric shock might be perceived, these discharges do not pose a risk to persons administering CPR, nor do they damage external monitoring devices.

External defibrillation is permissible, although the paddles or pads should be positioned away from the ICD. Individuals with epicardial patches may require higher energies for defibrillation. Current can be shunted from the myocardium through the patches. Moreover, the insulated portion of the patch serves as a shield from the administered shock. In patients with epicardial patches, an anteroposterior paddle configuration has been suggested for changing the defibrillation vector.[37]

The ICD may be reset after external defibrillation is delivered, especially if the paddles or pads are located in close proximity to the generator. It is important that ICDs be reinterrogated after the successful completion of a resuscitation to ensure that programmed parameters have not been altered, including the pacing thresholds.

INFECTION OF AN ICD

Technological advances have made a gradual reduction in the size of the pulse generator possible. This small size permits superficial implantation of the pulse generator in the anterior chest wall.[38] The ICD implantation technique is similar to pacemaker implantation. ICD infections can involve the generator pocket, the leads, or both. Infection is more likely after a recent generator replacement.[39] **An infected ICD system represents a serious medical situation that should be dealt with urgently.** The incidence of infection ranges from 2% to 11% in systems that were implanted via thoracotomy or sternotomy.[40] The infection rates for nonthoracotomy implants approach those of pacemakers and range from 0.8% to 1.5%.[39–43] Infections generally present clinically within 6 months of the implant, but more typically within the first 3 months. Infection should be suspected when local and systemic signs and symptoms of inflammation are apparent. Prompt referral to a specialist is warranted. In almost all cases, removal of the ICD and all leads is required. Endocarditis prophylaxis with antibiotics is not generally warranted.

Systemic symptoms are seen in up to 50% of patients, especially in those with infections caused by *Staphylococcus aureus*.[44] The pocket and/or incision site is often visibly erythematous, warm, and tender. A fever may be present. Blood work often reveals a leukocytosis. Frank suppuration or device erosion may be seen. Pericarditis may be evident if epicardial patches are infected. Blood cultures may aid in documenting the culprit organism. Infections occurring late are generally indolent and rarely present with fever or leukocytosis; moreover, blood cultures are generally negative.

The most common microorganisms in 50% of infections include *S. aureus* and coagulase-negative staphylococci. Other common organisms include *Escherichia coli, Pseudomonas, Serratia, Corynebacterium, Propionibacterium acnes, Candida* spp., Streptococci, and atypical mycobacteria.[45] Infection is generally the result of skin contamination during implantation of the ICD. It can also occur due to hematogenous seeding from distant intravenous sites, indwelling catheters, or from concomitant respiratory or urinary tract infections.

APPROACH TO AN INFECTED ICD

The goals of therapy include identifying the culprit organisms, establishing the extent of the infection, and containment of the infection. In the Emergency Department, routine laboratory tests should be obtained that include a complete blood count and differential. Blood for cultures should also be drawn, but it must be kept in mind that they are often negative. Wound cultures and gram stains may be helpful in differentiating an infection from a pocket hematoma, sterile subcutaneous fluid accumulation, or an inflammatory reaction to pacemaker components. Attempts to aspirate the pocket should be performed in consultation with an Electrophysiologist and/or a Surgeon. A sterile pocket or hematoma can often become infected after an aspiration.

There is no single diagnostic modality that can determine the extent of the infection. **ICD infections should never be assumed to be localized, as organisms can migrate from the leads into the heart.** In patients with epicardial patches, a chest radiograph may reveal patch deformities or wrinkling, suggesting distal migration of the infection. A computed tomography (CT) scan can also detect localized fluid accumulation and patch wrinkling. Echocardiography has been utilized to confirm the presence of vegetations on the leads or coil. Gallium and indium scans may be helpful in localizing an infection.

Although a few reports suggest that infection of a defibrillator system may be controlled, the treatment of choice continues to be removing the entire system followed by the administration of parenteral antibiotic agents. Some localized infections restricted to the ICD generator have been managed with the removal of the generator, debridement, and systemic antibiotic therapy. Vancomycin is frequently used as an empiric agent when cultures are still pending given its good coverage against coagulase-negative staphylococci and methicillin-resistant *S. aureus* (MRSA). Empiric gram negative and fungal coverage may be necessary in the immunocompromised patient.

ELECTROMAGNETIC INTERFERENCE AND ICDS

The ability of ICDs (and pacemakers) to function is dependent on their ability to sense intrinsic cardiac electrical activity. Hermetic shielding, filtering, interference rejection circuits, and bipolar sensing have safeguarded ICDs (and pacemakers) against the effects of common electromagnetic sources. However, exposure to electromagnetic interference (EMI) may still result in oversensing, asynchronous pacing, ventricular inhibition, and spurious ICD discharges. EMI may also lead to loss of output, increased pacing thresholds, and decreased R-wave amplitude. Common sources of EMI include cellular phones, electronic article surveillance (antitheft) devices, and metal detectors. Occupational sources of EMI include high-voltage power lines, electrical transformers, arc welding, and electric motors. Interference can also be encountered through medical equipment and procedures such as magnetic resonance imaging, electric cautery, spinal cord stimulators, transcutaneous electric nerve stimulator units, radiofrequency catheter ablation, therapeutic diathermy, and lithotripsy.[46]

Patients with ICDs and pacemakers should be instructed to avoid environments with large magnetic fields. The use of cellular phones is permissible. However, the US Food and Drug Administration (FDA) recommends that direct contact of the phone with the device should be avoided. Use of the contralateral ear while using the phone is suggested. Although inappropriate shocks have been documented through electronic article surveillance systems, recent studies have deemed it safe for patients to walk through these systems as long as they avoid lingering around these devices. New concerns have

been raised regarding household appliances. Patients can be reassured that EMI is unlikely to affect their devices if induction ovens are used in their kitchens.[47]

The strong magnetic fields of MRI can interfere with ICD functioning and induce electrical current flow in the ICD lead that can initiate an arrhythmia or be sensed as an arrhythmia and precipitate spurious therapies. In general, patients with an ICD should not be placed in an MRI field. Ongoing work is aimed at developing MRI-compatible ICDs. There is no such problem with fluoroscopy, CT scanning, or nuclear-based imaging.

FUTURE DIRECTIONS IN ICD TECHNOLOGY

There are constant improvements being made in ICD technology. A minimally invasive, entirely subcutaneous ICD (S-ICD®) has been developed (Cameron Health Inc., San Clemente, CA). The advantages include a simplified implantation procedure, it does not require vascular access or intracardiac leads, no imaging or fluoroscopy equipment is required, and the device may be as effective as current ICD systems.[48] Potential complications such as deep venous thrombosis, intracardiac thromboses, tricuspid valve disease, as well as those related to central venous access can be eliminated. The electrode is implanted parasternally, and the ICD generator is implanted on the anterolateral chest wall. Small trials have demonstrated that this system can effectively treat ventricular fibrillation.[48] Further clinical trials are required before this technology can be routinely implanted.

SUMMARY

Expanding clinical indications, advanced new technology, and the increasing number of annual implants require Emergency Physicians to become familiar with problems typically encountered by the patient with an ICD. Complications associated with ICDs are not uncommon. Troubleshooting and programming should ideally be performed in conjunction with a trained Electrophysiologist. Patients presenting with cardiopulmonary arrest may require the device to be deactivated and external defibrillation performed. Do not apply external defibrillation paddles directly over the ICD.

36 Pericardiocentesis

Eric F. Reichman, Elisabeth Kang, and Jehangir Meer

INTRODUCTION

Pericardiocentesis is the removal of fluid from the pericardial space surrounding the heart. The fluid is usually aspirated with a needle and syringe. Occasionally, a catheter is placed within the pericardium or a surgical approach is used. This may be performed for diagnosis, to obtain pericardial fluid; to relieve a pericardial effusion and improve cardiac output; or as a lifesaving measure to relieve a cardiac tamponade. **The technique is relatively simple to perform yet has a significant rate of complications.**

Since humanity's earliest times, penetrating cardiac injuries have held a dramatic place in both romantic and medical literature.[1–8] In 1649, Riolanus first described pericardial tamponade.[3] He noted that an abundance of moisture is collected therein [the pericardium], which causes suffocation, and overwhelms the heart. In 1827, Thomas Jowett described the first use of pericardiocentesis as an intervention for pericarditis.[4] In 1829, Baron Larrey, Napoleon's Surgeon, is reported to have performed the first successful pericardiocentesis.[5] By 1939, Bigger had suggested that some patients with cardiac tamponade could be managed with pericardial tubes alone, with prompt operation for recurrence.[7]

ANATOMY AND PATHOPHYSIOLOGY

ANATOMY OF THE HEART AND PERICARDIUM

The pericardium is an inverted cone-shaped sack surrounding the heart and lying on top of the diaphragm (**Figure 36-1**). The inner portion, or visceral pericardium, is a single layer of mesothelial cells covering the epicardium. The outer layer is composed of a dense outer fibrous tissue with an inner layer of mesothelial cells known as the parietal pericardium. The fibrous pericardium is attached to the central tendinous portion of the diaphragm inferiorly. Superiorly, the outer fibrous layer blends with the sheath covering the great vessels. Anteriorly, it attaches to the posterior surface of the sternum. Posteriorly, it is attached to the thoracic vertebral column, esophagus, bronchi, and aorta.

The heart is contained within the pericardial sac (**Figure 36-1B**). Numerous portions of the heart are exposed behind the anterior chest wall (**Figure 36-2**). This includes the right ventricle, left ventricle, right atrium, left atrium, aorta, pulmonary artery, and inferior vena cava (IVC). These structures are vulnerable to injury behind the anterior chest wall[9,10] (**Table 36-1**). The surface area that each of these structures contributes to the anterior cardiac silhouette is also listed in this table. These numbers reflect, roughly, the anatomic incidence of injury with cardiac trauma.[11] Traumatic injury to any of these structures can result in a pericardial effusion and cardiac tamponade.

The pericardial cavity is a potential space between the visceral and parietal layers of the pericardium. Up to 50 mL of fluid is normally contained within this space. The fluid acts as a lubricant to the motion of the heart. Accumulation of fluid in the pericardial space requiring drainage can have a variety of etiologies. From a review of several retrospective series, the estimated causes and relative frequencies of pericardial effusions are listed in **Table 36-2**.[12–18]

Cardiac tamponade is a life-threatening condition that must be diagnosed and treated emergently. The diagnosis of cardiac tamponade is primarily clinical. It may easily be overlooked unless a high index of suspicion is maintained in both medical and trauma patients. Sauer and Murdock describe a "danger zone" for penetrating torso trauma[19] (**Figure 36-3**). The superior border is bounded by a line through the sternal notch. The lateral borders are bound by a line through the midclavicle. The inferior border is identified by a line through the epigastric area. Any penetrating injury in the danger zone or through it has the potential to cause a cardiac injury and pericardial tamponade.

PATHOPHYSIOLOGY OF CARDIAC TAMPONADE

The clinical effects of cardiac tamponade occur due to accumulation of fluid under pressure in the pericardial space. This space can become quite large over time. In some chronic disease states, pericardial effusions of 1 to 2 L can occur without signs of cardiac tamponade.[14,20] **The ability of the pericardial sac to acutely stretch is limited. Estimates of the volume of fluid required to acutely accumulate and produce a cardiac tamponade range from 60 to 200 mL.**

Cardiac tamponade should always be considered as a cause of shock in the medical patient. This includes patients who are taking oral or parenteral anticoagulants, have known cancer, have known

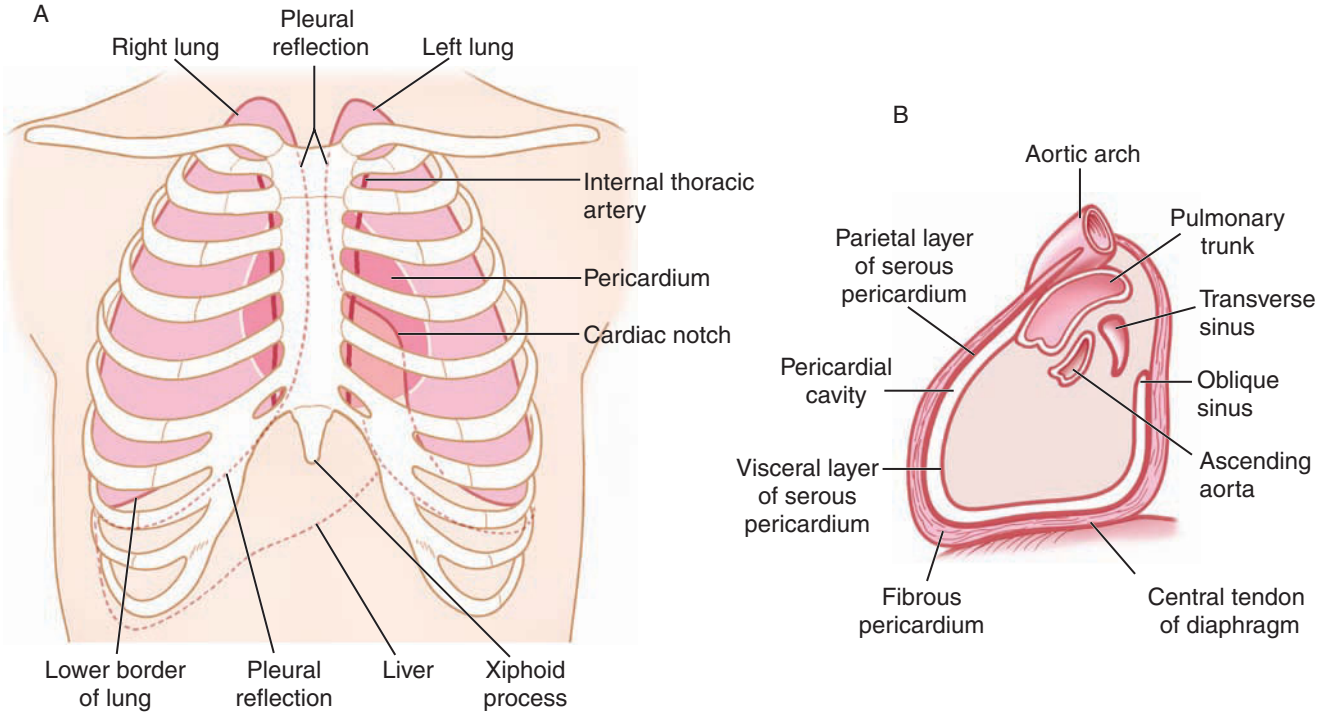

FIGURE 36-1. The pericardium. **A.** Relationship of the pericardium to the major thoracic structures. **B.** Midsagittal section through the heart and pericardium.

pericardial disease, are suspected of having an aortic dissection, or have had a recent myocardial infarction. Cardiac tamponade can also be due to iatrogenic causes, including central venous line placement, transthoracic cardiac pacing, transvenous cardiac pacing, and cardiopulmonary resuscitation.

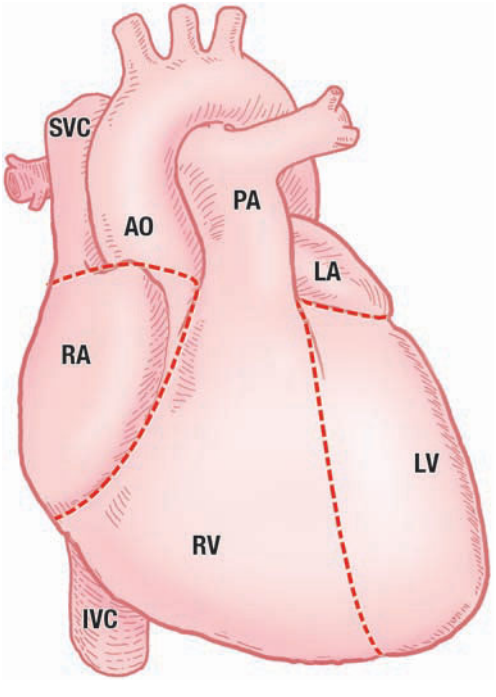

FIGURE 36-2. View of the heart and great vessels, which can become injured behind the anterior chest wall (AO, aorta; IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava).

The pressure–volume relationship between the size of the pericardial effusion and the pressure imposed on the cardiac chambers is exponential. The initial accumulation of fluid produces little or no clinical effect. The initial physiologic strategies of compensation include an increase in the systemic venous pressure, catecholamine release, and tachycardia. At some point, the ability of the pericardial space to distend and accommodate more fluid is overwhelmed. From this point on, even small amounts of fluid generate significant and increasing pressure on the heart chambers. As the pericardial pressure rises, venous filling of the right heart is drastically impaired. The interventricular septum bulges into the left ventricle. Left ventricular filling becomes compromised from the lack of flow from the right ventricle and the bulging inward of the interventricular septum. Eventually, cardiac perfusion decreases, the heart suffers injury, and the patient goes into a state of shock.

A progressive decline in cardiac output occurs as pericardial fluid accumulates and intrapericardial pressure increases.[21] Initially, the right atrial pressure is greater than the intrapericardial pressure as the body compensates by increasing venous return. This is followed by the equilibration of the right atrial and intrapericardial pressures. Eventually, as the heart chambers cannot achieve a pressure lower than the surrounding pericardial fluid pressure, equilibration of

TABLE 36-1 Structures Vulnerable to Injury Behind the Anterior Chest Wall

diastolic pressure in each heart chamber occurs and produces the greatest drop in cardiac output. As the intrapericardial pressure continues to increase, the cardiac chambers collapse, resulting in intractable hypotension and death. The disproportionate effects of the later accumulation of small amounts of fluid explain why withdrawal of even a small amount of fluid from the pericardial cavity can produce dramatic temporary improvements in the clinical status of the patient. It also explains why "monitoring" patients for the evolution of cardiac tamponade with central venous pressure lines is dangerous, as the patient will proceed from stable and compensated to profoundly unstable quite suddenly.

PATIENT EVALUATION

Several clinical findings are associated with cardiac tamponade. **Beck's triad of muffled heart sounds, hypotension, and jugular venous distention is associated with cardiac tamponade.** Almost all patients with cardiac tamponade will have at least one of these signs. **Unfortunately, very few patients with cardiac tamponade will have all three signs.** Beck's triad has been found in only up to 40% of patients with cardiac tamponade.[22] **These findings may be absent if the patient is hypovolemic due to hemorrhage.** Restlessness, fatigue, tachycardia, and tachypnea are often present. These can progress to shock, coma, and eventually death.

Changes in the jugulovenous waveforms may be seen in cardiac tamponade. Instead of the normal systolic X descent and diastolic Y descent, only the systolic X descent occurs in cardiac tamponade. This is a result of the increased diastolic pressure being exerted by the accumulating pericardial fluid. The only time the right heart can fill is during systole, when the internal volume of the heart is reduced. The changes in the jugulovenous waveforms cannot be evaluated in the supine and/or immobilized trauma patient.

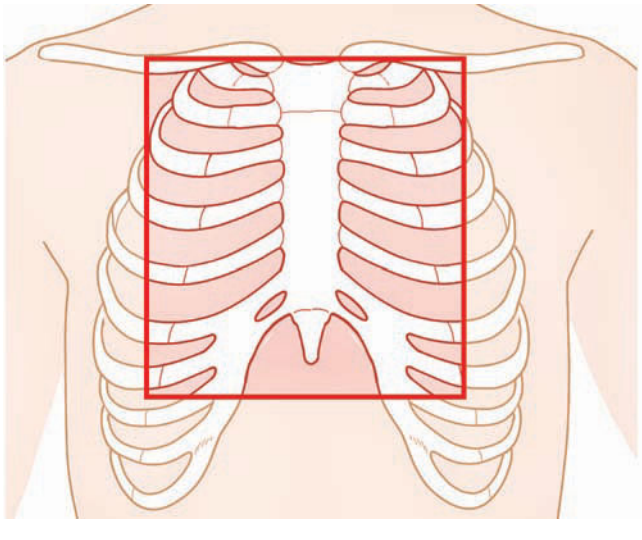

FIGURE 36-3. The "danger zone" for penetrating chest trauma.[19]

Kussmaul's two signs, paradoxical increase of the jugulovenous pressure during inspiration and pulsus paradoxus, may be seen in patients with cardiac tamponade. Pulsus paradoxus is a drop in systolic blood pressure of ≥10 mmHg during inspiration. To measure this, inflate the blood pressure cuff until the cuff pressure is greater than the patent's systolic pressure. Slowly release the cuff pressure until beats are heard only during expiration. Keep deflating the cuff pressure until beats are heard continuously in both inspiration and expiration. The difference between these two physiologic points is the amount of pulsus paradoxus. This normal physiologic finding is exaggerated by the accumulation of pericardial fluid, forcing the right heart and interventricular septum into the left ventricle.

Electrocardiographic and radiographic signs of cardiac tamponade are often not present. Changes on the electrocardiogram (ECG) may be present in patients with cardiac tamponade. A pericardial effusion surrounding the heart, if large enough, can result in a "low voltage" ECG tracing. Electrical alternans is a change in the morphology or amplitude of the QRS complexes on the ECG as the heart swings to and fro within the pericardial fluid (**Figure 36-4**). It may be associated with pericardial tamponade but is not pathognomonic. Pulseless electrical activity (PEA) in the absence of hypovolemia or a tension pneumothorax is highly suggestive of cardiac tamponade. Opinions differ as to the clinical significance of these findings. The finding of an enlarged cardiac silhouette on a chest radiograph may be useful in chronic pericardial effusions but is usually absent or nonspecific in the acute setting.

Traumatic cardiac tamponade can be caused by a variety of agents and etiologies. This includes bullets, knives, ice picks, displaced fractured ribs, central venous line placement, pacemaker insertion, pericardiocentesis, intracardiac injection, surgery, migrating pins or needles, nails ejected from machinery, and venous bullet embolization. **Cardiac tamponade is the most common presentation of penetrating cardiac injuries overall. It occurs in 80% to 90% of stab wounds and 20% of gunshot wounds.**[11]

Cardiac ultrasound has become the diagnostic procedure of choice to identify cardiac tamponade (**Table 36-3**). A prospective study showed that bedside ultrasound performed by Emergency Physicians and Trauma Surgeons was 96% accurate and 90% sensitive.[23] Cardiac ultrasonography performed on trauma patients can be 98% to 100% accurate and sensitive in diagnosing pericardial fluid and cardiac tamponade.[22,24–27] The series of 261 patients had no false negatives. Other studies have demonstrated false-negative rates in the range of 5% to 40%.[19,28,29]

Bedside ultrasound can rapidly confirm a suspected pericardial effusion or cardiac tamponade and guide drainage. Blind pericardiocentesis has a complication rate as high as 50%, and an associated mortality.[15,16,30] Ultrasound-guided pericardiocentesis can decrease the rate of complications by allowing visualization and avoidance of adjacent anatomic structures. This increased safety factor is supported by multiple studies from the cardiology literature.[31–33]

Other ultrasonographic findings in pericardial tamponade include a swinging heart, collapse of the right and left ventricular chambers, and marked inspiratory changes in ventricular dimensions.[10] Some authors advocate using transesophageal echocardiography, even in unstable patients, because of its superior imaging when compared to transthoracic echocardiography.[34] Other methods of imaging the pericardium include computed tomography (CT), helical CT, and magnetic resonance imaging. These modalities should be used only for stable patients in whom the diagnosis of a pericardial effusion and not cardiac tamponade is being considered.

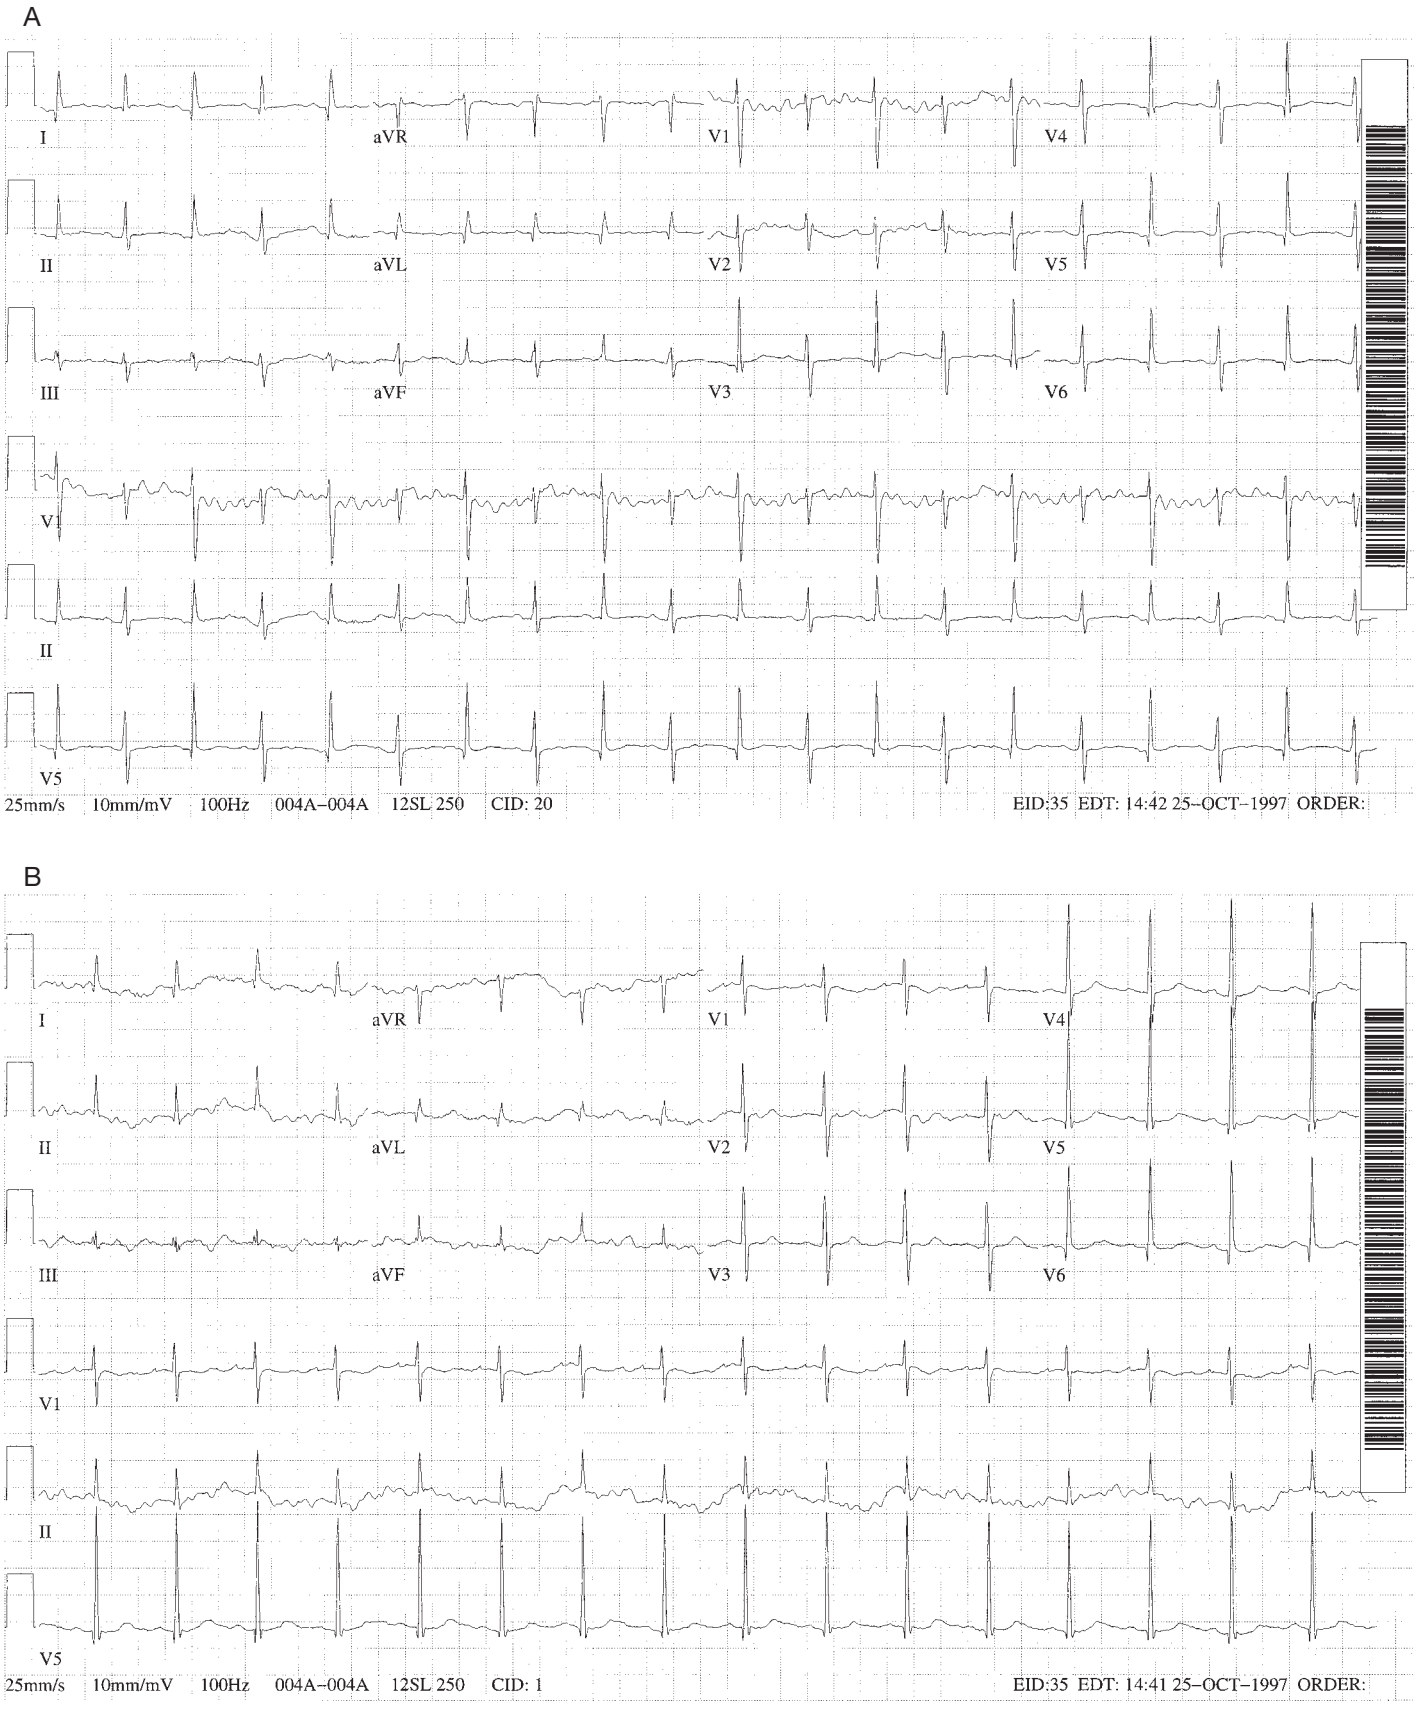

FIGURE 36-4. Electrocardiogram of electrical alternans. **A.** Initial ECG in the Emergency Department. Bedside echocardiography revealed a large pericardial effusion with right ventricular diastolic collapse. **B.** Resolution of electrical alternans after pericardiocentesis.

INDICATIONS

Significant controversy exists over the role of pericardiocentesis.[9] The only indication for emergent pericardiocentesis would be in a patient in whom the life-threatening physiologic changes of cardiac tamponade were present and the diagnosis was consistent with known prior disease, a traumatic mechanism of injury, or a bedside Emergency Department ultrasound demonstrating a pericardial effusion and/or cardiac tamponade. Pericardiocentesis is also performed in the cardiac catheterization laboratory or the intensive care unit to obtain pericardial fluid for diagnostic testing. It may also be performed in a cardiac arrest patient with PEA when other etiologies for PEA have been ruled out or a pericardial effusion is seen on ultrasonography.

CONTRAINDICATIONS

There are no absolute contraindications to performing a pericardiocentesis in the unstable patient with signs of cardiac tamponade. Uncorrected bleeding disorders in a stable medical patient would be an absolute contraindication to performing the procedure. Small, loculated, or posteriorly located effusions in a stable patient are also considered contraindications. It is also contraindicated in cardiac tamponade associated with an aortic dissection.[35]

While the dramatic beneficial effects of withdrawing even a small amount of pericardial fluid are well documented, many authors feel that there is little or no role for pericardiocentesis in the trauma patient. These authors argue that once the diagnosis of a pericardial effusion is made, the patient should receive a prompt sternotomy.[11] If the patient is too unstable for transport to the operating room, an emergent thoracotomy should be performed. Aggressive fluid replacement with crystalloid and blood products, as well as performing a needle thoracostomy (Chapter 38) to rule out a tension pneumothorax before a pericardiocentesis is contemplated in the trauma patient.[36]

EQUIPMENT

Pericardiocentesis

- Povidone iodine or chlorhexidine solution
- Sterile gloves and gown
- Face mask with eye shield or goggles
- Local anesthetic solution (1% lidocaine)
- 25 gauge needle, 5/8 in. long
- 18 gauge needle, 1½ in. long
- Syringes (10, 20, and 60 mL)
- Sterile drapes
- Towel clips
- 16 to 18 gauge spinal needle or catheter-over-the-needle, 7.5 to 12.5 cm long
- 18 to 20 gauge spinal needle or catheter-over-the-needle, 3.75 cm long
- #11 scalpel blade
- 4 × 4 gauze squares
- Alligator clips connected by a wire
- Collection basin
- ECG monitor
- J-tipped guidewire, 0.035 mm in diameter
- Size 6 to 10 French flexible multihole catheter, 5 to 6 in long, with or without a pigtail
- Three-way stopcock
- Plastic tubing
- Ultrasound machine
- 3.5 to 5.0 MHz phased-array or curvilinear ultrasound probe
- Sterile ultrasound probe cover (can be a sterile glove)
- Sterile ultrasound gel
- Variable-angle needle guide attachment if available
- Nasogastric tube

Subxiphoid Pericardial Window

- Electrocautery set
- Forceps
- Small retractor
- Small rib spreaders
- Sutures, 2-0 Vicryl and 3-0 nylon
- Sterile suction device
- Yankauer suction catheter
- Suction tubing

Most Emergency Departments do not have single guidewires and 6 to 10 French flexible catheters readily available to use for a pericardiocentesis. A commercially produced pericardiocentesis kit is available from numerous manufacturers and contains all the required equipment (e.g., Merit Medical, South Jordan, UT; Boston Scientific, Natick, MA). In an emergency situation, a 6 to 10 French single-lumen central venous line access kit may be substituted.

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative if time and the patient's clinical condition permit. A signed consent is not necessary as this is an emergent procedure. If possible, place the patient semirecumbent at a 30° to 45° angle (**Figure 36-5**). This position brings the heart closer to the anterior chest wall. The supine position is an acceptable alternative. Assess the patient for any mediastinal shift by physical examination and chest radiography (if time permits). Apply the cardiac monitor, pulse oximeter, and supplemental oxygen to the patient. While the placement of an arterial line is ideal, such a line may not be available. Place the noninvasive blood pressure cuff on the patient's arm. **Insert a nasogastric tube to decompress the stomach and decrease the possibility of gastric perforation during the procedure.**

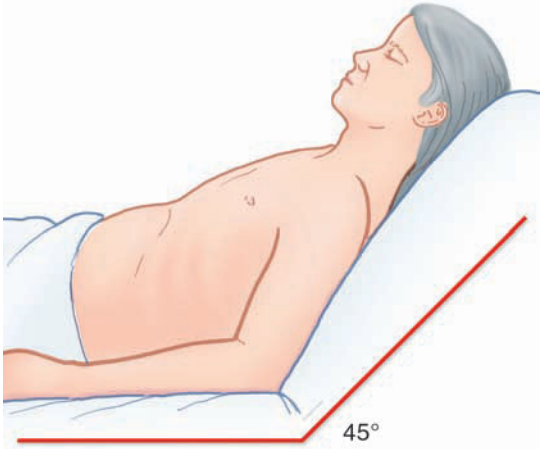

FIGURE 36-5. Ideal patient positioning for performing a pericardiocentesis.

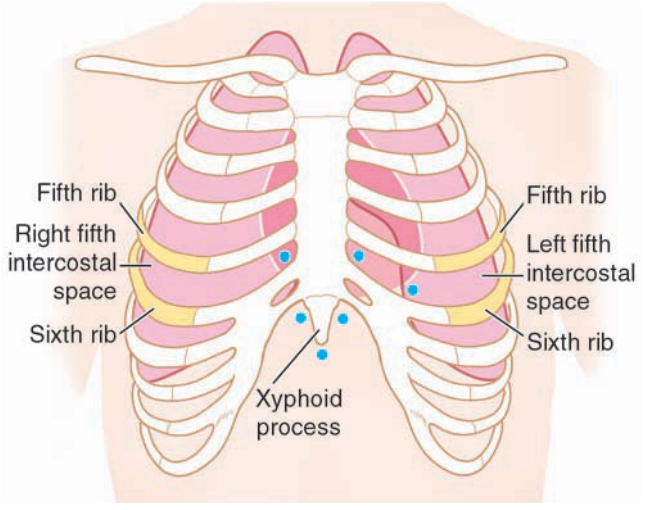

FIGURE 36-6. Potential sites to perform a pericardiocentesis.

Identify the anatomic landmarks necessary to perform this procedure. The needle can be inserted at numerous sites (**Figure 36-6**). These include the following: below the xiphoid process, at the right sternocostal margin, at the left sternocostal margin (subxiphoid approach), in the left or right fifth intercostal space parasternally (parasternal approach), or in the left fifth intercostal space at the midclavicular line (apical approach). The most commonly used site is at the left sternocostal margin or the subxiphoid approach. This is the approach described throughout the "Techniques" section of this chapter.

Surgically prepare the xiphoid and subxiphoid areas. Clean any dirt, debris, and fluid from the area. Apply povidone iodine or chlorhexidine solution to the xiphoid and subxiphoid areas and allow it to dry. Apply sterile drapes to delineate a sterile surgical field. Reidentify the anatomic landmarks. If the patient is awake, anesthetize the needle tract with local anesthetic solution. Place a subcutaneous wheal of local anesthetic solution at the site chosen to insert the needle. Inject local anesthetic solution through the skin wheal and into the subcutaneous and muscular tissues of the wall of the torso.

Prepare the equipment. Set up a sterile field on a bedside table. Open all required equipment and place it on the sterile field. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids. **While time is of the essence and this is an emergent procedure, aseptic technique should be followed.** Attach the spinal needle onto a 20 mL syringe containing 5 mL of sterile saline.

TECHNIQUES

BLIND INSERTION TECHNIQUE

Puncture the skin with a # 11 scalpel blade between the xiphoid process and the left costal margin. Grasp the syringe with the dominant hand. Insert the spinal needle through the skin incision and at a 45° angle to the midsagittal plane (**Figure 36-7A**) and at a 45° angle to the abdominal wall (**Figure 36-7B**). Aim the tip of the spinal needle toward the patient's left shoulder (**Figure 36-7A**). Alternatively, the spinal needle can be aimed toward the patient's left midclavicle, right midclavicle, or sternal notch to theoretically lessen the chance of iatrogenic damage to the coronary arteries.

Advance the spinal needle 4 to 5 cm while applying negative pressure to the syringe and observing the cardiac monitor. Inject 0.25 to 0.50 mL of saline occasionally to ensure that the needle remains patent while advancing the needle. Continue advancing the spinal needle while applying negative pressure until there is a return of blood, cardiac pulsations are felt, or an abrupt change in the ECG waveform occurs. **If the ECG waveform shows an injury pattern, withdraw the needle in 1 to 2 mm increments until the ECG pattern normalizes.** This indicates that the needle is touching or has penetrated the myocardium. Stop advancing the needle.

Aspirate with the syringe. If a large volume of blood is quickly and easily withdrawn, it often means that the tip of the spinal needle is within the ventricle. Techniques to confirm the intraventricular

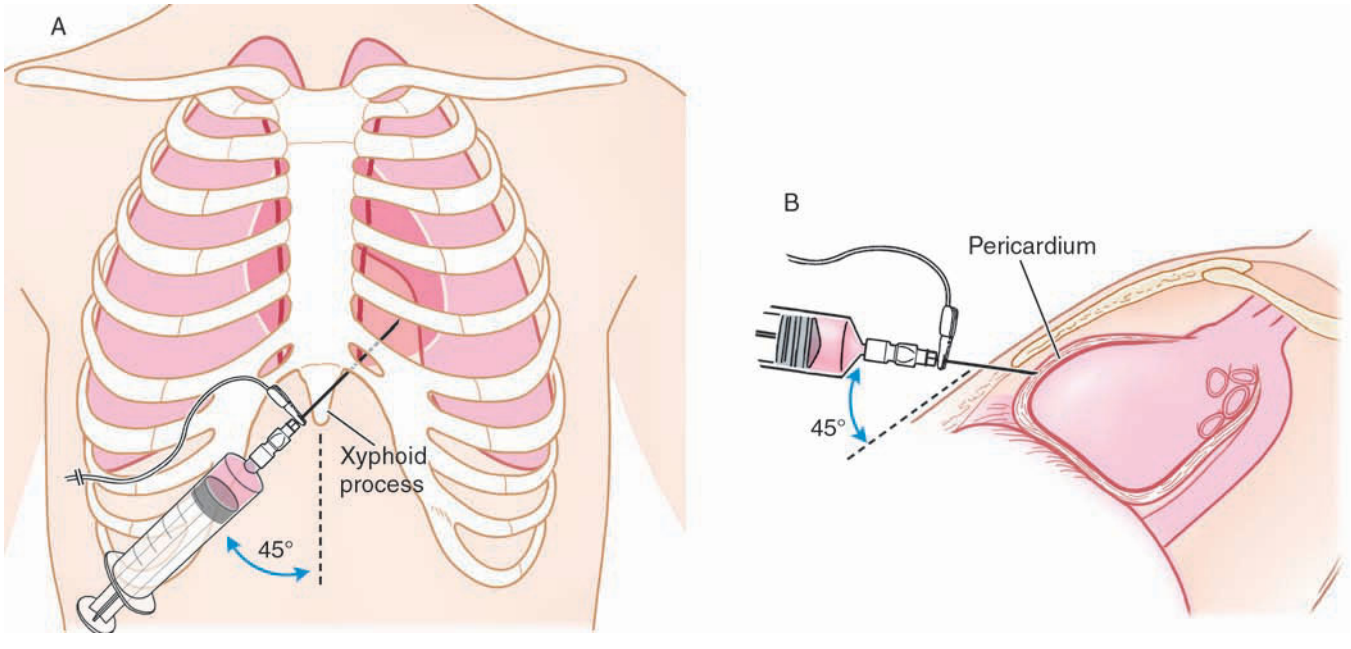

FIGURE 36-7. The subxiphoid approach. The needle is inserted at a 45° angle to the midsagittal plane (**A**) and at a 45° angle to the abdominal wall (**B**). The alligator clip attached to the spinal needle is for the ECG-monitored technique and not the blind technique.

placement of the needle tip have been described and include the following: observing that the aspirate does not form a clot, comparing the patient's hemoglobin to that of the aspirate, injecting fluorescein and looking for a fluorescent flush under the skin of the eyelids, or injecting 3 mL of dehydrocholic acid (decholin) and asking whether the patient experiences a bitter taste. These are time-consuming and less reliable than ultrasound, if available.

When the pericardial space is entered and fluid is aspirated, there should be a marked improvement in the patient's clinical status. The procedure can be terminated at this point. Alternatively, the Emergency Physician may want to withdraw as much fluid as possible. When the syringe is filled with fluid, stop withdrawing the plunger. Stabilize the spinal needle against the patient's torso and remove the syringe. Replace the syringe with a new one and continue the procedure. Alternatively, attach a three-way stopcock between the spinal needle and the syringe. Attach intravenous extension tubing to the stopcock. An assistant can open and close the stopcock while the physician aspirates fluid and ejects it through the intravenous extension tubing and into a basin. As the pericardial space is drained, the epicardium will approach the needle tip. If an injury pattern appears on the cardiac monitor, withdraw the needle slightly and continue to aspirate fluid. Remove the needle when fluid can no longer be aspirated.

ECG-MONITORED TECHNIQUE

The purpose of ECG monitoring is to prevent accidental ventricular puncture with the spinal needle. Attach one alligator clip to the base of the spinal needle and the other to the V_1 lead of the ECG machine or cardiac monitor (**Figure 36-8**). The V_1 lead will serve as an active electrode based at the tip of the spinal needle. As the spinal needle is advanced, an injury pattern noted by ST-segment elevation will be seen if the myocardium is contacted or penetrated by the spinal needle. The presence of a premature ventricular contraction or a ventricular arrhythmia can also signify contact with the myocardium.

Prepare the patient as previously described. Prepare the equipment (**Figure 36-8**). Turn on the ECG machine or cardiac monitor. Insert and advance the spinal needle, as described previously, while observing the ECG monitor or cardiac monitor. If an injury pattern or premature ventricular complexes are seen, withdraw the needle in 1 to 2 mm increments until the injury pattern disappears. Aspirate the pericardial fluid as described in the preceding section.

SELDINGER TECHNIQUE

An indwelling catheter may be placed in the pericardial cavity to drain the pericardial fluid (**Figure 36-9**). This may be done in cases of medical or traumatic pericardial effusions, since the pericardial fluid often reaccumulates. An indwelling catheter allows intermittent drainage of pericardial fluid without the potential complications associated with repeated needle sticks from a pericardiocentesis. This procedure can "buy time" if an operating room and/or a Surgeon is not immediately available to perform a pericardial window.

The technique is similar to that of placing an indwelling central venous line. Clean and prepare the patient. Insert the spinal needle, blindly or with ECG monitoring, as described in the previous sections (**Figure 36-7**). Aspirate to confirm that the tip of the spinal needle is within the pericardial cavity (**Figure 36-9A**). **It is imperative that the tip of the spinal needle be within the pericardial cavity and not within the cardiac chamber. If intracardiac placement of the needle is suspected, the position of the needle must be verified by one of the methods described in the section on "Blind insertion technique," by fluoroscopy, or using ultrasonography.**

Grasp and stabilize the spinal needle with the nondominant hand. Gently remove the syringe from the spinal needle with the dominant hand. Insert the guidewire through the needle and into the pericardial cavity (**Figure 36-9B**). Advance the guidewire until approximately one-third of its length is within the patient. Stabilize the guidewire with the nondominant hand. Remove the needle over the guidewire while leaving the guidewire within the pericardial cavity (**Figure 36-9C**).

Stabilize the guidewire with the nondominant hand. Advance the dilator over the guidewire and into the pericardial cavity (**Figure 36-9D**). **If the guidewire is within the heart, dilating a tract through the myocardium can result in cardiac tamponade and/or exsanguination. It is therefore imperative to know that the guidewire is within the pericardial cavity and not within the heart.** Remove the dilator while leaving the guidewire within the pericardial cavity. Advance the soft multihole catheter over the guidewire and into the pericardial cavity (**Figure 36-9E**). Remove the guidewire while leaving the catheter within the pericardial cavity

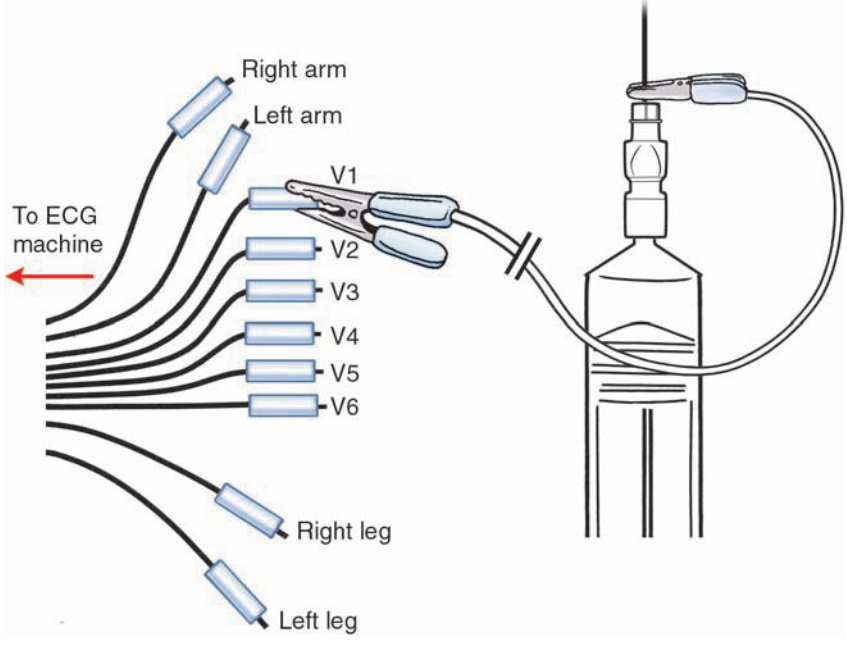

FIGURE 36-8. Equipment preparation for the ECG-monitored technique.

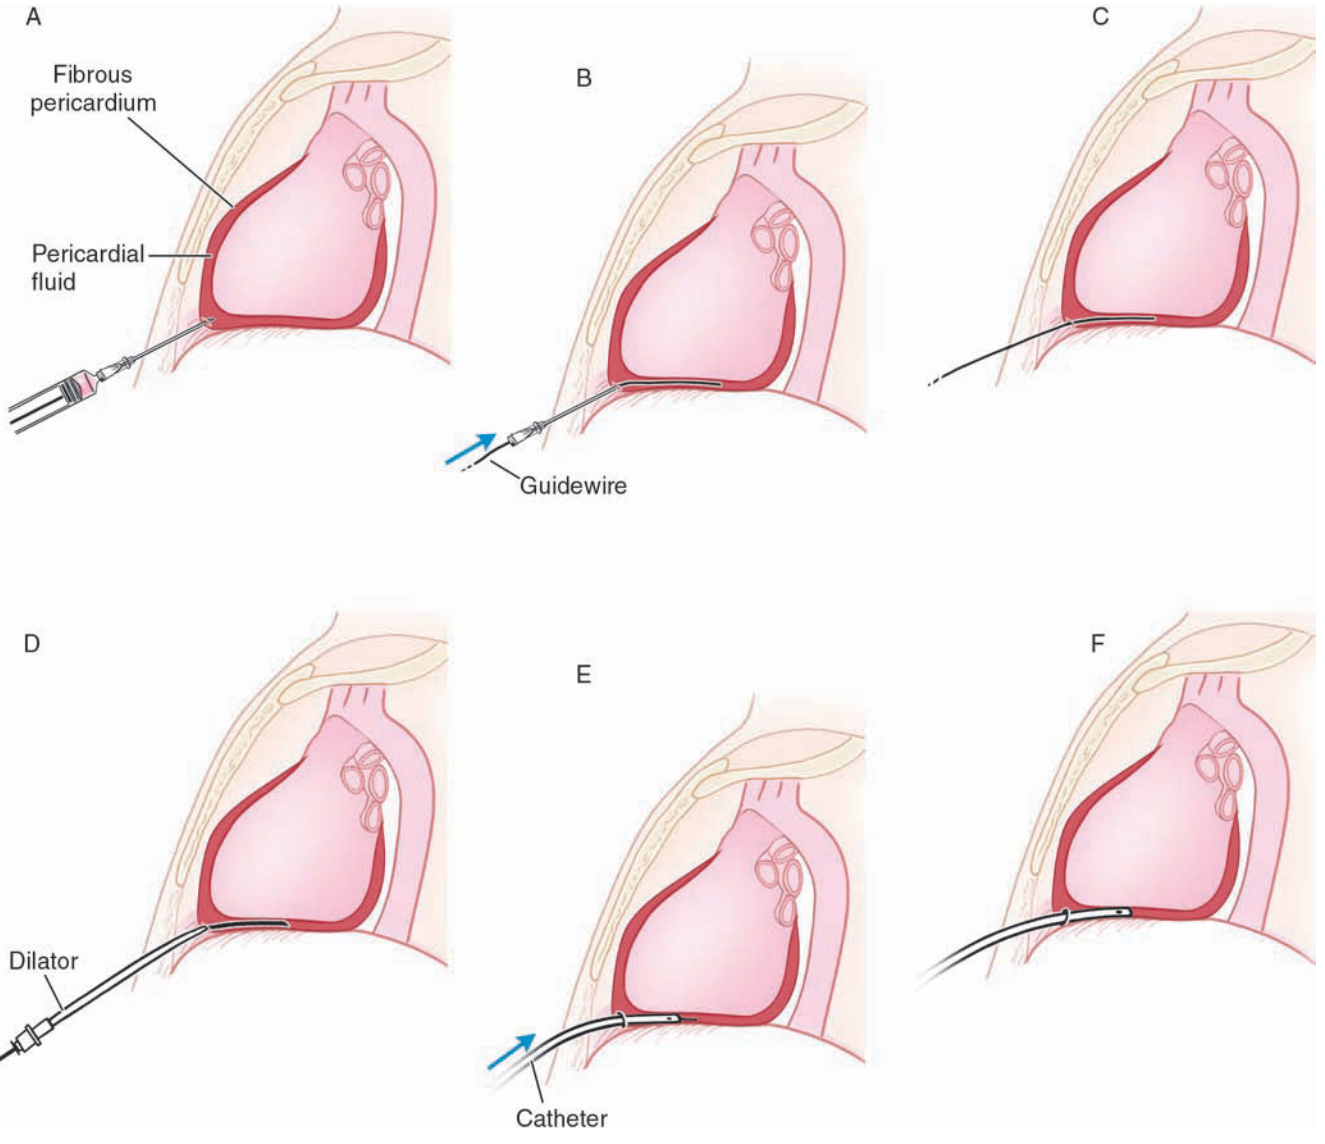

FIGURE 36-9. The Seldinger technique. **A.** The spinal needle is inserted into the pericardial space. **B.** The guidewire is inserted through the needle. **C.** The needle has been removed and the guidewire remains within the pericardial cavity. **D.** The dilator is advanced over the guidewire to dilate the needle tract. **E.** The catheter is advanced over the guidewire. **F.** The guidewire has been removed and the catheter remains within the pericardial cavity.

(**Figure 36-9F**). Secure the catheter at the skin with the nondominant hand. Attach a syringe to the catheter and aspirate pericardial fluid. This should cause a rapid improvement in the patient's clinical status. Detach the syringe and attach a three-way stopcock to the catheter.[20] Secure the catheter to the skin with nylon sutures.

ULTRASOUND-GUIDED TECHNIQUE

Many authors feel that ultrasound-guided pericardiocentesis is now the standard of care.[14,20,37,38,44] The heart is best scanned with the patient in the semierect or left lateral position if no contraindications exist. Use the 3.5 to 5.0 MHz phased-array or curvilinear ultrasound probe. Examine the heart and pericardial space in 2D and Doppler mode to determine the extent of the pericardial effusion and the area with the largest pericardial effusion.[39,40] This is usually around the apex of the heart. There are established ultrasonographic findings that help to distinguish a pericardial effusion from a cardiac tamponade (**Table 36-3**).[35]

View the heart and pericardial space using the three standard cardiac ultrasound views. These are the subxiphoid or subcostal view, the parasternal long axis view, and the apical four-chamber view. Refer

TABLE 36-3 Ultrasonographic Findings of Cardiac Tamponade

Ultrasonographic mode	Findings
Doppler	Mitral flow decreases during inspiration Mitral flow increases during expiration Tricuspid flow increases during inspiration Tricuspid flow decreases during expiration Peripheral flow decreases in expiration
M-mode color Doppler	Mitral flow decreases during inspiration Mitral flow increases during expiration Tricuspid flow increases during inspiration Tricuspid flow decreases during expiration
M-mode/2D	Diastolic collapse of the right ventricular free wall Inferior vena cava dilation Inferior vena cava does not collapse on inspiration Increase left ventricular wall thickness in diastole Left atrial collapse Left ventricular collapse Right atrial collapse Swinging heart to and fro

to Chapter 29 for a more complete discussion on cardiac ultrasonography. Pericardial fluid is anechoic, appears black on ultrasound, and will collect in a dependent location. Thus, small pericardial effusions will be first seen in the posterior pericardium. Large pericardial effusions appear circumferential, extending around the heart.

The decision to use a parasternal (**Figure 36-10**) or an apical (**Figure 36-11**) window depends on which ultrasound views of the pericardial effusion and heart are able to be obtained. The ideal site is where the pericardial effusion is most superficial, has a large stripe or thickness, and where no other structures (e.g., lung or liver) are in the path from the skin to the heart.[33,41] The subxiphoid window (**Figures 36-12 & 36-13**) is not recommended for ultrasound-guided pericardiocentesis. This view commonly includes the left lobe of the liver in the anterior portion of the ultrasound image. Under these conditions, the needle might puncture the liver on the way into the pericardial cavity.

FIGURE 36-11. A phased-array probe placed in the apical window at the point of maximal impulse (PMI). The probe marker is pointing to the patient's right.

FIGURE 36-12. A curvilinear probe placed in the subxiphoid region. The probe is aimed toward the patient's left shoulder. The probe marker is pointing to the patient's right. Note the shallow angle required to visualize the heart.

Ultrasonographic features that suggest cardiac tamponade are noted in **Table 36-3**. This includes right ventricular diastolic collapse (**Figure 36-14**), right atrial systolic collapse, large pericardial effusion, and dilatation of the IVC. Evaluate the IVC. Place the ultrasound probe in the subxiphoid region, with the probe marker pointing toward the patient's head. The IVC runs parallel with and to the right of the aorta. Use M-mode to measure the diameter of the IVC. The normal IVC ranges from 1.5 to 2.5 cm in diameter and displays respiratory variation. In cardiac tamponade, the IVC is dilated, measuring >2.5 cm in diameter, and does not display respiratory variation.

Position the patient. Determine the location to perform the pericardiocentesis. Clean, prep, and drape the patient as described

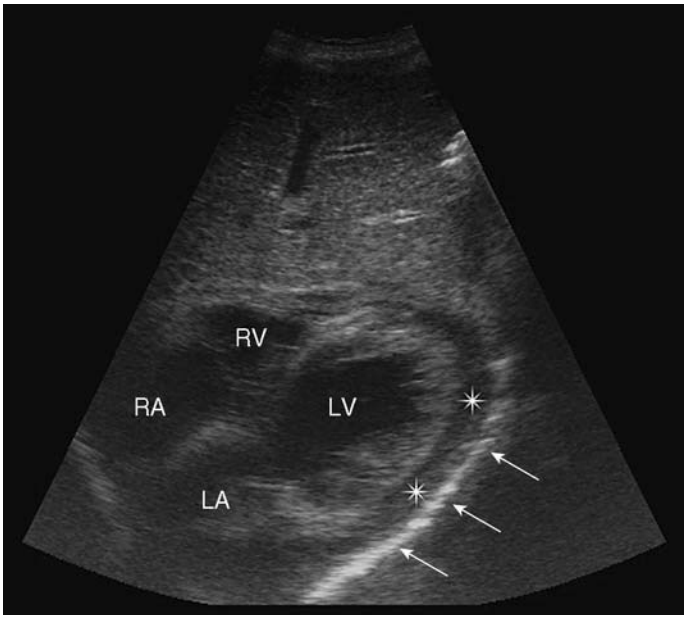

FIGURE 36-13. Subxiphoid ultrasound window demonstrating the four-chamber view (RV, right ventricle; LV, left ventricle; RA, right atrium; LA, left atrium) of a heart with a pericardial effusion (*asterisks*). The liver is noted anterior to the heart. The *arrows* point to the posterior pericardium.

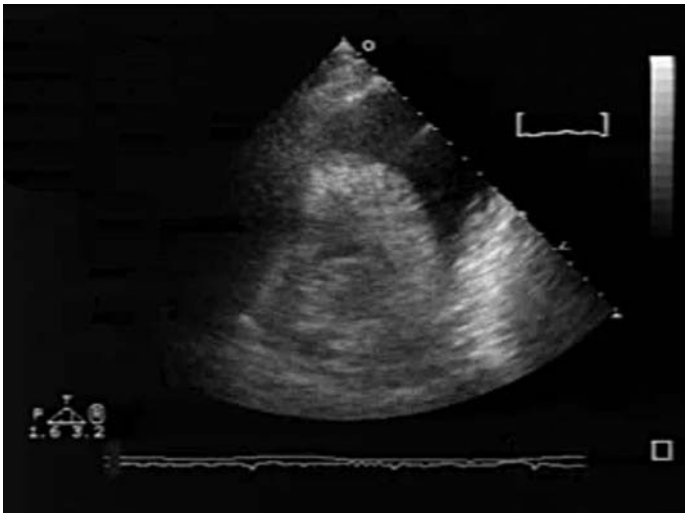

FIGURE 36-16. Needle seen entering the pericardial effusion from the right of the image (Ultrasound image courtesy of Beatrice Hoffman, MD.)

previously. Apply a sterile probe cover over the ultrasound probe. Apply sterile ultrasound gel over the prove cover. Reidentify and confirm the proper ultrasound probe position.[41] This is usually the point where the pericardial effusion is closest to the chest wall.[39,40] Insert the spinal needle under ultrasound guidance into the chest wall (**Figure 36-15**). Insert the needle over the superior border of the rib to avoid the neurovascular intercostal bundle under the inferior edge of the rib. Aspirate as the needle tip is carefully advanced under direct ultrasound visualization into the pericardial space (**Figure 36-16**).

If there is any question as to whether the needle tip is in the pericardial space, or if bloody fluid is aspirated, use agitated saline to confirm proper needle placement.[39–42,46] This requires two 5 mL syringes, one filled with sterile saline and the other filled with air. Attach the syringes to a three-way stopcock. Rapidly move the sterile saline back and forth through the two syringes, creating an aerated saline solution. Rapidly inject the aerated solution through the spinal needle. The identification of hyperechoic "bubbles" on the ultrasound image confirms the location of the needle. An alternative to this technique is to use color Doppler to localize the needle tip.[45]

FIGURE 36-15. Ultrasound probe and the pericardiocentesis needle in the apical window.

SUBXIPHOID PERICARDIAL WINDOW

A pericardial window will minimize false-negative results seen with a pericardiocentesis, iatrogenic bleeding, and cardiac tamponade from myocardial injury by the pericardiocentesis needle. Prepare the patient as previously described. Inject local anesthetic solution subcutaneously from the xiphoid process across the confluence of the lower ribs and 6 cm down the midline (**Figure 36-17A**). Inject local anesthetic solution into the muscular layers in the midline over the xiphoid process and continue approximately 8 cm inferiorly.

Make a midline longitudinal incision from the xiphisternal junction to about 8 cm below the tip of the xiphoid process (**Figure 36-17A**). Incise down to the linea alba. Bluntly dissect the space behind the xiphoid and lower sternum to separate the anterior diaphragm from the sternum. Lift the lower sternum with a retractor (**Figure 36-17B**). Use an electrocautery unit, if available, for hemostasis. Bluntly divide the fatty tissue and retrosternal attachments of the diaphragm to reveal the pericardium beneath the angle of the xiphoid and the left costal margin.[47] It will often appear blue in color due to underlying blood.

Grasp the pericardium with a forceps. Incise the pericardium with a scissors or with shallow strokes of a scalpel (**Figure 36-17B**). Fluid should rush out rapidly. Remove a piece of the pericardium to make sure that it remains open. Gently explore the pericardial space digitally and with the suction catheter to remove any clot and fluid. Allow the skin to stay open to permit free drainage of the pericardial space. Alternatively, place a 28 French chest tube in the pericardial space and secure it with a purse-string suture through the pericardium (**Figure 36-17C**). The chest tube may exit the skin incision or a separate incision in the skin. Attach the chest tube to a suction source. Close the linea alba with interrupted 2-0 Vicryl sutures. Close the subcutaneous tissue and skin with 3-0 nylon sutures.

ALTERNATIVE TECHNIQUES

CATHETER-OVER-THE-NEEDLE TECHNIQUE

A long catheter-over-the-needle mounted on a syringe may be used, if available, instead of a spinal needle mounted on a syringe. Use a

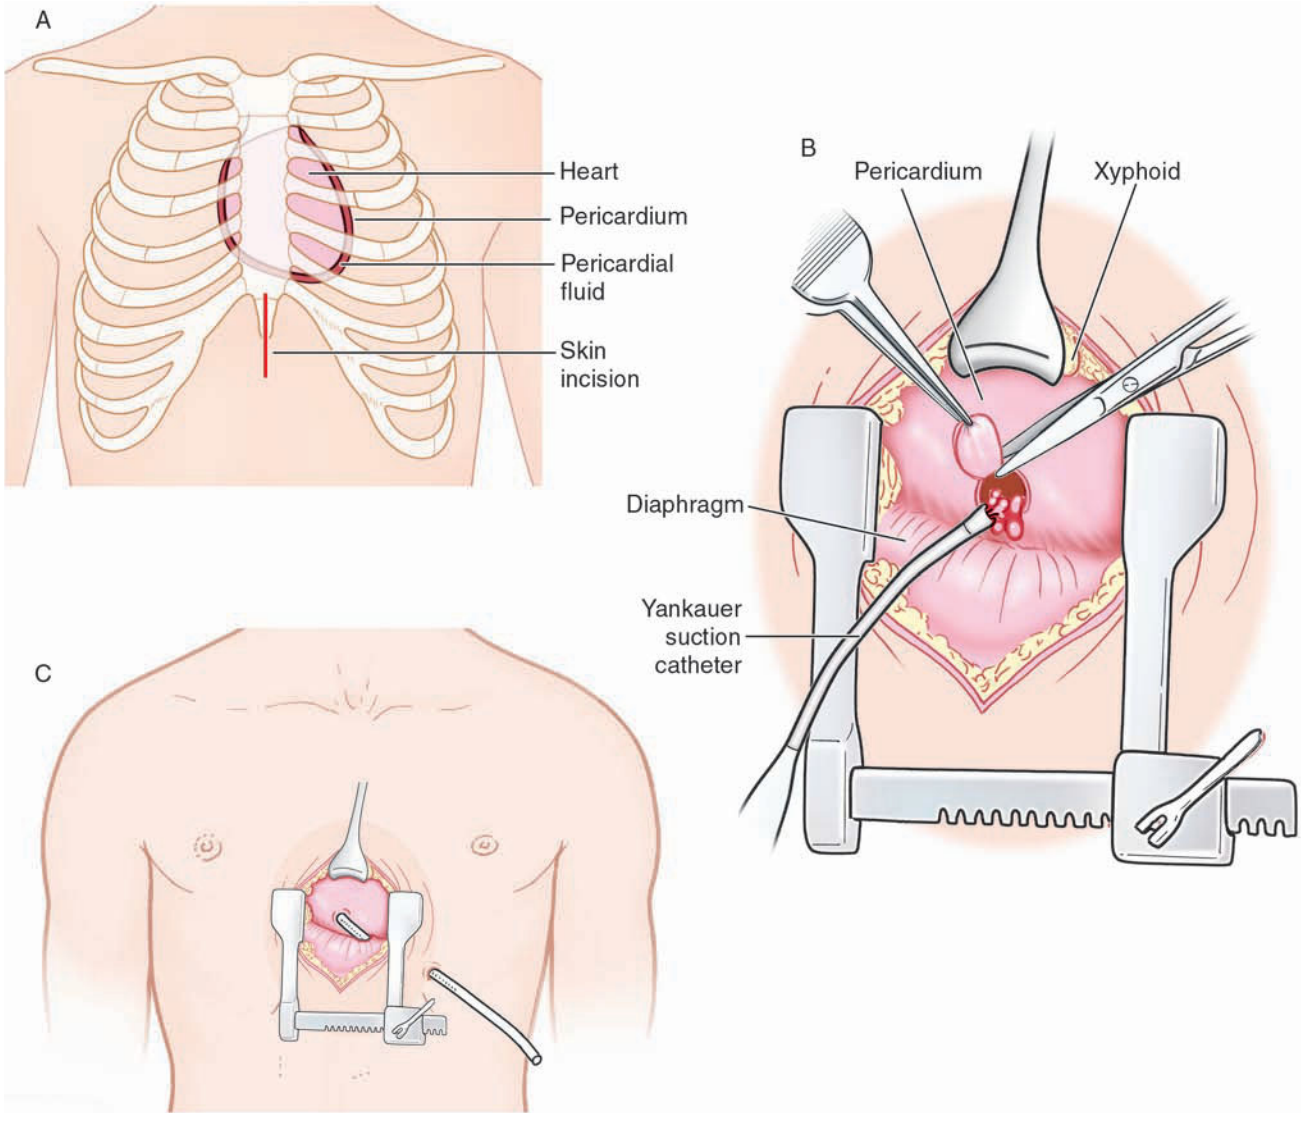

FIGURE 36-17. The pericardial window. **A.** The site of the skin incision. **B.** The xiphoid and sternum are lifted upward to expose the pericardium. An incision is made and a piece of the pericardium is removed. **C.** A chest tube is inserted into the pericardial space to allow continuous drainage of fluid.

16 to 18 gauge, 7.5 cm or longer catheter-over-the-needle for older children, adolescents, and adults. Use an 18 to 20 gauge, 3.75 cm catheter-over-the-needle for infants and small children. The procedure is the same as using a spinal needle up to the point of the needle entering the pericardial space. Stop advancing the catheter-over-the-needle once the pericardial space is entered. Securely hold the syringe so it does not move inward or pull outward. Advance the catheter over the needle and into the pericardial cavity. Continue to advance the catheter until its hub is against the skin. Securely hold the catheter hub against the skin. Remove the syringe and needle as a unit. Attach a 20 mL syringe to the catheter hub and aspirate. The remainder of the procedure is as described previously.

ALTERNATIVE APPROACHES

The subxiphoid approach is the classic or traditional approach, and has been described previously. The use of bedside ultrasonography is changing the technique to a more apical approach.[31,42] This area tends to be closer to the anterior chest wall and where the pericardial effusion is the largest; both of which make the procedure easier to perform under ultrasound guidance.

The blind technique can also be performed using the parasternal, intercostal, or periapical approaches. It was previously recommended to insert the needle perpendicular to the skin and 3 to 4 cm lateral to the sternum for the parasternal approach to avoid the internal mammary artery. Needle insertion just lateral to the sternal border will also avoid the internal mammary artery.[48] The intercostal approach should not be blindly used as it increases the risk of lung penetration by the needle and a subsequent pneumothorax. A blind apical approach is also not recommended. The lingula of the left lung and the pleural space are close to this site. A needle can puncture the lung or aspirate a pleural effusion.

ASSESSMENT

It must be emphasized that the lack of blood return does not rule out the diagnosis of cardiac tamponade. False-negative aspirations from a pericardiocentesis are well documented and are described at rates as high as 80%.[36] The occurrence of false-negative aspirations is often due to clotted blood in the pericardial space that cannot be aspirated or from failure to enter the pericardial space.

A dramatic improvement in the patient's clinical status should be observed after the successful drainage of the pericardial space. This is true even if only a small volume of 15 to 20 mL is drained. The patient's blood pressure and cardiac output should increase while intracardiac pressure and intrapericardial pressure decrease. Obtain a chest radiograph after the procedure to rule out a hemothorax and/or pneumothorax. Obtain an ECG to look for changes consistent with coronary artery injury from the needle.

A pericardiocentesis is often performed in the nontraumatic medical patient. In these cases, send the pericardial fluid for chemical, cytologic, and microbial analyses to determine the etiology of the pericardial effusion. Routine laboratory analysis should include the appearance of the fluid, a cell count and differential, glucose level, lactate dehydrogenase (LDH) level, pH, and total protein level. Cytology may reveal a malignant etiology of the effusion. The microbiology lab should perform a gram stain, acid-fast stain, aerobic and anaerobic bacteria cultures, fungal cultures, and viral cultures.

AFTERCARE

Secure the catheter with sutures to the skin and check for stability. If not already done, consult a Surgeon for definitive care of trauma patients. Prepare these patients for rapid transport to the Operating Room. Monitor patients for reaccumulation of pericardial fluid and for hemodynamic instability. If fluid reaccumulates, the procedure should be repeated or the stopcock opened (if placed) and the pericardial space reaspirated. Flush with sterile saline after each aspiration to maintain the patency of the catheter. Consult a Thoracic Surgeon if purulent fluid is aspirated in medical patients. All patients must be admitted to an intensive care unit for further monitoring, evaluation, and treatment.

COMPLICATIONS

Complication rates vary from 4% to 40%.[14,43] The complication rates of ultrasound-guided aspirations have been reported to be less than 5%.[14] Death may result from recurrence or occurrence of tamponade, bleeding, or dysrhythmias. Few if any deaths have been reported with ultrasound-guided aspirations. Reaccumulation of pericardial fluid may occur in up to 70% of blind aspirations.[14] Continuous drainage with a pericardial catheter can reduce this to 25%.[14] Bleeding, hemothorax, and/or cardiac tamponade can occur due to injury of the myocardium, coronary arteries, pericardial vasculature, or internal mammary vessels by the spinal needle. **To minimize injury, do not rock the spinal needle or change its direction once it is inserted into the patient.** A pneumothorax or pneumopericardium can form from penetration of the lung by the spinal needle. Dysrhythmias, ventricular fibrillation, ventricular tachycardia, or asystole can occur if the needle penetrates the myocardium. Hepatic damage leading to leakage of bile or blood can be seen if the needle penetrates the liver. If the patient is awake and alert, a vasovagal reaction can occur. False-negative aspirations (i.e., a dry tap) occur if the blood in the pericardial cavity is clotted or if the needle is not within the pericardial cavity. False-positive aspirations may be seen if the needle is within the heart chamber or a vascular structure.

SUMMARY

Pericardiocentesis is an infrequently performed procedure. It can be lifesaving when a patient has a pericardial tamponade. The procedure is relatively simple yet has a significant rate of complications, morbidity, and mortality. The use of bedside Emergency Department ultrasonography to assist in making the diagnosis and in guiding the placement of the pericardiocentesis needle dramatically reduces false diagnoses and complications. The exact role of pericardiocentesis in trauma remains controversial, but it may be lifesaving in the unstable patient before they are able to receive definitive surgical therapy.

37 Intracardiac Injection

Payman Sattar

INTRODUCTION

The practice of intracardiac injection originated in the 1800s. It was quite commonly performed throughout the 1960s, as it was thought to be the most expeditious route of drug delivery during a cardiac arrest.[1,2] By the mid-1970s, the practice of intracardiac injection declined. Safer and simpler routes of medication administration (i.e., intravenous, endotracheal, and intraosseous) became available. Experimental data suggested that there was no advantage to intracardiac injection over intravenous administration of medications. Cardiopulmonary resuscitation (CPR) must be interrupted to perform an intracardiac injection. In difficult patients or in inexperienced hands, the time required for this procedure may be too prolonged. Finally, many serious complications may occur as a result of an intracardiac injection.[2]

ANATOMY AND PATHOPHYSIOLOGY

The technique of intracardiac injection is similar to that of a pericardiocentesis (Chapter 36). Both techniques use the same anatomic landmarks, the same anatomic approach, and the transthoracic insertion of a needle through the pericardium. In performing a pericardiocentesis, the tip of the needle is inserted into the pericardial space. Intracardiac injection requires the tip of the needle to be inserted through the myocardium and into a cardiac chamber. Echocardiography or bedside ultrasound may be useful in pericardiocentesis to avoid the lung or myocardium.

Time is of the essence when performing an intracardiac injection. Since the objective is to quickly enter the myocardial cavity, ultrasonographic guidance is generally not necessary. Keeping this in mind, certain situations such as COPD, a prior lung resection, or dextrocardia may benefit from ultrasonographic guidance to avoid puncturing the lung.

The technique of intracardiac injection is easy to teach, is rapid and simple to perform, and requires no special equipment. It begins with identification of the anatomic landmarks required to perform the procedure (**Figure 37-1**). For the subxiphoid approach, identify and palpate the xiphoid process of the sternum and the left costosternal angle. For the left parasternal approach, identify and palpate the left fourth or fifth intercostal spaces immediately adjacent to the sternum.

INDICATIONS

The primary indication for an intracardiac injection is when vascular access is not readily available or unobtainable in a patient with asystole, pulseless electrical activity, pulseless ventricular tachycardia, or ventricular fibrillation. The intracardiac injection of resuscitative medications may be warranted and can be attempted as a last effort to resuscitate the patient if other routes of medication administration have failed.

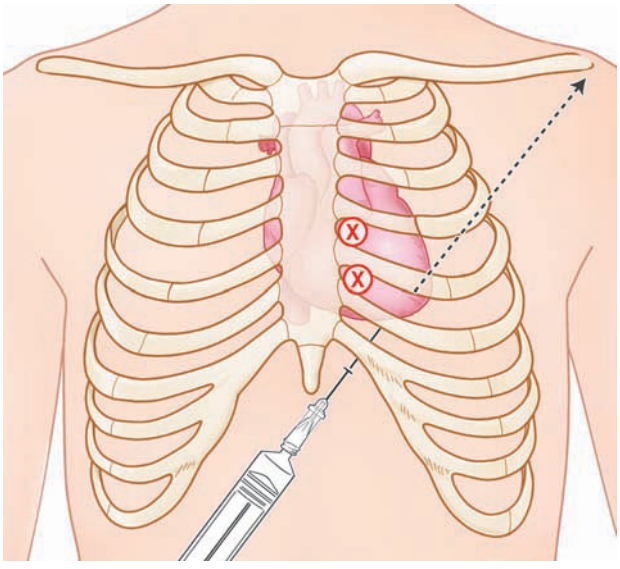

FIGURE 37-1. Intracardiac injection. The needle is inserted 1 cm to the left of the xiphoid process and aimed toward the left shoulder. The needle may also be inserted parasternally in the left fourth or fifth intercostal space (as denoted by the symbol "⊗").

CONTRAINDICATIONS

As candidates for this route of medicinal delivery have undergone a cardiac arrest, there are no absolute or relative contraindications to performing this procedure. A few clinical conditions may make the procedure more difficult to perform. Chronic obstructive pulmonary disease can shift the heart from its normal position and increase the risk of a pneumothorax (with or without tension). Therapeutic or overanticoagulation may result in a hemopericardium and cardiac tamponade. Dextrocardia requires identification of different anatomic landmarks and alterations in needle positioning.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- 18 gauge spinal needle or 18 gauge 3½ in. needle (for adults)
- 22 gauge spinal needle (for children)
- Syringes, 5 and 10 mL
- Nasogastric tube
- Epinephrine, 1:1000 and 1:10,000

Epinephrine is the only resuscitative medication that should be administered by intracardiac injection. Administer 1 mg of epinephrine as the initial and subsequent doses in an adult patient. Administer 0.01 mg/kg (or 0.1 mL/kg) of the 1:10,000 concentration of epinephrine as the initial dose in children. Administer 0.1 to 0.2 mg/kg (or 0.1 to 0.2 mL/kg) of the 1:1000 concentration of epinephrine for subsequent doses in children.

PATIENT PREPARATION

This procedure is often performed on a patient who is clinically "dead" and as a last effort at resuscitation. An informed consent is not required to perform this procedure. The patient will be supine with CPR in progress. If time permits, insert a nasogastric tube to decompress the stomach. Apply povidone iodine or chlorhexidine solution to the area around the lower sternum, xiphoid process of the sternum, upper epigastric, and left costosternal angles. Identify, by palpation, the anatomic landmarks required to perform the procedure. Draw up the required dose of epinephrine into a syringe or use prefilled syringes. Attach a spinal needle to the syringe containing the epinephrine.

TECHNIQUES

The two routes for intracardiac injection are the subxiphoid and left parasternal approaches (**Figure 37-1**). Both are utilized in a similar fashion. The left parasternal approach offers a more direct and shorter route. However, it is associated with a higher rate of complications. Both approaches require cessation of CPR in order to perform the procedure. **The procedure of intracardiac injection should be performed as rapidly as possible to avoid prolonged cessation of CPR, but not at the expense of safety to the Emergency Physician, Nurses, and ancillary staff.** It should take less than 10 seconds to perform an intracardiac injection.

SUBXIPHOID APPROACH

Stop performing CPR. Stop ventilating the patient and allow the lungs to passively deflate. Identify the spot 1 cm to the left of the patient's xiphoid process in the costosternal angle (**Figure 37-1**). Insert the needle with the bevel up, at a 30° to 45° angle to the skin of the abdominal wall, and aimed toward the patients left shoulder. Advance the needle while applying negative pressure to the syringe. Stop advancing the needle when blood flows freely into the syringe. This signifies that the tip of the needle is within the cardiac chamber. Quickly inject the epinephrine, then withdraw the needle. Resume CPR and ventilation of the patient.

If the attempt at intracardiac injection is unsuccessful, the needle should be withdrawn and flushed and intracardiac injection reattempted. The needle can become plugged with subcutaneous fat. **CPR and ventilation must be resumed after each attempt at intracardiac injection, whether successful or not.** Variations on the direction of the needle can be made for subsequent attempts. The needle may be directed toward the suprasternal notch, left midclavicle, or right midclavicle.

As an alternative, the spinal needle can be inserted through the skin and into the subcutaneous tissue with its obturator in place. Remove the obturator when the tip of the spinal needle is in the subcutaneous tissue. Attach the syringe containing epinephrine to the spinal needle. Gently depress the plunger of the syringe to expel the air within the needle into the subcutaneous tissues. Advance the needle while applying negative pressure. Stop advancing the needle when blood flows freely into the syringe. Quickly inject the epinephrine, and withdraw the needle. Resume CPR and ventilation of the patient.

LEFT PARASTERNAL APPROACH

This approach utilizes the fourth or fifth intercostal space, approximately 1 cm (or 1 finger breadth) lateral to the left sternal border (**Figure 37-1**). Stop performing CPR. Stop ventilating the patient and allow the lungs to passively deflate. Insert the needle perpendicular to the chest wall. Stabilize the needle with one hand and the syringe with the other. **Advance the needle with both hands and without excessive force.**[3] It is very easy to plunge into the heart if too much force is applied to the needle. Apply negative pressure to the syringe as it is advanced. Stop advancing the needle when blood flows freely into the syringe. Quickly inject the epinephrine, then withdraw the needle. Resume CPR and ventilation of the patient.

INFANTS AND CHILDREN

The technique of intracardiac injection for infants and children is essentially the same as that described above for the adult patient.[4]

While the subxiphoid approach has been "adopted as the standard," the left parasternal approach can also be effectively utilized. Use a 22 gauge spinal needle for infants and children. **Use caution when inserting and advancing the spinal needle since the pediatric skin and subcutaneous tissue are thin and easily penetrated.** The dose of epinephrine administered is weight-based and varies from the initial dose to subsequent doses (see the "Equipment," section, for discussion).

COMPLICATIONS

Overall, according to pooled data, complications are rare.[2,5–7] A pneumothorax is the most common complication, especially with the parasternal approach. Other reported complications include coronary artery laceration, myocardial laceration, hemopericardium, cardiac tamponade, pulmonary artery laceration, and perforation of the stomach or liver. Intramyocardial injection has been reported and is associated with intractable ventricular fibrillation. **Identification of the appropriate anatomic landmarks for needle insertion and direction can minimize complications. Careful adherence to proper technique can also minimize complications.** The use of a small-gauge spinal needle and the subxiphoid approach may result in fewer complications versus a large-gauge needle and the left parasternal approach.[8]

SUMMARY

Although intracardiac injection is an effective route of medication delivery to a patient in cardiac arrest, its popularity has declined due to safer, simpler, and more effective methods of vascular access. When intravenous access is not readily accessible or when the endotracheal administration has not provided the desired effect, intracardiac injection should be considered as an alternative technique. It is important not to permit prolonged cessation of CPR during the procedure.

38 Needle Thoracostomy

Eric F. Reichman and Elizabeth Sowell

INTRODUCTION

A tension pneumothorax is a unilateral progressive collection of air in the pleural space. If not treated, it results in increasing intrapleural pressures, shifting of intrathoracic structures, hypoxemia, and death. It occurs from a one-way air leak into the pleural cavity from the airway conduits, the lung, or the thoracic wall. The air leak causes air to enter the pleural cavity and become trapped, without a method of egress. Rapid decompression of the tension pneumothorax with a catheter-over-the-needle is known as a needle thoracostomy and can be lifesaving.

A tension pneumothorax is an immediate life-threatening condition that requires prompt recognition and treatment to prevent the patient's imminent demise. The diagnosis must be suspected based upon the patient's prior medical history, the mechanism of injury, physical examination findings, and a patient in extremis. **Importantly, treatment must not be delayed to obtain further diagnostic testing (e.g., chest radiograph).** These patients most often present with acute and dramatic cardiopulmonary compromise, which may be manifest by a combination of the following signs and symptoms: respiratory distress, chest pain, air hunger, hypotension, tachycardia, diaphoresis, unilateral absence of or decrease in breath sounds, hyperresonance to percussion, increased central venous pressure, hypoxemia, cyanosis, deviation of the cardiac point of maximal impulse, and tracheal deviation.

ANATOMY AND PATHOPHYSIOLOGY

The most common cause of a tension pneumothorax is mechanical ventilation with positive pressure in a patient with a visceral pleural injury.[1] A tension pneumothorax is present in 50% of ventilator-associated pneumothoraces.[2] When this occurs in intensive care unit (ICU) patients, they often have minimal functional reserve. To further cloud the issue, they are frequently on other supports (i.e., inotropic agents, complex ventilator settings, etc.), making their physical examination difficult and confusing. They may also have a number of other coexisting factors that are making them unstable. This group of patients has a particularly disastrous course if a tension pneumothorax develops. Rapid diagnosis and treatment are imperative.[3]

The placement of a central venous catheter has been associated with the development of a pneumothorax. The incidence of this is approximately 3% to 6% with use of the subclavian approach. A tension pneumothorax may be delayed in approximately 0.4% of attempts to gain central venous access. In one case report, a patient developed a tension pneumothorax while under general anesthesia 10 days after the placement of a subclavian central venous line.[4]

A tension pneumothorax may also occur in the setting of blunt or penetrating trauma of the lung. It may occur uncommonly following a tracheobronchial or esophageal injury. It may complicate a simple pneumothorax if the parenchymal lung leak does not seal spontaneously. In this case, the site of the lung injury acts as a one-way valve, allowing air entry into the pleural space and not allowing it to escape. Occasionally, chest wall defects may result in a tension pneumothorax if the wound is completely covered by an occlusive dressing or if the wound itself acts as a ball-valve mechanism. More rarely, it may occur following markedly displaced fractures of the thoracic spine. In the past, based on studies using the canine model, the pathophysiology of this disease was considered to be associated primarily with a mechanical pressure-related phenomenon.[5] Air accumulated in the involved pleural space and caused an increasing intrapleural pressure. This pressure caused compression of the ipsilateral lung, displacement of the diaphragm caudally, movement of the mediastinum and heart toward the uninjured side, kinking of the great vessels, and compression of the contralateral lung. This anatomic shift of structures would result in impaired filling of the heart and a disastrous fall in cardiac output.[6] Unfortunately, the canine model is not as similar to the human as was once thought. The mediastinum in the dog is more mobile. It is fenestrated, so that air communicates from one hemithorax to the other. Therefore, elevations of intrapleural pressure in dogs would affect central structures and cause cardiovascular compromise more readily than in humans.

Recently, this pressure-related mechanism has come into question as the primary event. Experiments have been performed in goats, monkeys, sheep, and swine; all of which have a mediastinum that is more similar to that of the human than the dog.[7–10] These studies support the hypothesis that central hypoxemia is the primary factor in the lethality of a tension pneumothorax and occurs prior to the development of significant hypotension. In this hypothesis, the mechanical pressure-related phenomenon is a late event.

These mechanisms become more confusing and mixed in the ventilator-dependent patient. There is a lack of studies documenting hemodynamic changes in the human subject with a tension pneumothorax.[11–14] In one case report, three ventilated ICU patients demonstrated decreased cardiac output as the first sign of a tension pneumothorax.[12] The authors proposed that the absence of spontaneous breathing did not allow increased variations in negative

intrathoracic pressure to act as a compensatory mechanism to prevent hemodynamic compromise. In another similar case, decreased cardiac output and mixed venous oxygen saturation were the dominant signs of a tension pneumothorax.[13] Hemoglobin desaturation via pulse oximetry was shown to be the earliest sign in a ventilator-dependent patient with a tension pneumothorax.[14]

Electrocardiographic (ECG) changes may be seen in association with a tension pneumothorax. In a left-sided tension pneumothorax, the more commonly described ECG changes are a rightward shift of the mean frontal QRS axis, precordial T-wave inversions, reduced R-wave voltage, and decreased and/or alternating QRS amplitude.[15–17] Other unique changes include PR-segment elevation in the inferior leads and reciprocal PR-segment depression in lead aVR.[18] A case report cited transient bradycardia, hypotension, and precordial ST-segment elevation; all of which reversed after treatment of a right-sided tension pneumothorax.[19]

Numerous mechanisms have been proposed as the causes of these ECG changes. They include simple displacement of the heart, rotation of the heart around its anteroposterior or longitudinal axis, transient hypoxia, changes in coronary artery blood flow, changes in pleural pressure, pulmonary resistance, pericardial tension, acute ventricular dilatation, alterations in ventricular repolarization, pressure-induced atrial injury, and insulation of the chest wall from the associated air.[15–20] The vast majority of ECG changes have been noted with left-sided rather than right-sided tension pneumothoraces. **The degree of pneumothorax and the severity of symptoms do not seem to correlate with the magnitude of the ECG abnormalities. In summary, ECG changes are not uncommon in tension pneumothorax and should not distract from the true diagnosis.**

INDICATIONS

A tension pneumothorax must be considered in the differential diagnosis of any patient in extremis. If it is a possible etiology for the patient's cardiopulmonary collapse, needle decompression should be performed without delay. In every circumstance, and especially in the emergent setting, one may not be able to be 100% certain of the diagnosis. However, needle decompression is a relatively low-risk procedure with great lifesaving potential.

One setting that may be particularly confusing is in the dying patient with left precordial penetrating trauma. The immediate differential would be tension pneumothorax versus pericardial tamponade versus massive hemothorax. Physical examination findings are usually helpful but may also be confusing, mixed, or difficult to elicit in a chaotic and noisy resuscitation. **Needle decompression should be the first maneuver in this situation.** It may be lifesaving and will aid in the diagnosis. It is less invasive, quicker, and easier to perform than a pericardiocentesis or a thoracotomy. A tension pneumothorax is more common than pericardial tamponade in this setting. As for a massive hemothorax, a chest tube setup requires some time but should be requested at the time needle decompression is proceeding.

CONTRAINDICATIONS

There are no absolute contraindications to performing a needle thoracostomy to decompress a tension pneumothorax. It is imperative to identify the anatomic landmarks properly and perform this procedure carefully if the patient has a known or suspected coagulopathy.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- 12 to 16 gauge catheter-over-the-needle, 4.5 cm in length
- 5 or 10 mL syringe
- Sterile gloves and gown
- Face mask with an eye shield or goggles
- Ultrasound machine (optional)
- Low frequency (2-5 MHz) ultrasound probe
- Sterile ultrasound probe cover
- Sterile ultrasound gel

PATIENT PREPARATION

Briefly describe the procedure to the patient if they are competent, able to understand, and cooperative. Place the patient supine. Some Emergency Physicians place the patient supine with the head of the bed elevated to 30°. This will allow the air to rise to the anterior upper chest. Unfortunately, this is not the most functional position. It is from the supine position that the patient can most easily be accessed and controlled by the greatest number of practitioners. The supine position is optimal to allow for other lifesaving maneuvers (e.g., airway management, cardiopulmonary resuscitation, etc.). Clean the skin of any dirt and debris in the area of the procedure. Apply povidone iodine or chlorhexidine to the skin.

Simultaneous with the performance of this procedure, other interventions should be requested: 100% face-mask oxygen (if the patient is not already intubated), pulse oximetry, cardiac monitoring, chest tube setup, intravenous access, and STAT chest radiography. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids. **While time is of the essence and this is an emergent procedure, aseptic technique should be followed.**

TECHNIQUE

The safest, easiest, and most reliable site for a needle thoracostomy to decompress a tension pneumothorax is the second intercostal space in the midclavicular line[1,2,6,21] (**Figure 38-1**). Apply a 12, 14, or 16 gauge catheter-over-the-needle onto a 5 or 10 mL syringe without the plunger. Identify the second intercostal space in the midclavicular line. Place the nondominant index finger over the needle insertion site. Grasp the syringe with the dominant hand. Insert the catheter-over-the-needle perpendicular to the skin and just above the superior border of the third rib (**Figure 38-2A**). This will avoid injury to the neurovascular bundle underlying the inferior

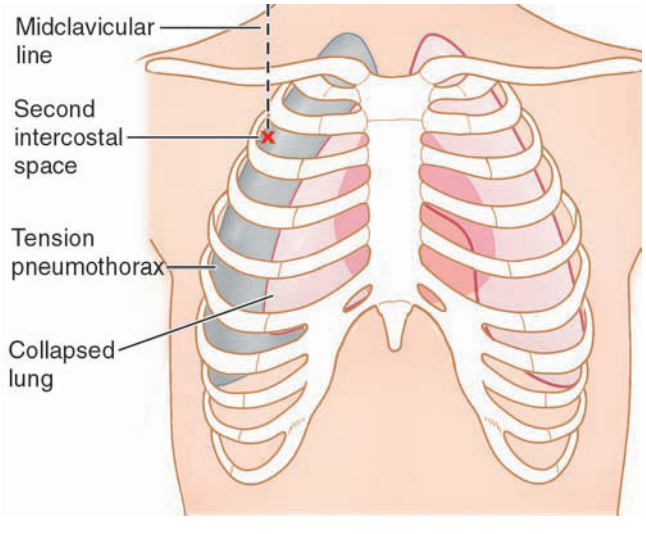

FIGURE 38-1. A right-sided tension pneumothorax. The preferred site for a needle thoracostomy is the second intercostal space in the midclavicular line.

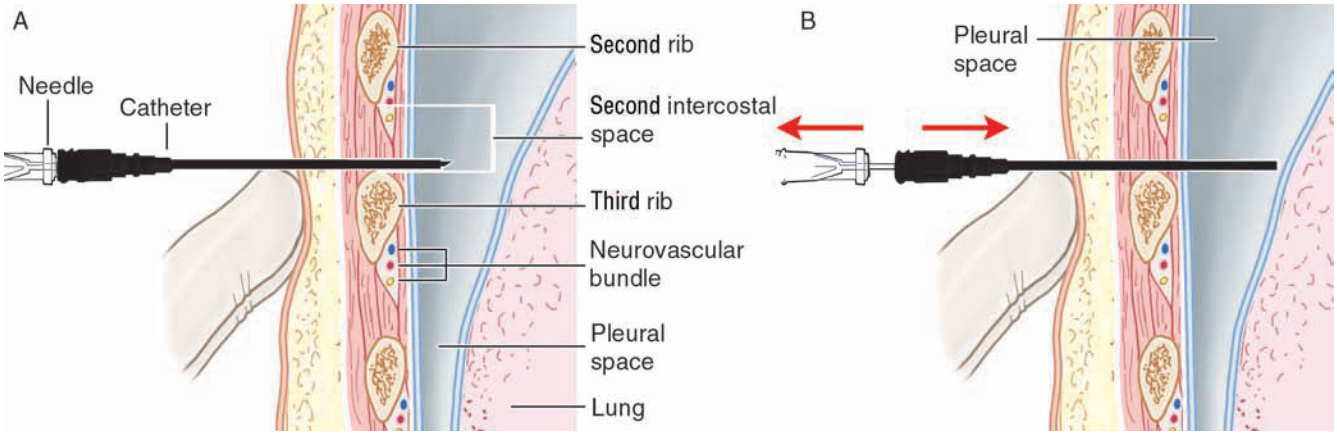

FIGURE 38-2. Decompression of a tension pneumothorax with a catheter-over-the-needle. **A.** The catheter-over-the-needle is inserted through the second intercostal space and into the pleural cavity. **B.** The catheter is advanced and the needle is removed.

border of the second rib. Some Emergency Physicians prefer to contact the upper portion of the third rib with the tip of the needle, walk it up the rib until it goes over the edge, and then advance it into the pleural space.

Advance the catheter-over-the-needle until a loss of resistance is felt as the tip of the needle penetrates the pleural space. A rush of air, with or without blood, will be heard escaping from the syringe. Stop advancing the catheter-over-the-needle. Advance the catheter until the hub is against the skin while simultaneously withdrawing the needle (**Figure 38-2B**).

ALTERNATIVE TECHNIQUES

Other sites have been described for performing a needle thoracostomy. These include the fourth or fifth intercostal space in the midaxillary line or the second intercostal space in the anterior axillary line.[22–25] There are several problems with these alternative sites. In the fourth or fifth intercostal space, the ribs are close together, with narrower interspaces making needle placement more difficult. There is more rib motion with breathing and arm movement can make catheter dislodgment more likely. In the supine patient, air will rise ventrally rather than laterally. Practically speaking, during the resuscitation of the unstable patient, the most important position for the Emergency Physician is at the patient's head. Insertion of a catheter in the second intercostal space in the midclavicular line is easier from this position than inserting a laterally placed catheter. The fourth or fifth intercostal space in the midaxillary line is the ideal space for a chest tube. Placement of the catheter in these alternative sites would mean having to penetrate more tissue, especially in the obese patient, making reaching the pleural space more difficult, and dislodgment of the catheter more likely. The major drawback to using the fourth or fifth intercostal space is the risk of inserting the catheter-over-the-needle below the diaphragm and into the liver (on the right) or the spleen (on the left).

If the first attempt at needle thoracostomy fails to decompress the pleural space, ultrasound can be used to measure chest wall thickness in order to determine the appropriate needle length and to confirm the presence or absence of a pneumothorax. Subcutaneous fat and tissue can be differentiated from air in the pleural space by the presence of the pleura seen deep to the pneumothorax and represented by a bright white line along with the absence of "lung slide."

If the patient is in extremis, a definitive chest tube should not be the primary therapy for a tension pneumothorax. The setup and performance of a tube thoracostomy take much longer than rapid decompression with a catheter-over-the-needle.

HANGING DROP TEST

A novel idea has been proposed to use the "hanging drop" test to identify the pleural space and determine if a tension pneumothorax is present.[26] It is quick, easy to perform, and uses supplies readily available in the Emergency Department. Be aware that gathering the supplies and performing this test can take a few minutes, thus delaying the needle decompression.

Using strict aseptic technique, insert a 4.5 cm long spinal needle into the second intercostal space in the midclavicular line and advance it until the tip is touching the upper border of the third rib. Remove the trocar. Place one to two drops of sterile saline or sterile water into the hub of the spinal needle. The fluid bubble will be elevated above the needle hub. Gently walk the needle up and over the edge of the third rib. Slowly advance the needle through the intercostal tissues while observing the fluid bubble. The negative intrathoracic pressure will suck the fluid bubble into the chest of there is no tension pneumothorax. The fluid bubble will be pushed out of the hub if a tension pneumothorax is present.

The author suggests using a spinal-type needle.[26] This cannot be recommended for two reasons. First, if a tension pneumothorax is present, the sharp needle should not be advanced or left in the pleural cavity to relieve a tension pneumothorax. It can puncture an organ or blood vessel. Second, the spinal needle would have to be removed and the procedure repeated with a catheter-over-the-needle. Consider using a catheter-over-the-needle to perform this procedure to avoid these issues.

PEDIATRIC CONSIDERATIONS

The basic technique is the same in pediatric patients. Use a smaller length and gauge catheter-over-the-needle in pediatric patients. A 20 or 22 gauge, 1 inch (in) or 2.5 cm catheter-over-the-needle should be used in preterm children and neonates. This same size can also be used in children up to approximately 1 to 2 years of age. Between the approximate ages of 2 and 6 years, consider using an 18 or 20 gauge, 1.5 in or 3.75 cm long catheter-over-the-needle. Over the age of 6 and into early adolescence, consider using a 16 or 18 gauge, 4.5 cm long catheter-over-the-needle. Use the adult size catheter-over-the-needle for older adolescents or obese children. These are just general recommendations. The individual child's size and body habitus need to be taken into consideration when choosing a catheter-over-the-needle size and length.

Some Physicians prefer to use a butterfly needle with attached tubing instead of a catheter-over-the-needle in preterm children,

neonates, and up to the first year of life. Select a butterfly needle size as described above. Place sterile water or sterile saline in a sterile specimen cup. Insert the distal hub end of the butterfly tubing into the bottom of the specimen container and submerged in the liquid. Tape the tubing onto the rim of the specimen container to secure it and ensure it does not pull out of the liquid in the specimen container. Insert the butterfly needle into the pleural space as described above. Air bubbles will move through the tubing and into the sterile liquid as the tension pneumothorax is decompressed. The specimen container also forms a water seal, preventing ingress of air into the pleural space, until a tube thoracostomy can be performed.

ASSESSMENT

Once the catheter has been placed into the pleural space, a gush of air should rush out of the syringe. **The procedure will have converted a tension pneumothorax into a simple pneumothorax requiring a tube thoracostomy.** The patient should improve hemodynamically and symptomatically. Saturations on pulse oximetry should rise after the decompression. If this does not occur, too short of a catheter-over-the-needle may have been used and the procedure should be repeated with a longer one. If a longer catheter-over-the-needle is not available, rapidly perform a tube thoracostomy. The other possibility is that the pleural space was entered appropriately but the diagnosis was incorrect. In this event, another cause of the patient's shock state should be sought and consideration should be given to "prophylactic" chest tube placement. This may prevent later sequelae from the iatrogenic catheter stab wound to the chest and simplify the further workup and monitoring of this unstable patient.

AFTERCARE

After insertion of the catheter and improvement in the patient's clinical status, the immediate life threat has been treated. Secure the catheter against the skin with a suture or an assistant holding it in place. **Continue to observe and monitor the patient closely for recurrence of the tension pneumothorax and procedural complications.** Establish intravenous access, cardiac monitoring, and pulse oximetry if not already done. Obtain baseline laboratory studies, an arterial blood gas, and a chest radiograph. Obtain a thorough history and physical examination to search for the etiology of the tension pneumothorax. **A definitive chest tube should be placed using sterile technique to prevent recurrence of the tension pneumothorax and to treat the simple pneumothorax.** Refer to Chapter 39 for the complete details regarding the placement of a chest tube. After a chest tube is inserted, remove the needle thoracostomy catheter and place a simple bandage over the puncture site.

COMPLICATIONS

An incorrect diagnosis of a tension pneumothorax in an unstable patient is always a possibility, even in the best of hands. If this is the case, the cause of the patient's shock state must still be aggressively sought and treated. A prophylactic chest tube should be considered for a presumed parenchymal lung injury and potential pneumothorax from the needle thoracostomy.[27–29] This is especially true if the patient is going to be transported out of the resuscitation area, will be given a general anesthetic, or is to be placed on positive-pressure ventilation.

Failure to reach and decompress the pleural space is the major argument against the use of needle thoracostomy. Depending on the patient's body habitus and the catheter length, the pleural space may not have been reached to be decompressed. In an initial study from the UK, the chest wall thickness was estimated to range from 1.3 to 5.2 cm by ultrasound in the second intercostal space.[30] A 3.0 cm cannula would fail to penetrate into the pleural cavity in 57% of the patients in this study. A 4.5 cm cannula would fail to penetrate into the pleural cavity in 4% of the patients. In this case, the procedure should be repeated with a longer catheter-over-the-needle. If one is not immediately available, a tube thoracostomy should be performed immediately.

Several studies have evaluated chest wall thickness using ultrasound and computed tomography (CT) scans in order to determine the needle length required to appropriately decompress the pleural space in the general adult population. Initial studies using ultrasound seemed to indicate that using needle lengths of 4.5 cm would be sufficient to reach the pleural space in most patients.[30] More recent studies using CT have shown that chest wall thickness varies significantly by gender and age. A study by Zengerink et al. found that chest wall thickness was greater than 4.5 cm 10% of the time in men younger than 40 and 19% of the time in men older than 40 years of age.[31] The same study found almost one-third of women less than 40 years had a chest wall thickness greater than 4.5 cm, falling to one-fourth for those over 40. Harcke et al. found a mean chest wall thickness of 5.36 cm in autopsy CT scan studies.[34] They recommended a 3.25 in or 8 cm long catheter-over-the-needle be used. It is important to note these variations. However, most authors still advocate a needle length of 4.5 cm as longer needle lengths increase the risk of vascular, pulmonary, or cardiac injury.

The second intercostal space in the midclavicular line is the recommended location for a needle thoracostomy. A prospective study of needle thoracostomy sites found that a more medial placement was often used.[35] A needle thoracostomy insertion point not in the midclavicular line is more likely to be associated with vascular injury and hemorrhage. This includes injury to the internal mammary artery medially, subclavian vessels superiorly, and the pulmonary trunk and heart inferiorly.

After the initial effective decompression of a tension pneumothorax, the catheter may become dislodged, clotted, kinked, or its tip may retract from the pleural space into the surrounding soft tissues. **If the tension pneumothorax recurs, immediately repeat the procedure.** Once needle decompression is reaccomplished, immediately perform a tube thoracostomy. If possible, a tube thoracostomy can be initiated by the Emergency Physician while other members of the resuscitation team continue with other interventions. This would hopefully prevent recurrence of the tension pneumothorax secondary to a delay in chest tube placement because other interventions (e.g., CPR, intubation, venous access, etc.) must also be performed.

There may be complications secondary to the catheter placement.[37–40] A local hematoma or underlying lung laceration may occur. Infectious agents may be introduced into the pleural cavity. If the catheter-over-the-needle is introduced too close to the sternum, the underlying mediastinal vessels or internal mammary artery may be penetrated or lacerated. If the catheter-over-the-needle is introduced under the inferior border of the second rib instead of over the superior border of the third rib, the intercostal vessels or nerve may be lacerated. **A proper technique in placing the catheter-over-the-needle should be observed to minimize preventable complications.**

The standard approach to relieving a tension pneumothorax is the placement of a large-bore needle in the ipsilateral second intercostal space. This works well in the standard patient where there are no adhesions or scarring in the pleural space. However, this may not be the proper needle location in the patient with prior pulmonary disease, pleural disease, or pleural adhesions. The classic hospital patient in this category is the patient with adult respiratory distress syndrome on positive end-expiratory pressure (PEEP) with high airway pressures who develops a loculated tension pneumothorax. The needle placed in the standard manner often fails to reach the

affected pleural area. Stat chest radiographs are often required to help guide placement of the needles and/or chest tubes in these more complex patients.[6] Bedside ultrasonography is also useful to help guide the procedure.

The needle thoracotomy procedure is not without its complications. This leads some to question the performance of a needle thoracostomy instead of just performing a tube thoracostomy. There are no clinical trials comparing needle versus tube thoracostomy to relieve a tension pneumothorax in human subjects. This study was recently undertaken in a swine model.[36] The authors demonstrated that a properly performed needle thoracostomy is as effective over a 4-hour period as a tube thoracostomy. While the authors did not record the time it took to perform the procedures, performing a needle thoracostomy is quicker, easier, and simpler and now just as effective when compared to a tube thoracostomy.

SUMMARY

Tension pneumothorax is a clinical diagnosis that is often made in an agonal patient with respiratory distress, absent (or decreased) breath sounds over a hemithorax, and severe cardiopulmonary compromise. Needle thoracostomy to decompress the tension pneumothorax should be performed immediately in the second intercostal space in the midclavicular line. This is a lifesaving procedure that is quick, simple to perform, easy to learn, and requires no special equipment. Needle thoracostomy should be followed as soon as feasible by a definitive tube thoracostomy.

39 Tube Thoracostomy

Kimberly T. Joseph

INTRODUCTION

A tube thoracostomy is the placement of a tube through the thoracic wall and into the pleural cavity. It is commonly referred to as a chest tube. It is placed in order to evacuate air, blood, or other fluid that collects within the pleural space. The etiology of the air or fluid collections can be due to iatrogenic complications, infection, lung disease, malignancy, or trauma.

Thoracic trauma continues to account for nearly one-quarter of all trauma-related mortality.[1,2] Although some injuries require surgical intervention, the majority may be treated nonoperatively. Injuries to the chest wall, lung, trachea, bronchi, or esophagus may lead to the presence of abnormal air and/or fluid in the pleural space. The use of a tube thoracostomy (chest tube) in these situations may be both diagnostic and therapeutic. Historically, closed-tube drainage of the pleura has been used for various indications for more than a century.[3] This chapter deals primarily with the use of tube thoracostomy following trauma. However, much of the information remains the same regardless if the patient is a trauma victim or a medical patient.

ANATOMY AND PATHOPHYSIOLOGY

On inspiration, the diaphragm and accessory muscles of respiration contract and generate negative pressure within the pleural space. Penetration of the visceral or parietal pleura due to injury disrupts this pressure gradient and allows air to enter the "potential space" between the parietal and visceral pleurae, resulting in a pneumothorax.[1,2] **A simple pneumothorax is the accumulation of air that is not under pressure within the pleural space.** It may cause the ipsilateral lung to collapse. As air continues to accumulate and if there are no adhesions, the increased pressure in the thoracic cavity may push the mediastinum toward the noninjured side. This can cause angulation of the atriocaval junction, impairment of atrial filling, and a subsequent decrease in cardiac output manifest by hypotension. **The presence of a pneumothorax under pressure accompanied by respiratory and/or circulatory compromise is termed a tension pneumothorax and is an immediate life threat**.

There are two important points to remember about a tension pneumothorax. First, it is a clinical diagnosis based on the patient's presenting signs and symptoms. Do not wait for a chest film to establish the diagnosis. Second, the initial treatment of this entity is needle decompression followed by tube thoracostomy. A large-bore needle is inserted in the second intercostal space (ICS) in the midclavicular line at the superior border of the rib. If the patient has a tension pneumothorax, a gush of air will ensue and the patient's symptoms will improve. Thus, the tension pneumothorax is converted to a simple pneumothorax and a chest tube is inserted for more definitive management. Refer to Chapter 38 for complete details regarding the needle thoracostomy procedure.

An open pneumothorax is caused by a traumatic chest wall injury that results in a defect that is greater than or equal to two-thirds the diameter of the patient's trachea. Air passes via the path of least resistance (i.e., the defect) and leads to equilibration of the intra- and extrathoracic pressures, thus compromising both oxygenation and ventilation. Like a tension pneumothorax, this is an immediate life threat. Initial treatment may consist of a nearly occlusive "three-sided" dressing creating a one-way valve for egress of air from the pleural cavity. Alternatively, the patient may be placed on positive-pressure ventilation. The chest tube can then be inserted at a site remote from the actual defect. Refer to Chapter 41 for complete details regarding the management of open chest wounds.

Injury to the chest may also result in laceration of vascular structures, including the lung parenchymal vessels, intercostal vessels, internal mammary arteries, great vessels, or the heart. Although the body can absorb small amounts of free blood from the pleural space, the presence of free blood over a prolonged period of time leads to increased risk of infection and fibrosis.[3,4] The body cannot effectively clear large quantities of blood or clot from the pleural cavity. Blood in the pleural space, otherwise known as a hemothorax, can in most cases be treated with the insertion of a chest tube. However, when a major systemic or pulmonary vessel has been injured, resulting in massive hemothorax (i.e., greater than 1500 mL of blood in the pleural space), tube thoracostomy is usually followed by urgent surgical intervention.

Penetrating wounds or blunt rupture of the thoracic esophagus may result in a pneumomediastinum, pneumothorax, hydrothorax, or some combination thereof. Esophageal injury should be suspected in any patient with a knife or ice pick wound in a suspicious location, a transmediastinal bullet trajectory, or a severe and sudden compression of the chest or abdomen.[2] If a pneumothorax or hydrothorax is a presenting finding, tube thoracostomy is used as part of the treatment. However, these patients require urgent surgical attention. Tube thoracostomy may also be used in the treatment of traumatic chylothorax resulting from injury to the thoracic duct.

One special circumstance deserves mention. Certain patients who have sustained significant blunt trauma to the torso may have a diaphragmatic rupture. Chest radiographs may reveal an air density in the hemithorax that could be mistaken for a pneumothorax. However, this may actually represent the presence of the stomach or colon in the thoracic cavity. When a chest tube is inserted in such a case, extra care must be taken when entering the pleural cavity so as not to injure a hollow viscus inadvertently.

INDICATIONS

The indications for a tube thoracostomy following blunt or penetrating trauma to the chest include the presence of a simple pneumothorax, hemothorax, hemopneumothorax, hydrothorax, or chylothorax. A chest tube is placed prophylactically in patients with penetrating injuries to the chest who do not have evidence of a pneumothorax on initial chest radiographs but are expected to undergo endotracheal intubation and general anesthesia. The medical indications for a tube thoracostomy include a pneumothorax, empyema, recurrent pleural effusion, pleurodesis, or a malignant pleural effusion. A tube thoracostomy should also be performed after the needle decompression of a tension pneumothorax into a simple pneumothorax.

OCCULT PNEUMOTHORAX

With the advent of computed tomography (CT), traumatic pneumothoraces and hemothoraces that are not evident on plain chest radiographs are being diagnosed more frequently. The question then arises as to whether or not these pneumothoraces should be treated. The management of these "occult pneumothoraces/hemothoraces" is somewhat controversial. One study looked at 40 patients who sustained chest trauma and were discovered by CT scan to have pneumothoraces.[5] The study concluded that patients undergoing positive-pressure ventilation should have placement of a chest tube. However, the study could not confirm that patients with small pneumothoraces who were not going to be ventilated could safely be observed. Plurad et al. reviewed 2326 CT scans, 80.5% after negative chest radiographs, in which 102 occult pneumothoraces and/or hemothoraces were noted.[6] Only 12 of these patients required tube thoracostomy. Similar results for small, isolated occult hemothoraces were seen by Stafford et al.[7] A smaller study by Enderson et al. noted a higher percentage of patients requiring tube thoracostomy, but these patients were undergoing positive-pressure ventilation.[8] As a general guideline, nonprogressive occult pneumothoraces can usually be managed without a tube thoracostomy.[9] However, close clinical observation and/or follow-up plain radiographs are recommended. An initially occult pneumothorax that is increasing in size or in a patient who develops respiratory distress requires a tube thoracostomy.[9] A patient with an occult pneumothorax and who also requires positive-pressure ventilation, endotracheal intubation, and/or general anesthesia is an indication for a tube thoracostomy.

CONTRAINDICATIONS

The only absolute contraindication to performing a tube thoracostomy is in the patient who requires an open thoracotomy. Although there are no firm contraindications to performing a tube thoracostomy in a trauma patient, there are some areas of controversy. It has been suggested that a patient with a small (<20%) pneumothorax without an associated hemothorax following trauma may be managed with close observation rather than a chest tube, especially in the case of blunt injuries. If observation is selected for such a patient, chest radiographs should be repeated within 3 to 6 hours to rule out an enlarging pneumothorax or the delayed manifestation of a hemothorax.[2,5]

There are several relative contraindications to performing a tube thoracostomy in the medical patient. These include the presence of a skin infection over the chest tube insertion site, a coagulopathy, large pulmonary blebs or bullae, pulmonary adhesions, loculated pleural effusions, tuberculosis, or previous tube thoracostomies. These patients may require CT or ultrasound guidance to place the chest tube. A coagulopathy should be corrected before the chest tube is inserted if such placement is not required emergently.

There has been some suggestion in the literature that there may be a role for the prehospital placement of chest tubes.[10,11] Although this has not gained widespread acceptance, aeromedical crews frequently perform tube thoracostomies in the field.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- 10 to 20 mL syringe
- Local anesthetic solution with epinephrine (1% lidocaine or 0.25% bupivacaine)
- 25 or 27 gauge needle
- #10 scalpel blade on a handle
- Kelly clamps, large and medium
- Chest tubes, sizes 12 to 42 French
- Sterile water
- Chest tube drainage apparatus with a water seal
- Christmas tree connector
- Suction source and tubing
- Needle driver
- Mayo scissors, large curved
- Size 0 or 1-0 suture, silk or nylon
- Petrolatum-impregnated gauze
- 4 × 4 gauze squares
- Adhesive tape, 3 to 4 in. wide
- Sterile drapes
- Sterile gloves and gown
- Face mask with a face shield or goggles
- Tincture of benzoin spray or swabs
- 0.25% bupivacaine

Most hospitals and Emergency Departments have prepared their own "chest tube trays" that contain all the equipment required to place a chest tube except the chest tubes, local anesthetic solution, and a collection system. These last three items will vary based on the etiology of the air and/or fluid in the pleural cavity, the age and size of the patient, and physician preference. Commercially produced chest tube kits are also available (e.g., Atrium Medical Corp., Hudson, NH and Centurion Medical Products, Howell, MI).

Chest tubes used in the Emergency Department are hollow, clear, straight plastic tubes (**Figure 39-1**). The distal end of the chest tube

FIGURE 39-1. The chest tube. The proximal end is beveled while the distal end is fenestrated.

has numerous fenestrations or holes that allow the passage of air and/or fluid into and through the tube. A radiopaque stripe allows for radiographic localization of the chest tube after it is inserted into the patient. The proximal end of the chest tube is beveled to allow it to fit better on a plastic connector.

Chest tubes are available in numerous sizes and from multiple manufacturers. The lower the number, the smaller the size of the chest tube. A spontaneous pneumothorax may be drained with an 18 to 26 French tube in adults, a 14 to 16 French tube in children, a 12 to 16 French tube in infants and small children, and an 8 to 12 French tube in neonates. Traumatic pneumothoraces are usually drained with a 32 to 36 French tube in adults and a 16 to 20 French tube in children. Traumatic hemothoraces, traumatic hemopneumothoraces, and empyemas require larger-size tubes. A 36 to 42 French tube in adults and a 20 to 24 French tube in children will provide adequate drainage without becoming occluded by blood clots or purulent material.

The procedure requires the use of a large Kelly clamp to bluntly dissect a subcutaneous tract as well as to puncture and dilate a tract through the intercostal muscles. The Kelly clamp requires the Emergency Physician to pull the ringed handles apart and in opposite directions to open the jaws of the clamp. Opening the jaws of the Kelly clamp when it is within the subcutaneous tissues or intercostal muscles can be quite difficult. A new clamp, the Centurion Blunt Dissector (**Figure 39-2**), was specifically designed to aid in the insertion of a chest tube (Centurion Medical Products, Howell, MI). The mechanical action of this new clamp is opposite that of the Kelly clamp. In the resting position, the jaws are closed and the ringed handles are held open with a spring mechanism. To open the jaws of the clamp, the ringed handles are squeezed together. This is a more natural, intuitive, and easier motion to perform. This chest tube clamp is disposable and available individually or incorporated into a chest tube insertion tray.

DRAINAGE SYSTEMS

It is important to know how to use the drainage system available at your institution to prevent any complications arising from the use of these devices. The classic glass bottle system with rubber corks is rarely, if ever, used in the United States today in the Emergency Department. Commercially available drainage systems are currently available in most hospitals (**Figure 39-3**). They are made of lightweight plastic, sterile, and intended for single-patient use. They are preassembled, disposable, and also may be used for autotransfusions. They have clear plastic covers to allow easy visualization of the fluid within the unit.

FIGURE 39-2. The Centurion Blunt Dissector (Photo courtesy of Centurion Medical Products, Howell, MI).

FIGURE 39-3. A commercially available chest tube drainage system.

The system is a single unit that consists of three or four chambers, depending on the manufacturer. The first chamber connects to the chest tube with flexible rubber tubing. It collects blood clots and/or other fluid expressed through the chest tube. The second chamber is the water seal. It allows one-way flow of air away from the patient and maintains a negative intrathoracic pressure gradient compared to the atmosphere. The third chamber is the suction regulator, which attaches to the wall suction. It draws in atmospheric air when needed to limit the negative pressure of the vacuum. Some manufacturers have included a fourth chamber to assess the patient's intrapleural pressure (e.g., Sentinel Seal, Sherwood Medical, Ireland).

PATIENT PREPARATION

Explain the risks, benefits, complications, and aftercare to the patient and/or their representative if time and the patient's clinical condition permit. Obtain an informed consent for a tube thoracostomy or document in the medical record the verbal discussion whenever possible. It should be understood that following trauma, a tube thoracostomy is often performed under urgent or emergent conditions. Lifesaving care should always proceed on the patient's

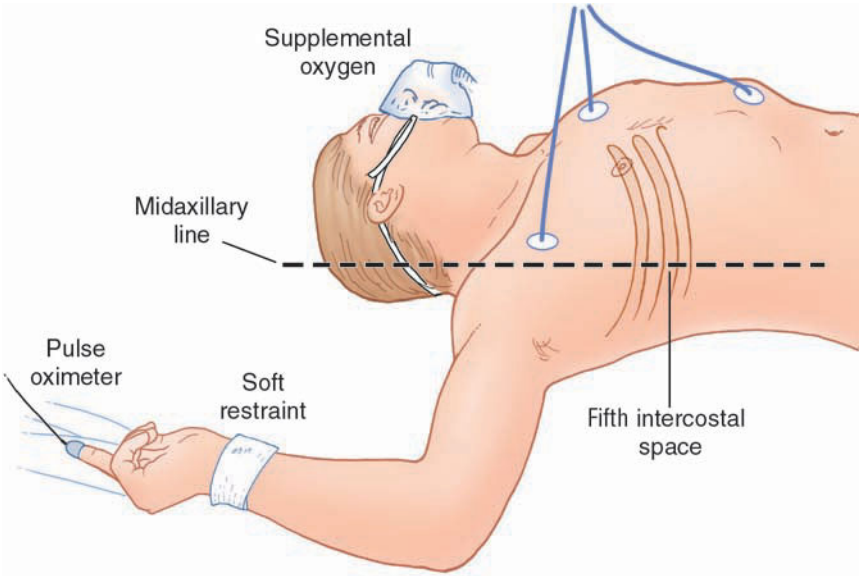

FIGURE 39-4. Patient positioning for a tube thoracostomy. Note the application of supplemental oxygen, pulse oximetry, cardiac monitoring leads, and a soft restraint.

behalf with the appropriate documentation in the medical record after the patient is resuscitated.

In recent years, there has been considerable discussion in the literature regarding the use of antibiotics in patients requiring a tube thoracostomy for trauma in the hope of preventing an empyema.[12–14] The Eastern Association for the Surgery of Trauma (EAST) practice management guidelines work group reviewed the literature regarding the use of antibiotics in conjunction with chest tube insertion. They found several trials, including four double-blinded, randomized trials that evaluated infectious complications after a tube thoracotomy using Centers for Disease Control (CDC) criteria. The studies each had their weaknesses. Despite these weaknesses, the working group recommended that there was sufficient class 1 and class 2 evidence to support a recommendation of administering a first-generation cephalosporin intravenously just before making the skin incision and continuing the intravenous antibiotic for 24 hours.[15]

If not contraindicated, the administration of parenteral analgesics, sedatives, and/or procedural sedation (Chapter 129) will be greatly appreciated by the patient, as the procedure is quite painful. Appropriate protocols for patient monitoring should be employed. At minimum, the patient should have supplemental oxygen applied, continuous pulse oximetry, and frequent checks of vital signs. Continuous cardiac monitoring should also be employed and monitored.

Place the patient supine or semierect with the arm on the involved side raised away from the chest (**Figure 39-4**). Identify the fifth ICS in the mid-to-anterior axillary line (**Figure 39-4**). Consider marking this point on the patient's skin with a pen or marking pen. A soft restraint may be placed around the wrist to prevent the arm from moving during the procedure. Apply povidone iodine or chlorhexidine solution to the chest wall and allow it to dry. Apply sterile drapes to demarcate a sterile field. **Sterile technique should be observed and followed by all involved personnel, who should be fully capped, gowned, masked, and gloved.**

Reidentify the fifth ICS in the mid-to-anterior axillary line (Figure 39-4). This is the preferred site for chest tube insertion. The reasons for this are twofold. The diaphragm rises during respiration to the level of the nipple. Chest tube insertion below the fifth ICS unnecessarily risks puncture of the diaphragm or abdominal organs. The area of the midaxillary line is the least muscular area of the chest wall and is thus an easier area from which to gain access to the pleural cavity.[1–3]

If the patient is awake and aware of their surroundings, infiltrate local anesthetic solution into the chest wall and pleural cavity. This should be performed regardless of whether the patient receives parenteral analgesics, sedatives, and/or procedural sedation. Approximately 10 to 20 mL of local anesthetic solution with epinephrine (e.g., lidocaine or bupivacaine) is required to provide adequate analgesia. Consider using bupivacaine as it provides longer analgesia than lidocaine. Be aware of the maximum weight based volume of local anesthetic solution to administer to prevent toxicity (Chapter 123). Raise a subcutaneous wheal of local anesthetic solution one interspace below the one to be used to insert the chest tube (i.e., the sixth ICS). Infiltrate local anesthetic solution subcutaneously and upward to a point above the fifth ICS. Redirect the needle to anesthetize the intercostal muscles and parietal pleura of the fifth ICS. Advance the needle into the pleural cavity and inject 2 to 3 mL of local anesthetic solution to adequately anesthetize the pleura (**Figure 39-5**).

TECHNIQUE

The technique described here is an "open" technique, as opposed to that employing the use of a trocar. Trocar-aided insertion of chest tubes is associated with a higher incidence of major complications

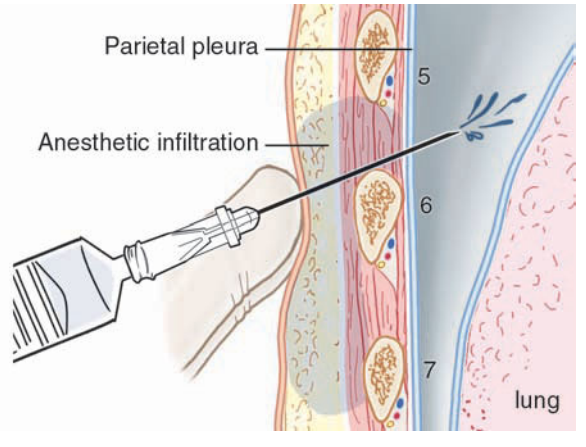

FIGURE 39-5. Infiltration of local anesthetic solution into the chest wall and pleural cavity.

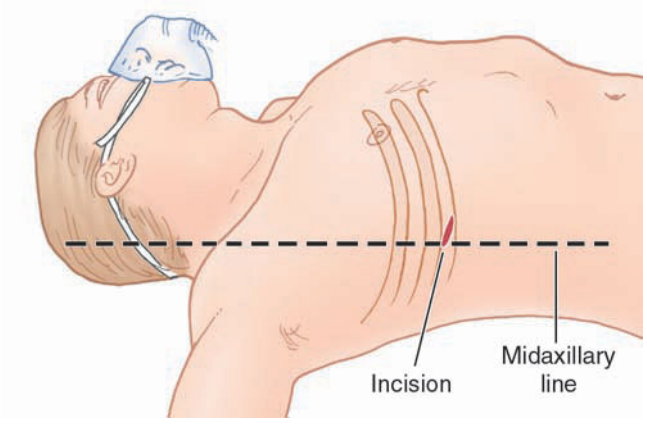

FIGURE 39-6. The initial skin incision is made over the rib one interspace below the desired chest tube insertion site.

and does not result in any significant saving of time.[1–3] **For these reasons, a trocar should never be used.**

Make a 3 to 5 cm incision with the #10 scalpel blade over the rib one ICS below (i.e., the sixth ICS) the desired ICS (**Figures 39-6 & 39-7A**). Bluntly dissect a tract or tunnel with the 6 in Kelly clamp in the subcutaneous tissue in a cephalic direction to the rib above. Orient the clamp with the tips curved toward the skin. Advance the closed tips of the clamp in 1 cm increments and open the jaws to dissect the tract (**Figure 39-7B**). The tract should terminate at the upper border of the fifth rib. **This will avoid injury to the neurovascular bundle lying under the inferior border of the rib.** Rotate the clamp 180° such that the tip is aimed just above the superior border of the fifth rib and toward the pleural cavity. Briskly push the closed tips of the clamp through the intercostal muscles and parietal pleura and into the pleural cavity (**Figure 39-7C**). **This maneuver requires a significant amount of force to enter the pleural cavity.** A twisting motion as the clamp is advanced may facilitate penetration into the pleural cavity. If the clamp is advanced slowly, the intercostal muscles will stretch and entering the pleural cavity will be difficult.

A loss of resistance associated with a rush of air or fluid should occur as the pleural cavity is entered with the closed tips of the clamp (**Figure 39-7C**). If under pressure, the fluid contained within the pleural cavity may exit the tract forcibly. **It is important not to plunge too deeply with the clamp as the pleural cavity is entered.** The tips of the clamp can injure the diaphragm, great vessels, heart, or lung. The forward motion of the clamp can be partially opposed by bracing the nondominant hand on the underside of the clamp and applying counterpressure away from the patient as the clamp enters the pleural cavity.

Spread the jaws of the clamp to enlarge the tract through the subcutaneous tissue, intercostal muscles, and parietal pleura. Insert a finger through the tract and into the pleural cavity (**Figure 39-7D**). The lung should be felt as it expands with inspiration and contracts with expiration. Rotate the finger to ascertain the presence or absence of adhesions. Gently break any loose adhesions between the lung and thoracic cage with the finger. Dense adhesions require the chest tube to be inserted at another site.

Prepare to insert the chest tube. Estimate the distance from the skin incision to the apex of the lung by laying the chest tube over the patient. Apply a clamp onto the chest tube at the estimated site at which it should exit the skin incision. This location should be 4 to 5 cm proximal to the fenestrations in the chest tube. Cut off the beveled proximal end of the chest tube just above the bevel.

Grasp and clamp the tips of the large Kelly clamp onto the distal end of the chest tube. Insert the tips of the clamp and chest tube

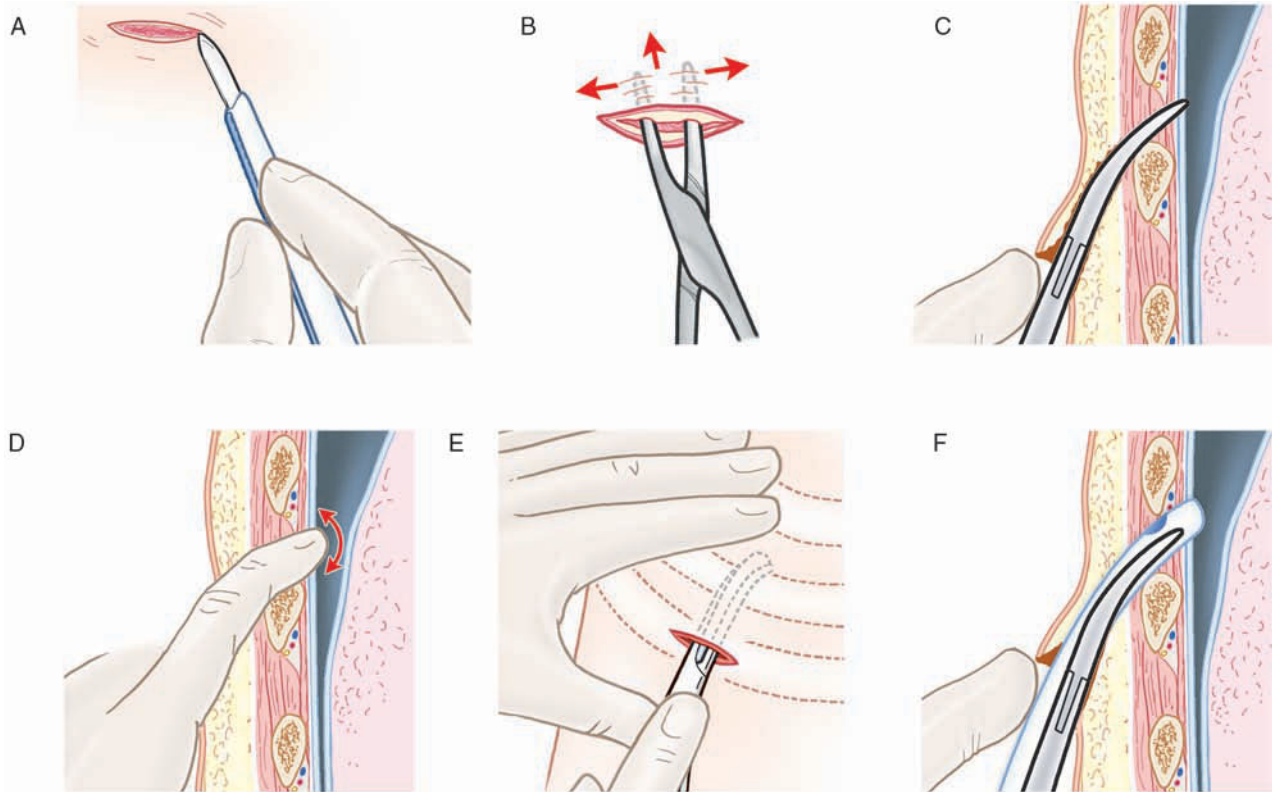

FIGURE 39-7. The tube thoracostomy. **A.** The skin incision is made. **B.** A tract is bluntly dissected in the subcutaneous tissues. **C.** The Kelly clamp is forced into the pleural cavity. **D.** A finger is inserted through the tract to feel for adhesions. **E.** The chest tube is held in the Kelly clamp and inserted through the tract. **F.** The chest tube is guided into the pleural cavity.

through the tract and into the pleural cavity (**Figures 39-7E & F**). Use the clamp to direct the tip of the chest tube posteriorly and superiorly. Alternatively, the dominant index finger can be placed through the tract to direct the chest tube. The use of the finger in the tract is the preferred method to guide the chest tube. The finger will be able to confirm the proper intrapleural placement of the chest tube. Release the Kelly clamp and advance the chest tube until all the fenestrations are within the pleural cavity and the preplaced clamp on the chest tube is at the skin incision. Hold the chest tube securely in place. Remove the Kelly clamp from the incision. Release the clamp on the chest tube.

Secure the chest tube with 0 or 1-0 silk or monofilament nylon suture (**Figure 39-8**). The many techniques that have been described for securing chest tubes are idiosyncratic and probably equivalent. Suffice it to say that the tube should be sewn in such a way that the incision is closed fairly tightly around the tube to assure a better seal and that routine movements of the patient should not dislodge it.

Place the first stitch as a simple interrupted stitch at one end of the skin incision (**Figure 39-8A**). Leave both ends of the suture long after tying the knot in the first stitch. Wrap the needle end of the suture firmly around the chest tube three or four times. Tie a knot in the suture to secure the chest tube to the skin (**Figures 39-8A & 9A**). Place the second stitch as a purse-string suture encompassing the chest tube (**Figure 39-8B**). Leave both ends of the suture long. Wrap both ends of the suture around the chest tube and tie a bow, not a knot. This stitch will be used later to close the skin incision after the chest tube is removed. Place simple interrupted or horizontal mattress sutures to close the remainder of the skin incision.

Apply an occlusive dressing over the incision site (**Figure 39-9B**). Apply petrolatum gauze over the incision site and around the chest tube as it exits the incision. Place gauge squares over the incision site. Apply tincture of benzoin to the chest wall surrounding the gauze squares. Tape the gauze and chest tube to the torso. The ends of the tape should be adherent to the tincture of benzoin. **Do not place tape over the patient's nipple. If the tape must cover the nipple, protect it with a piece of gauze.**

An alternative to the above dressing is a new product, the Centurion Chest Tube Anchor (Centurion Medical Products, Howell, MI). This is a sterile, adherent patch that surrounds the chest tube as it exits the skin (**Figure 39-10**). It forms an occlusive dressing. It has an attached cable tie to wrap around the chest tube and secure it in place. This cable tie replaces suturing the chest tube in place. The device can be trimmed to a smaller size for pediatric patients. The cable tie will secure all sizes of chest tubes.

Connect the chest tube to a drainage system (**Figure 39-11**), which is a self-contained multichamber device.[3] The first chamber is a collecting chamber that connects directly to the chest tube. The second chamber contains a small amount of saline or water and acts as a one-way valve. This assures flow only in the direction away from the patient. The third chamber controls suction, with a capability of at least 20 cm of water suction, and attaches to the wall suction system. Commercially available systems encompass all three chambers in one unit.

ASSESSMENT

Obtain an anteroposterior portable chest radiograph. Observe the position of the chest tube. Remove the chest tube and insert a new one if it is bent, kinked, or in the fissure of the lung. If its tip is against

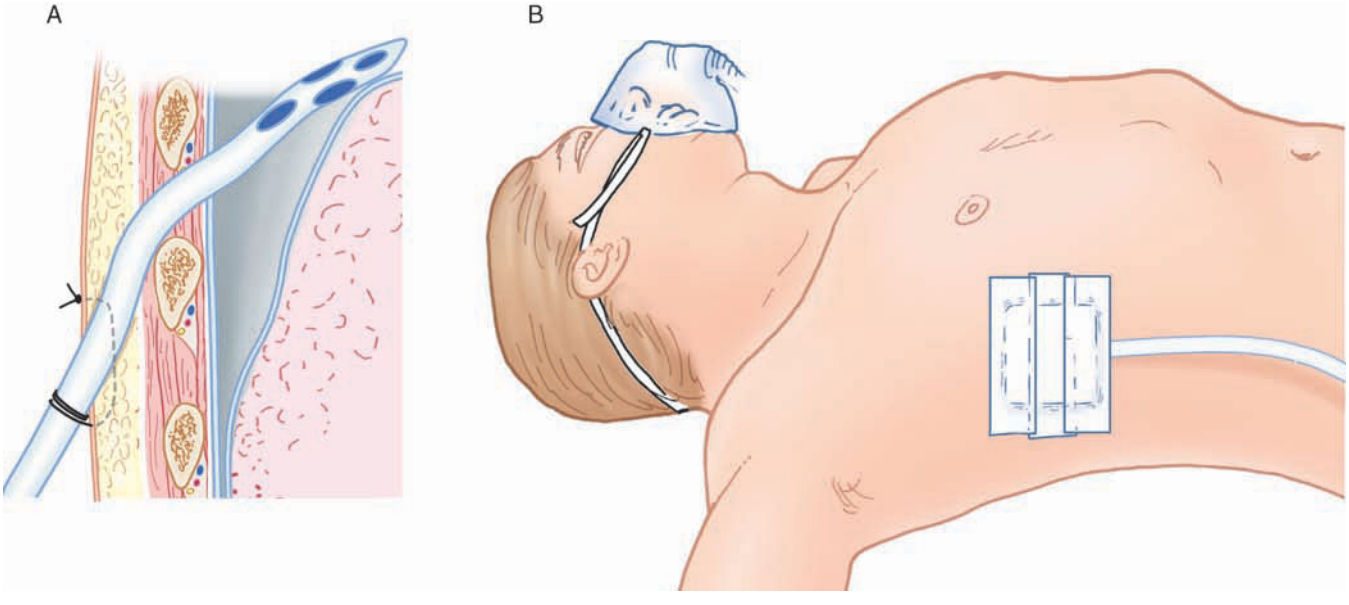

FIGURE 39-9. Securing the chest tube. **A.** The chest tube has been secured with suture to the chest wall. **B.** An occlusive dressing has been placed over the incision and taped to the chest wall.

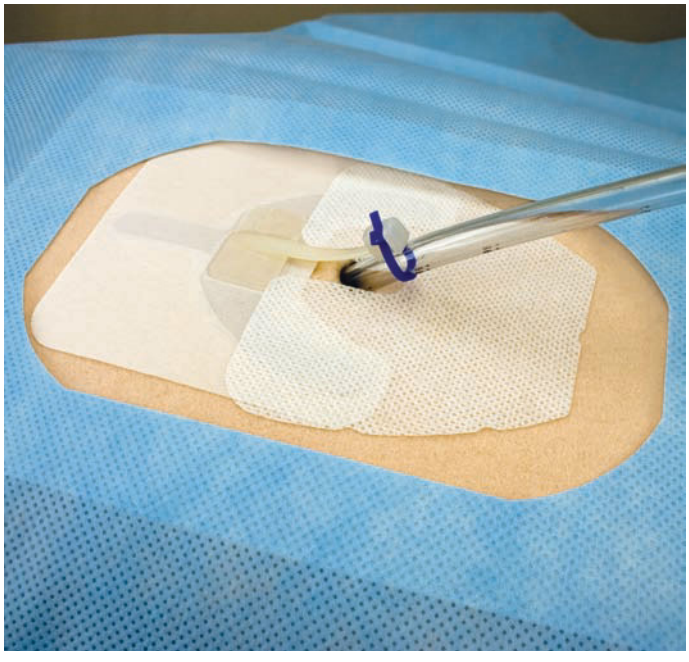

FIGURE 39-10. The Centurion Chest Tube Anchor (Photo courtesy of Centurion Medical Products, Howell, MI).

the mediastinum, unsecure the tube, withdraw it a few centimeters, resecure the tube, and obtain a repeat radiograph. If the chest tube is located in the subcutaneous tissue, remove it and insert a new one. Observe the fenestrations on the distal end of the chest tube in the radiograph. They all must be within the thoracic cavity. If not, remove the chest tube and insert a new one. **Never advance a chest tube further into the thoracic cavity after obtaining a chest radiograph, as this may track infectious material into the pleural cavity.**

Persistent bubbling in the system or failure of the lung to reexpand indicates a leak in the system. Check the system to ensure that all connections are secure. Place tape over the connections to eliminate leaks and prevent the components from becoming dislodged. Check the tubing for any holes or fissures. Examine the chest tube and the radiograph to confirm that all fenestrations are within the thoracic cavity. If not, replace the chest tube. An injury to the trachea, mainstem bronchus, a large bronchiole, or the esophagus can cause a persistent air leak. Insert a second chest tube to keep up with the leak and prepare the patient for bronchoscopy and/or esophagoscopy to diagnose the etiology of the persistent air leak.

AFTERCARE

Patients with chest tubes require close monitoring. If administered, continue prophylactic antibiotics for 24 hours. Obtain daily serial chest radiographs to monitor for resolution of the inciting process. The presence of air leaks from the chest tube indicates that the injury has not completely healed and the seal between the parietal and visceral pleurae has not yet been restored. Suction should be maintained until there is no evidence of an air leak. The acceptable minimal daily output from a chest tube as a criterion for removal varies according to the institution, the physician, and the reason for insertion. It is also unclear whether a trial period of water seal following suction is strictly necessary. There is literature to suggest that both suction and water seal protocols for removing chest tubes are effective and have similar incidences of recurrent pneumothoraces.[16] However, there is also literature supporting an abbreviated trial of water seal following suction, as it may allow time for occult pneumothoraces to manifest themselves and thus alleviate the need for reinsertion of a chest tube.[17] The chest tube insertion site should be monitored for signs of infection.

The chest tube and collection tubing should be checked periodically for blockage. If blocked, the tubing may be milked or stripped to alleviate the blockage and avoid the need to replace the chest tube. Milking refers to forcing air, fluid, or clots back into the chest. Stripping refers to creating negative pressure within the tubing to move fluid or clots distally and into the collecting chamber. To milk the tube, clamp or pinch the tubing shut distally while using the other hand to compress the tubing and move proximally to force the contents back into the thoracic cavity. To strip the tube, clamp or pinch the tubing shut proximally while using the other hand to compress the tubing and move distally followed by the sudden release of the proximal tubing.

CHEST TUBE REMOVAL

In planning to remove a chest tube, one must be prepared to replace it. All the necessary equipment and supplies should be readily available in case the patient urgently requires a new chest tube. The physician should wear gloves, a gown, a face mask with an eye shield

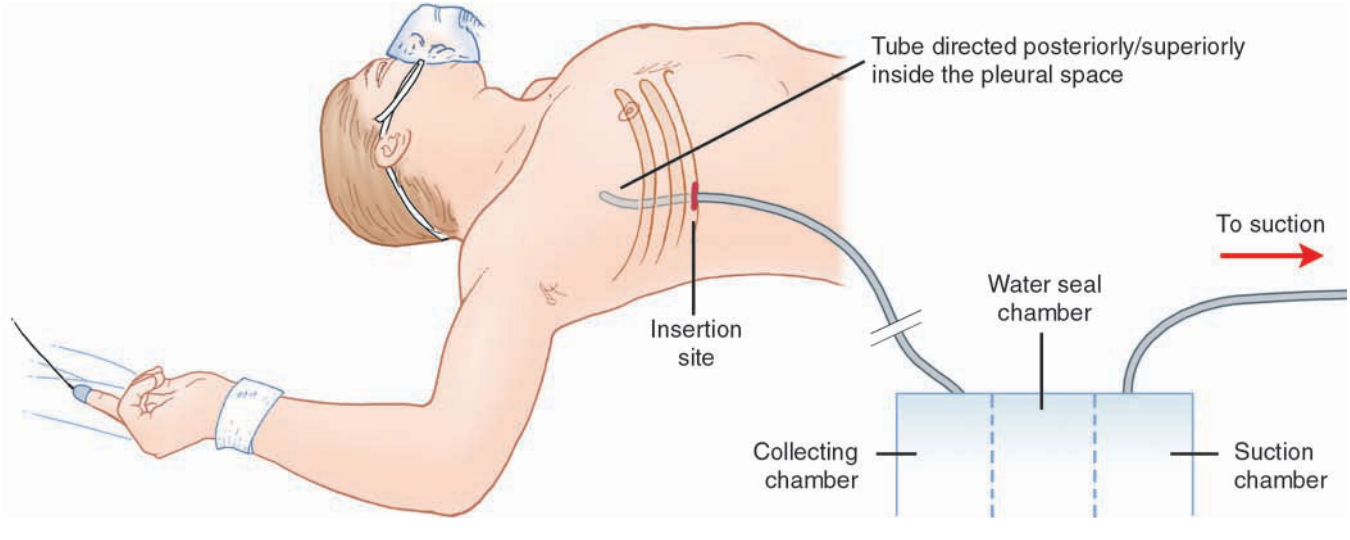

FIGURE 39-11. The chest tube is connected to a drainage system.

or goggles, and a cap to prevent becoming contaminated when the chest tube is removed.

Place the patient supine or semirecumbent. The use of parenteral sedation and soft restraints is rarely necessary when removing a chest tube. Carefully remove the tape securing the chest tube to the chest wall. Be cautious when removing the tape if it covers the patient's nipple, so as to prevent any injury. Remove the gauze squares and petrolatum gauze covering the incision site. Untie the bow securing the free ends of the purse-string suture that was previously placed. Cut the suture that is holding the chest tube to the chest wall. Remove this suture. Place the first half of a surgeon's knot in the free ends of the purse-string suture. Pass the ends of the suture to an assistant. **Instruct the patient to inhale or exhale fully and hold their breath.[18] This results in a Valsalva-type maneuver, and will prevent ambient air from being drawn through the chest wall and into the pleural cavity**. Quickly and smoothly remove the chest tube while the assistant cinches down the knot of the suture to seal the skin incision. Tie additional knots to secure the purse-string suture. Place petrolatum jelly or topical antibiotic ointment over the incision. Cover the site with gauze squares and tape it securely.

Observe the patient for 4 to 6 hours for any signs of cardiovascular or respiratory compromise. If the patient remains asymptomatic, obtain expiratory posteroanterior and lateral chest radiographs. Evaluate the radiograph for the recurrence of the pneumothorax, hemothorax, pyothorax, and/or hydrothorax. The dressing may be removed in 24 to 48 hours. Remove the chest wall sutures in 8 to 10 days.

COMPLICATIONS

Tube thoracostomy is often described as a simple procedure. But if it is not performed with care and attention, it can result in serious complications, including injuries to thoracic and abdominal organs.[1,2,19] An unusual occurrence of sudden death following chest tube insertion has been reported.[20] It was attributed to hemorrhage near the vagus nerve, causing irritation and stimulation of the vagus nerve and refractory bradycardia. Injury to the thoracic duct from the chest tube being inserted too deeply can result in a chylothorax.[21] Injury to the heart and great vessels can occur if the chest tube is placed anteriorly or a trocar was used to insert the chest tube. Lung injury can occur if the clamp plunges inward on entering the pleural cavity. **It is imperative that the Kelly clamp be controlled as it enters the pleural cavity.** If the lung is adherent to the chest wall, it may be penetrated by the Kelly clamp or the chest tube. **A trocar should never be used to insert a chest tube, as it can cause significant injury to the heart, lung, or other intrathoracic structures.**

Other complications associated with chest tube placement and removal include recurrent, residual, and loculated pneumothoraces. These may require the placement of additional chest tubes. A retained hemothorax may require decortication and may develop into an empyema.[4,22,23]

Posttraumatic empyema remains a serious complication of thoracic trauma with incidences ranging from 2% to 25%.[1,2,4,23] The etiology of the infection is not always clear. A break in sterile technique on chest tube insertion, nosocomial pneumonia, superinfected pulmonary contusion, and undrained hemothoraces have all been implicated. Empyemas that can be attributed to the chest tube insertion process are completely preventable complications that can be avoided by strict adherence to aseptic technique.

Bleeding can occur from several sites. Incision site bleeding is often due to superficial venules and arterioles. The application of pressure and the suturing of the incision closed will alleviate this bleeding in most cases. If the dissection or penetration into the pleural cavity occurs along the inferior surface of a rib, an intercostal artery or vein can be lacerated. Securing the chest tube against the inferior surface of the rib may tamponade the bleeding. If the bleeding continues, attempt to tamponade it with a Foley catheter. Insert the catheter into the pleural cavity, inflate the cuff, and withdraw the catheter to lodge the cuff against the posterior surface of the rib. Another option is to extend the incision to expose and ligate the bleeding vessel. Lung injury and bleeding from penetration into the pleural cavity are often self-limited and minor. Rarely will an injury be serious enough to warrant surgical intervention. **A trocar should never be used, as risk of injury to intrathoracic structures is significantly increased.** An anteriorly placed chest tube should be at least 3 cm from the lateral border of the sternum to prevent injury to the internal mammary artery.

The chest tube can become occluded and stop functioning. A large tube should always be inserted if its purpose it to drain blood, clots, or purulent material. Attempt to milk and/or strip the tubing, as described previously. Obtain a chest radiograph to determine if the chest tube is kinked. Twist the chest tube 180° and release it. If it spins back into its original position, it is kinked.[24] If the occlusion cannot be dislodged or the tube is kinked, the chest tube should be removed and a new one inserted.

Subcutaneous emphysema results from air from an inadequately decompressed pneumothorax that tracks into the subcutaneous tissues. Ensure that the chest tube, drainage system, and suction source are functioning properly. Replace any component that is not functioning. Verify that the chest tube is within the pleural cavity and not within the subcutaneous tissues using either plain chest radiography or ultrasound.[25] Evaluate the chest radiograph to ensure that all of the drainage holes are within the pleural cavity and not in the subcutaneous tissues.

Reexpansion pulmonary edema occurs from the rapid expansion of a lung that has been collapsed for over 48 to 72 hours or from the removal of a large pleural effusion.[26,27] Patients will begin to experience increasing shortness of breath and hypoxemia within a few hours of the procedure. Repeat chest radiographs will show an expanded lung with pulmonary edema. The exact etiology of this complication is unknown. This complication may be prevented by the slow expansion of a lung and the removal of pleural fluid in increments. Treatment includes supportive care, supplemental oxygenation, and positive-pressure ventilation (i.e., BiPAP, CPAP, and/or intubation). Diuretics have no role in relieving the edema. Reexpansion pulmonary edema has an associated mortality rate of up to 20%.[27]

The sources of pain for a patient with a tube thoracostomy are numerous. These include the skin incision, subcutaneous dissection, intercostal muscle transection, the chest tube, and the underlying injury. Pain can often be managed with parenteral analgesics and sedation. Intrapleural bupivacaine has been found to be effective in reducing pain.[28,29] Administer 20 to 40 mL of 0.25% bupivacaine through the chest tube and into the pleural cavity. Clamp the chest tube or the tubing for up to 10 minutes to allow the bupivacaine to thoroughly coat the pleural cavity. **Carefully monitor and observe the patient to ensure that they do not develop a tension pneumothorax while the chest tube is clamped.** Unclamp the chest tube and allow the excess anesthetic to drain into the collection system. This can provide several hours of pain relief to a patient who may have limits on or contraindications to parenteral analgesics.

SUMMARY

Tube thoracostomy is useful in the treatment of thoracic injuries resulting in pneumothoraces, hemothoraces, hydrothoraces, and chylothoraces. Attention must be paid to observe sterile technique, choose the proper insertion site, carefully enter the pleura, and verify entry via digital exam. Appropriate drainage systems should be employed to assure maintenance of a closed, water-tight system.

Monitor the patient regularly while the chest tube is in place. Emergency Physicians performing this procedure should be cognizant of the serious complications that may be associated with tube thoracostomies, some of which are directly related to the insertion technique. Adherence to the principles described above will assist in avoiding many of these complications and provide optimal care for victims of thoracic trauma.

40 Thoracentesis

Eric F. Reichman, Cristal R. Cristia, and Jehangir Meer

INTRODUCTION

Thoracentesis is a term derived from the Greek meaning "to pierce the chest." It is used today to refer to the removal of air or fluid from the thoracic cavity. Accumulation of pleural fluid is not a specific diagnosis but rather a reflection of an underlying process. In almost all newly discovered pleural effusions, thoracentesis should be performed to aid in the diagnosis and management of the underlying etiology.

Hippocrates first described thoracentesis in the management of an empyema.[1] Thoracentesis was used widely in World War II and the Korean conflict in lieu of a thoracotomy for chest drainage. By the time of the Vietnam War, this practice was replaced by tube thoracostomy. Today, thoracentesis is used in the diagnosis and therapy of pleural effusions, emergent and temporizing treatment of a tension pneumothorax, and the management of small, nontraumatic pneumothoraces.[1–4]

A pleural effusion can be identified clinically and radiologically. Clinically, the patient may develop pain related to irritation of the parietal pleura, compromised pulmonary mechanics, or interference with gas exchange.[3] The pain may be located in the chest, abdomen, or ipsilateral shoulder. Another common symptom is a cough; its mechanism is unclear. Dyspnea occurs secondary to the space-occupying effect of the fluid and alterations in gas exchange. In extreme cases, pleural effusions can reduce cardiac output. On physical examination, tactile fremitus is absent or attenuated and there is dullness to percussion. Auscultation reveals decreased breath sounds on the involved hemithorax.

Radiographically, on a posteroanterior (PA) chest radiograph, an effusion can be diagnosed when there is homogeneous opacification in the hemithorax, absent air bronchograms, and clouded vesicular vascular markings. In a cadaveric study, the minimum fluid volume needed to blunt the costophrenic angle was 175 mL.[5] More than 500 mL had to be injected into some cadavers to blunt the costophrenic angle.[5] In a study on mechanically ventilated patients, ultrasound consistently identified nonloculated pleural effusions when the effusion was at least 500 mL.[6] A lateral decubitus film is often necessary and will determine whether the fluid is loculated or free-flowing. It will also be helpful if one of the following signs is present on the PA chest radiograph: a clear costophrenic angle, an elevated hemidiaphragm, a blurred contour of the diaphragmatic dome, or the gastric bubble seen more than 2 cm from the lung border in patients with left-sided pleural effusions.[2] If the fluid collection is 10 mm thick on the lateral decubitus film, thoracentesis can most likely be performed using clinical skills to locate the fluid.[7] If it is less than 10 mm thick, ultrasound may be needed for localization.[3]

The use of ultrasound is no longer limited to Radiologists. With proper training, Emergency Physicians can utilize ultrasound for thoracentesis procedural guidance. The portable AP (anteroposterior) radiograph cannot always reliably distinguish between a pleural effusion, a pneumonia, or atelectasis.[8] In these indeterminate cases, ultrasound can be clinically useful. Pleural fluid can be identified as a black hypoechoic area, which appears darker than the surrounding lung, diaphragm, and liver. Ultrasound can aid in the identification of small effusions. Thoracentesis performed blindly has an associated complication rate of up to 30%.[9] Ultrasound allows the Emergency Physician to map the pleural effusion and choose the best site for thoracentesis, thereby reducing the rate of pneumothoraces to less than 3%.[10–14] Ultrasound guidance has been shown to be very safe in assisting with thoracentesis in intubated and mechanically ventilated patients, both high-risk populations for complications.[12,15]

A pneumothorax may be simple or under pressure (also known as tension). A simple pneumothorax may present clinically with chest pain, dyspnea, hypoxia, and tachycardia. Physical examination may reveal, on auscultation, decreased breath sounds on the affected side. Performance of a thoracentesis to relieve a tension pneumothorax is based on the mechanism of lung injury, the patient's symptoms, and physical examination findings. Mechanisms of injury to the lung include mechanical ventilation, chest trauma, instrumentation of the chest, and spontaneous lung rupture. Classically, the patient has a clinical presentation of hypotension, tachycardia, and absent breath sounds on the affected side. Other symptoms may include a deviated trachea, acute change in mental status, air hunger, chest pain, cyanosis, diaphoresis, hypoxia, and cardiorespiratory arrest.[1,4] Sometimes a patient with a tension pneumothorax may have a normal physical examination due to subtle auscultation findings often missed in a noisy Emergency Department. Tactile fremitus may be absent and percussion is typically hyperresonant over the hemithorax with the tension pneumothorax.

There are two major indications for performing a thoracentesis.[1–3,6] The first is for the evacuation of air. This includes a simple pneumothorax and the emergent diagnosis and temporizing treatment of a tension pneumothorax. The second is for the evacuation of fluid. This may be done to help diagnose the etiology of pleural effusion or for the treatment of a symptomatic pleural effusion.

PLEURAL EFFUSIONS

ANATOMY AND PATHOPHYSIOLOGY

The pleura is a serous membrane that covers the lungs, mediastinum, diaphragm, and thoracic cavity. The pleural space is a potential space between the lung and the thoracic cavity. A thin layer of fluid normally exists between the visceral pleura covering the organs and the parietal pleura covering the chest wall. This fluid acts as a lubricant.[3] Pleural fluid originates from three sources: parietal capillaries, visceral capillaries, and the interstitium. Hydrostatic and oncotic forces govern the flow of fluid in the pleural space. These forces are summarized in **Figure 40-1**. In a healthy person, protein-free fluid enters the pleural space from the parietal pleura and is absorbed by the visceral pleura. Small amounts of protein then leak into the pleural space. Approximately 10% of the pleural fluid and large proteins are removed by the lymphatics at a rate of up to 20 mL/h for each hemithorax.[2] Ventilation and muscular activity facilitate the action of the lymphatics.[3]

Alterations in pleural fluid homeostasis will lead to a pleural effusion: a pathologic collection of excess fluid, located between the visceral and parietal pleura. Hydrostatic changes result in protein-free effusions (transudates). Changes in oncotic pressure (abnormality in the lung or pleura) lead to effusions. The differential diagnosis of transudates and exudates is listed in **Table 40-1**.

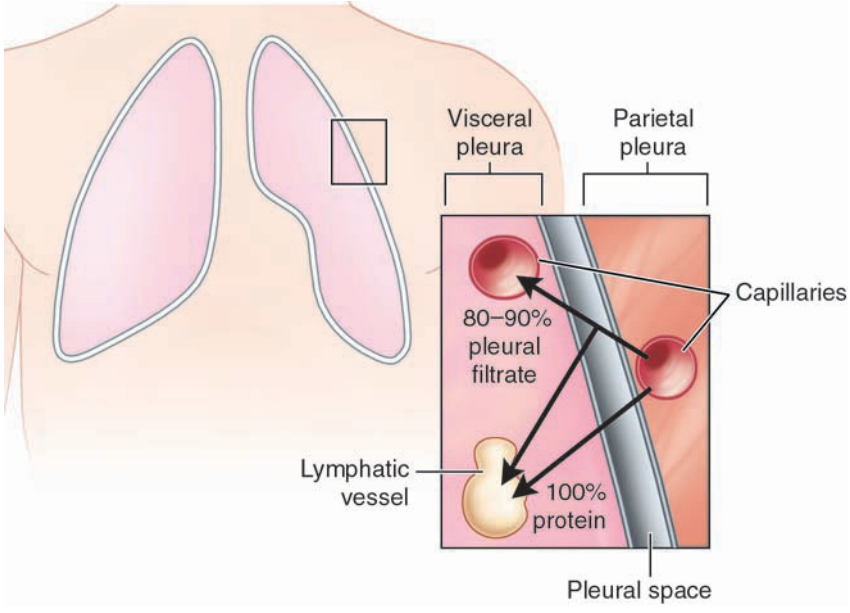

FIGURE 40-1. Schematic of pleural fluid homeostasis in a normal lung.

INDICATIONS

A thoracentesis may be performed to remove pleural fluid for analysis to diagnose the etiology of the fluid (e.g., malignancy, infection). It may also be performed to relieve the patient's symptom of dyspnea when a large pleural effusion interferes with normal respiration or results in respiratory compromise.

CONTRAINDICATIONS

The only absolute contraindications are an uncooperative patient or a patient who refuses to give informed consent for the procedure.[16] Uncooperative patients or patients with altered levels of consciousness may require sedation for the procedure.

There are numerous relative contraindications to performing a thoracentesis. Patients receiving anticoagulants, with a bleeding diathesis (whether known or suspected), or thrombocytopenia have a significant risk of bleeding.[2,16] Consider reversing the anticoagulant or the bleeding disorder prior to performing the thoracentesis. A small volume of pleural fluid may make the procedure difficult to perform and increase the risk of complications.[16] Patients undergoing positive-pressure ventilation (i.e., mechanical ventilator, BiPAP, or CPAP) are at an increased risk of developing a pneumothorax and a tension pneumothorax.[1] Although, one study has shown that a thoracentesis can be done as safely in a ventilator-dependent patient as in patients not being mechanically ventilated.[17] Pleural adhesions may limit the amount of fluid obtained or require multiple thoracenteses to drain the fluid.[1] Loculated pleural adhesions should be drained under ultrasound guidance. Areas of cellulitis or other infection on the chest wall should be avoided unless no alternate site can be identified for the procedure.[1,3] Unsupervised physicians with little or no experience should not perform this procedure, as the risk of complications is increased.[7] Patients with chronic obstructive pulmonary disease are at increased risk for complications.

TABLE 40-1 Differential Diagnosis of Fluid Exudates and Fluid Transudates in the Pleural Space

Exudates	Transudates
Asbestos exposure	Atelectasis
Collagen vascular disease	Cirrhosis of the liver with ascites
Drug-induced	Congestive heart failure
Empyema	Nephrotic syndrome
Esophageal rupture	Peritoneal dialysis
Idiopathic	Pulmonary embolism
Malignancy	
Pancreatitis	
Parapneumonic	
Pulmonary embolism	
Rheumatoid arthritis	
Systemic lupus erythematosus	
Thoracic duct exposure	
Trauma	
Tuberculosis	
Viral	

EQUIPMENT

Diagnostic Thoracentesis for Pleural Effusions

- Sterile gloves and gown
- Face mask with a face shield or goggles
- Local anesthetic solution, 1% to 2% lidocaine
- Heparin, 1000 U/mL
- Atropine, 1 mg
- Alcohol pads
- Povidone iodine or chlorhexidine solution
- Gauze 4 × 4 squares
- Sterile drapes
- Sterile towels
- Sterile gloves
- Band-aids
- 25 or 27 gauge needle
- 21 and 22 gauge needles, 1.5 in. long
- 10 mL syringes
- 50 mL syringe
- 18 or 20 gauge needle

Ultrasound Guidance

- Ultrasound machine
- 3.5 to 5.0 MHz phased-array ultrasound probe
- Sterile ultrasound gel
- Sterile ultrasound probe cover

Therapeutic Thoracentesis for Pleural Effusions

- The supplies listed above
- 16 to 18 gauge catheter-over-the-needle
- 14 to 18 gauge catheter-through-the-needle
- Three-way stopcock
- Connector tubing (connects to three-way stopcock and sterile container)
- Sterile container for pleural fluid
- 50 mL syringe
- Intravenous extension tubing

Commercial kits have been developed and are available to provide the equipment needed to perform a thoracentesis. The kits are disposable, intended for single-patient use, and contain the required equipment. They save time in that the equipment does not have to be found and set up. Disadvantages include potential increased cost and limited equipment in the kit.[18] Common kits include the Pharmaseal, distributed by Baxter (Jacksonville, TX); the Arrow Clark Thoracentesis Kit, distributed by Arrow (Reading, PA); the Argyle Turkel Safety Thoracentesis Kit, distributed by Boston Scientific (Miami, FL), and the Turkel Thoracentesis Kit, distributed by Tyco Healthcare (Mansfield, MA).[3]

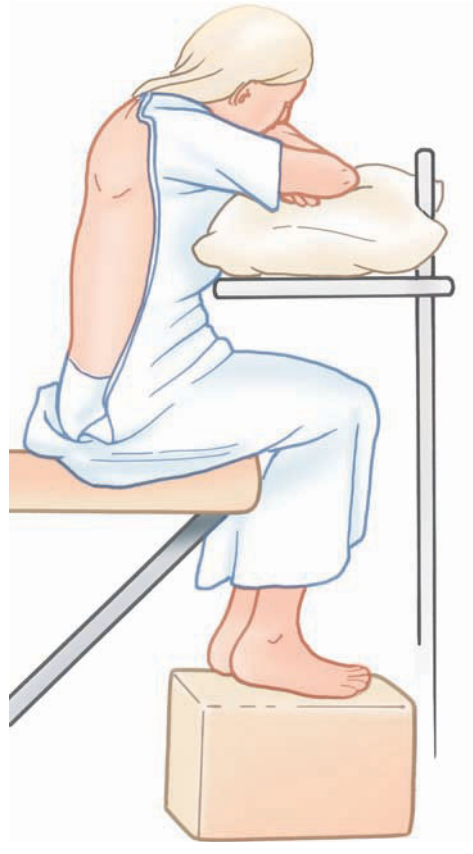

FIGURE 40-2. Recommended positioning of an ambulatory patient for a diagnostic or therapeutic thoracentesis for the evacuation of fluid.[2]

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative and obtain a signed consent form.[1] The position of the patient can vary depending on their clinical condition. Patients who are ambulatory and cooperative should sit up at the edge of a bed with their feet on the floor or a stool (**Figure 40-2**). Place the patient's head and arms on an elevated bedside tray. The patient's back should be as vertical as possible so that the lowest part of the hemithorax is posterior. This will ensure that the free-flowing fluid remains posteriorly.[1–3,16]

In debilitated patients, one of three other positions is recommended. Place the patient in the lateral decubitus position, lying on the side of the pleural effusion. The patient's back should be along the edge of the bed. The procedure would then be performed in the midscapular line or the posterior axillary line. Place a ventilator-dependent patient into the lateral decubitus position, lying on the side with the pleural effusion.[17] Second, place the patient supine and elevate the head of the bed as much as maximally possible. The patient would then be sitting with the assistance of the bed, and the procedure would be performed in midaxillary or posterior axillary line.[3] Finally, the patient can be placed supine. The procedure would then be performed at the posterior or midaxillary line. With the patient supine, ultrasonography may be required to locate the pleural fluid. Sedation or paralysis may be needed for optimal positioning depending on the patients clinical condition.

After positioning the patient, clean any dirt or debris from the skin. Identify the anatomic landmarks required to perform the procedure. After viewing the chest radiograph and estimating the amount of pleural fluid, percuss from superior to inferior starting at the midscapular or posterior axillary line. **The site chosen for aspiration should be a single interspace below the top of the dullness to percussion.**

If the fluid thickness is less than 10 mm on radiographs, ultrasound may be used to locate the fluid.[5,16] Alternatively, ultrasound can be routinely used to locate pleural fluid. Ultrasound has been shown to be comparable to CT for diagnosing and managing a pleural effusion.[19]

Although not required, some Emergency Physicians place the patient on the cardiac monitor, noninvasive blood pressure cuff, pulse oximetry, and supplemental oxygen to monitor them during and after the procedure. Apply povidone iodine or chlorhexidine solution to the skin surface and allow it to dry. Apply sterile drapes around the site of the procedure. If using an ultrasound-guided technique, be sure to fit the transducer with a sterile glove or probe cover before exposing the probe to the sterile skin. Use sterile ultrasound gel. Atropine should be at the bedside. It can be administered (1.0 mg subcutaneously or intramuscularly or 0.5 mg intravenously) to patients who develop symptomatic bradycardia during the procedure. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids as well as protect the patient from infection.

Place a skin wheal of local anesthetic solution over the thoracentesis site using a 25 or 27 gauge needle on a 10 mL syringe containing the local anesthetic solution. Remove the 25 or 27 gauge needle from the syringe. Apply a 21 or 22 gauge, 1.5 to 3.0 in needle to the syringe containing the local anesthetic solution. Anesthetize the subcutaneous tissues and the periosteum of the rib (**Figure 40-3**). Walk the needle up the rib while simultaneously injecting local anesthetic solution. Gently aspirate prior to injecting each time the needle is advanced to ensure that the needle is not within a blood vessel. When the superior border of the rib is located, slowly and

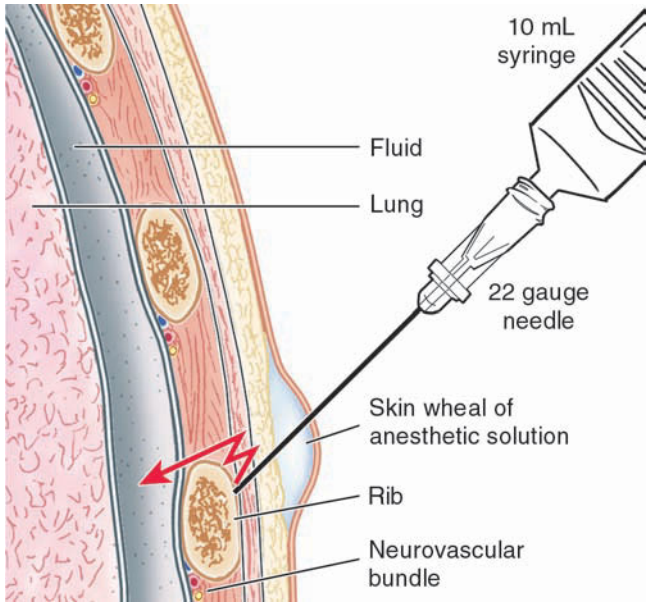

FIGURE 40-3. Administration of local anesthesia. A skin wheal is made. The needle is inserted through the skin wheal while local anesthetic solution is injected to anesthetize the subcutaneous tissues and the periosteum of the rib. The needle is "walked" above the upper border of the rib (red jagged line) to avoid the neurovascular bundle inferior to the rib. The intercostal muscles, parietal pleura, and pleural space are then infiltrated with local anesthetic solution.

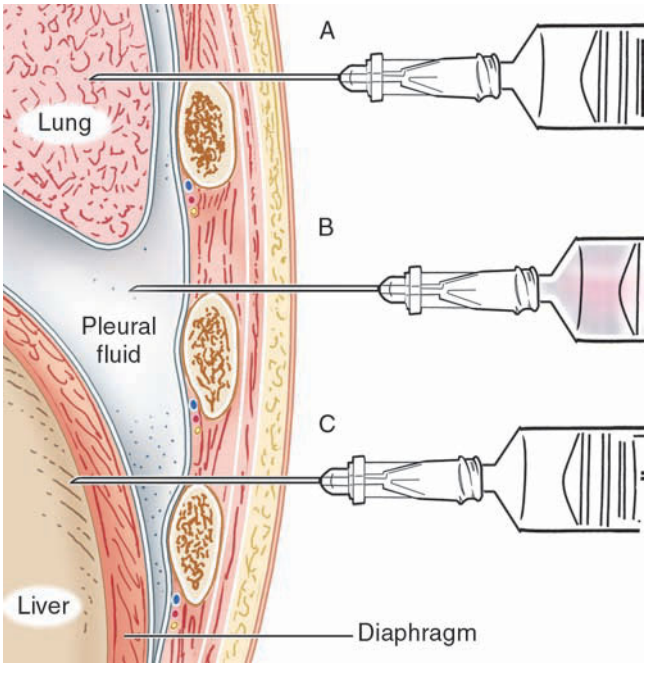

FIGURE 40-4. Needle positioning for a diagnostic thoracentesis. **A.** The pleural space is entered above the effusion (too high). **B.** The pleural space is entered properly, over the rib and into the fluid. **C.** The needle is too low and enters the abdominal cavity below the diaphragm.

carefully advance the needle over the rib while applying negative pressure on the syringe. Be sure not to insert the needle below the rib to avoid injury to the neurovascular bundle inferior to the rib. When the pleural space has been entered, fluid will flow into the syringe. Inject and aspirate small volumes (1 to 2 mL) while the needle is within the pleural cavity. This will distribute the local anesthetic solution into the pleural fluid and ensure anesthesia of the pleura. Withdraw the needle from the pleural cavity and out the skin.

DIAGNOSTIC THORACENTESIS TECHNIQUE FOR PLEURAL EFFUSIONS

Attach an 18 gauge needle to a 50 mL syringe containing 1 mL of heparin. The heparin will ensure accurate pH and cell counts as it prevents the fluid from clotting. Introduce the needle through the anesthetized track and into the pleural cavity (**Figure 40-4B**). Aspirate up to 50 mL of fluid. Withdraw the needle and place the fluid into the appropriate sterile containers. **Use proper techniques when transferring the fluid into containers or specimen tubes to prevent a needlestick injury.**

If pleural fluid cannot be aspirated, also known as a dry tap, four possibilities must be considered. The needle may be too short, positioned too high to reach the fluid (**Figure 40-4A**), positioned too low to reach the fluid (**Figure 40-4C**), or there may not actually be an effusion. Repeat the physical examination and review the chest radiograph to reconfirm the presence of a pleural effusion. Use ultrasound, if available, to assess the presence of a pleural effusion. Penetration of the lung with the needle is rarely catastrophic but can result in a pneumothorax.[3]

For debilitated patients, the principles are the same with the exception of the site for the procedure. If the patient is supine, use the midaxillary line or the posterior axillary line. Be cautious of the diaphragm, as it can be as high as the fifth interspace on expiration at the anterior axillary line. If the patient is in the lateral decubitus position, use the midscapular line or the posterior axillary line for the procedure.

THERAPEUTIC THORACENTESIS TECHNIQUES FOR PLEURAL EFFUSIONS

The same sterile preparation, location of fluid, positioning, and anesthesia considerations apply for therapeutic thoracentesis as with the diagnostic procedures. However, there is one difference between a diagnostic and a therapeutic thoracentesis—that is, the quantity of fluid removed. Up to 1.5 L is removed in a therapeutic thoracentesis. A diagnostic thoracentesis requires approximately 10 to 20 mL of pleural fluid.

CATHETER-OVER-THE-NEEDLE TECHNIQUE

Two types of catheters can be used to perform this procedure. They are the catheter-over-the-needle and the catheter-through-the-needle (**Figures 40-5 & 40-6**). The catheter-over-the-needle technique

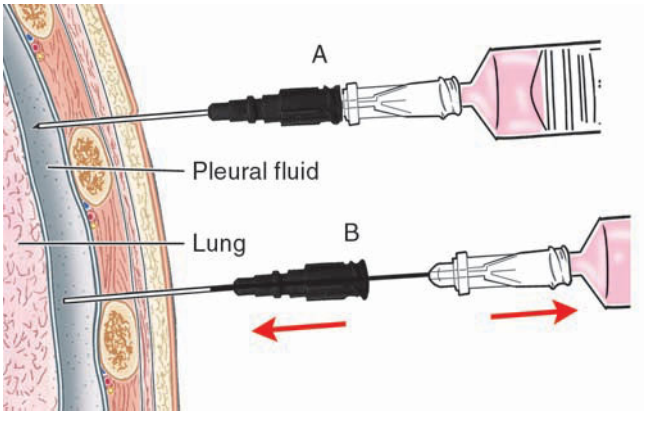

FIGURE 40-5. The catheter-over-the-needle technique. **A.** The needle and catheter are inserted over the rib and aimed slightly caudally into the pleural cavity. **B.** The catheter is advanced into the pleural cavity and the needle is removed.

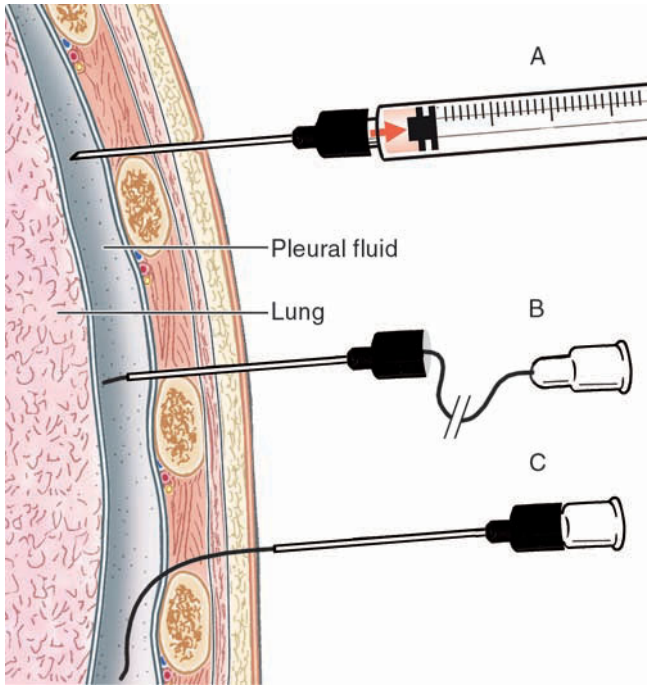

FIGURE 40-6. The catheter-through-the-needle technique. **A.** The needle is inserted over the rib and aimed slightly caudally into the pleural space. **B.** The catheter is inserted through the needle and into the pleural cavity. **C.** The needle is removed and the catheter remains within the pleural cavity.

is most commonly used (**Figure 40-5**). Make a small "nick" in the skin with a #11 surgical blade at the needle insertion site. Attach a 14 to 18 gauge catheter-over-the-needle to a 10 mL syringe as a handle. Insert the catheter-over-the-needle into the nick and advance it, reproducing the original anesthetized tract (**Figure 40-5A**). Apply negative pressure to the syringe as the catheter-over-the-needle is advanced. Stop advancing the catheter-over-the-needle when fluid is aspirated. Angle the catheter-over-the-needle caudally. Securely hold the syringe and needle so they do not move. Advance the catheter until the hub is against the skin. Withdraw the needle and syringe as a unit while the catheter remains in the pleural cavity (**Figure 40-5B**). **When the needle is removed, quickly cover the catheter with a gloved finger. This will prevent ambient air from entering the pleural cavity.** Attach intravenous catheter extension tubing to the hub of the catheter. Place a three-way stopcock attached to a 50 mL syringe onto the extension tubing. Hold the catheter hub against the skin securely. Aspirate fluid into the syringe and then advance the fluid into the sterile container by adjusting the three-way stopcock.

An alternative option is to set up a siphon through the three-way stopcock. Prime the tubing with pleural fluid. Place the end of the tubing into a sterile container that is located below the site of the catheter. This allows the fluid to flow freely into the sterile container. Fluid can be removed in 50 mL aliquots up to 1.5 L. As a general rule, this is the limit, due to the risk of postevacuation pulmonary edema and excessive protein loss.[1]

CATHETER-THROUGH-THE-NEEDLE TECHNIQUE

The second option is to utilize the catheter-through-the-needle system (**Figure 40-6**), known as the Bardig Intracath system. It is not as popular as the catheter-over-the-needle systems. Place the needle on a tuberculin syringe. Insert the needle and advance it through the anesthetized tissues (**Figure 40-6A**). A small "nick" in the skin with a #11 surgical blade will facilitate needle entry. Apply negative pressure to the syringe as the needle is advanced along the anesthetized tract and into the pleural cavity (**Figure 40-6A**). Stop advancing the needle when fluid is aspirated. Securely hold the needle so it does not move. **Remove the syringe and cover the needle hub with a gloved finger. This will prevent ambient air from entering the pleural cavity.** Angle the needle slightly caudally and advance the catheter through the needle (**Figure 40-6B**). Withdraw the needle, leaving the catheter within the pleural cavity (**Figure 40-6C**). **Once the needle is removed, do not readvance the needle, as the catheter may shear off and fall into the pleural cavity.** Place a three-way stopcock or a large syringe onto the hub of the catheter. Place the needle guard on the needle. Secure the catheter by taping it to the skin. Withdraw fluid as previously described. Fluid can be removed in 50 mL aliquots up to 1.5 L. As a general rule, this is the limit, due to the risk of postevacuation pulmonary edema and excessive protein loss.[1]

SELDINGER TECHNIQUE

An alternative approach is to use the Seldinger technique to insert a small bore catheter into the pleural cavity. The major disadvantages to this technique include the time it takes to insert the catheter, the cost of the catheter kit versus a catheter-over-the-needle, and catheter blockage (from cells, debris, and protein) requiring insertion of a second catheter. Another option is to use a central venous catheter kit.[20,21] The larger catheter opening may not become obstructed as easily.

ULTRASOUND-GUIDED TECHNIQUE FOR PLEURAL EFFUSIONS

Ultrasound can be used to map the location and the extent of pleural effusion, and to help identify the appropriate site of needle entry. Real-time guidance is usually not required. A 3.5 to 5.0 MHz phased-array probe is recommended for ultrasound-guided examination of the pleural space.[22] In general, orientation of the probe follows the convention that the probe marker should correlate to the reference point in the left upper corner of the screen.

With the patient in an upright sitting position, percuss and auscultate the posterior thorax to estimate the location of pleural fluid. Apply sterile ultrasound gel onto the ultrasound probe cover. Place the probe at the intercostal space of the estimated level of pleural fluid in the posterior axillary line, usually at the level of ribs 9 to 11. Sweep the probe superiorly and inferiorly, as well as transversely, to assess the location and size of the fluid collection. Identify the liver on the right, the spleen on the left, and the diaphragm.

In a debilitated patient in the lateral decubitus position, place the ultrasound probe in the midscapular line or, if possible, the posterior axillary to locate the fluid. A ventilator-dependent patient should be placed in the lateral decubitus position. If the patient is supine, place the probe in the posterior or midaxillary line. The real-time movement of the diaphragm can be used as a key reference point when examining the pleural space.[23] The liver may also be used as a echogenic reference point for the identification of adjacent hyperechoic or hypoechoic structures. Keep in mind that the best window to view the intrathoracic contents is through the intercostal space, as ultrasound penetration through the soft tissue is superior to that of bone.

The ultrasound waves will initially penetrate the skin, subcutaneous tissue, and muscle to produce multiple layers of varying echogenicity. The echogenic ribs cast an acoustic shadow (**Figure 40-7**). The parietal and visceral pleura are encountered posterior to the rib as two hyperechoic lines, each <2 mm thick.[23,24] The diaphragm can be identified as a hyperechoic transverse structure at the base of the chest wall. The lung is visualized as a bright, hyperechoic structure just cephalad to the diaphragm. The lung should become more

FIGURE 40-7. Ultrasound image of a normal lung. Visualized from top to bottom are the subcutaneous tissues, muscle (M), rib shadow (*arrowhead*), and pleural line (*arrows*).

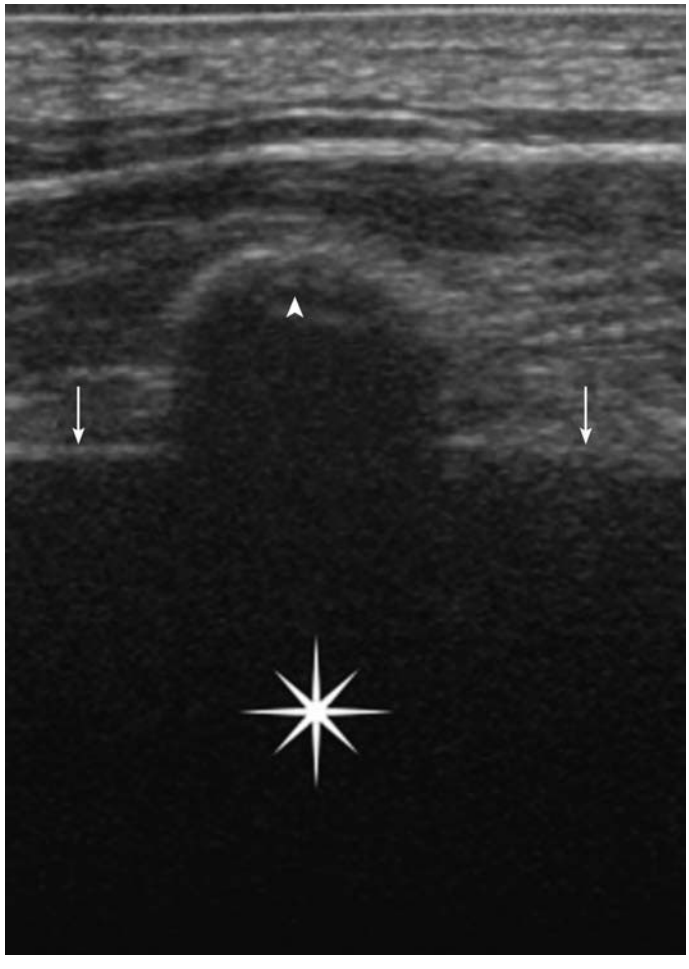

FIGURE 40-8. Ultrasound image of a pleural effusion. The pleural effusion appears black or anechoic (*asterisk*). The pleura is not brightly echogenic (*arrows*) due to the separation of the two layers. Note the rib shadow (*arrowhead*) in the upper part of the image.

intensely hyperechoic, or brighter in the inspiration phase. A pleural effusion can be identified as an anechoic to a hypoechoic image above the diaphragm that decreases in size with inspiration.

Two additional ultrasound findings should be identified on exam: "lung slide" and "comet tail" artifact. The movement of the lung in reference to the surrounding parietal pleura with inspiration and expiration produces an artifact referred to as "lung slide." Normal inspiration should produce a "slide" with each breath, representing movement between the visceral and parietal pleural interface. The thin, hyperechoic sliding line is located approximately 0.5 cm below the surface of the rib, and should move back and forth with each inspiration.[25] A "comet tail artifact" is another normal finding that can be readily identified in a healthy patient. The comet tail artifact is identified as a hyperechoic vertical artifact that slides transversely and is oriented perpendicular to the transverse "lung slide" previously mentioned.[25]

A pleural effusion is easily visualized using ultrasound (**Figure 40-8**). It appears black or anechoic. A distinct hyperechoic pleural line is not seen as the parietal and visceral pleura are separated by the effusion. Lung tissue appears hyperechogenic compared with the anechoic effusion (**Figure 40-9**). The pleural effusion can be seen moving during the respiratory cycle.

The posterior approach is the preferred choice in the stable, cooperative patient who is able to sit up and lean over a table (**Figure 40-10**). To survey the lung anatomy and map the effusion, scan the posterior hemithorax from the inferior border of the scapula to the upper lumbar region and from the paravertebral area to the posterior axillary line. Note the minimum depth of the effusion and the location of other vital structures (i.e., diaphragm, liver, spleen, and lung). Scan with the probe parallel to and perpendicular to the ribs, and observe the structures during the full respiratory phase. The diaphragm can go as low as the 12th rib posteriorly and as high as the 8th rib laterally. Determine the location of the skin entry site. Mark the site with a pen, surgical marker, or by indenting the skin with the cap of a needle. The ideal site should have a large area of pleural effusion and be free of any internal structures (i.e., liver, spleen, or diaphragm) along the needle path.

The lateral approach is used for mechanically ventilated patients and for those who are unable to sit up for the procedure. Abduct the ipsilateral arm and place the hand behind the patient's head, as one would in preparation for the placement of a chest tube (**Figure 40-11**). Survey the anterior and lateral thorax from the midclavicular line to the posterior axillary line. Note the depth of the effusion and the location of any vital structures to be avoided. Determine and mark the skin entry site.

The lateral decubitus approach is an alternative for patients unable to sit upright. Place the patient on their side with the pleural effusion side down. Use ultrasound to map the effusion. Note the distance from the skin to the effusion, the depth of the effusion, as well as the presence of any important structures to be

FIGURE 40-9. Ultrasound image of a pleural effusion (*asterisk*) with the underlying hyperechoic lung tissue (L). Note the rib shadow (*arrowhead*) in the upper left of the image.

FIGURE 40-10. Posterior approach in the sitting patient. A linear ultrasound probe is seen here, although a phased-array probe is often preferred to visualize deeper structures.

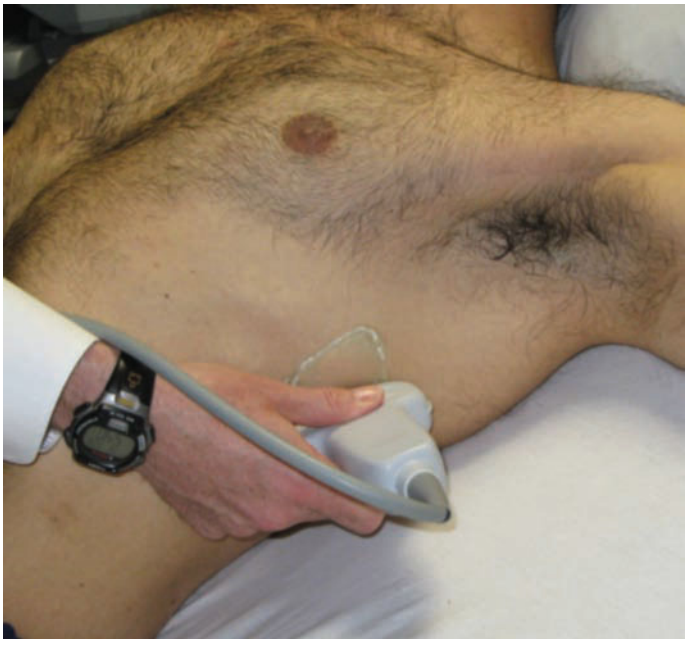

FIGURE 40-11. Lateral approach in the supine patient. A curvilinear probe is positioned in the midaxillary line. Note the coronal plane of the probe.

avoided. Determine and mark the skin entry site, usually at the posterior axillary line.

Regardless of the patient position or approach, do not allow the patient to move once they have been scanned and the skin entry site marked. Prep and drape the patient similar to that for the blind thoracentesis approach. Use local anesthetic to anesthetize the skin, rib, and pleura. The catheter-over-the-needle can be inserted blindly, as described previously, at the skin insertion site or using real-time ultrasound guidance.

The use of ultrasound guidance can be helpful. Place a sterile cover over the ultrasound probe. Apply sterile ultrasound gel over the cover. Rescan the patient in the area previously identified the skin entry site (**Figure 40-12**). Verify that no structures are along

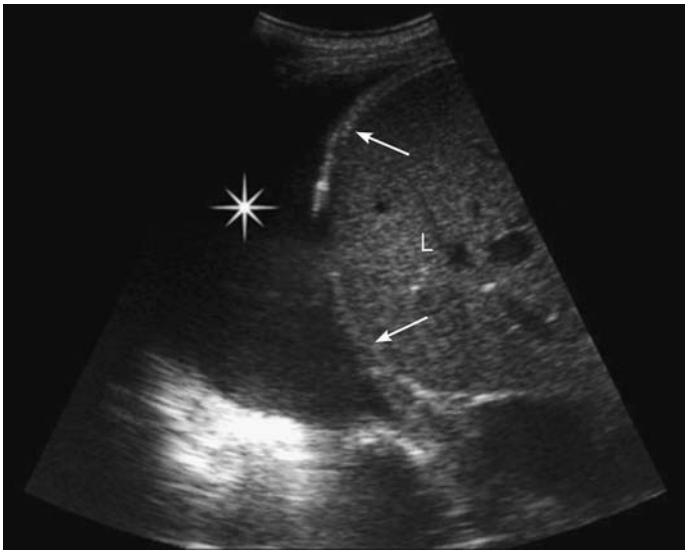

FIGURE 40-12. The pleural effusion (*asterisk*) is visible above the diaphragm (*arrows*). The liver (L) is seen below the diaphragm.

the needle path between the skin and the pleural effusion. Insert an 18 gauge catheter-over-the-needle into the pleural space using the technique already described while using ultrasound for real-time visualization of the needle entering the pleural cavity. The needle will appear as a thin, bright, hyperechoic structure moving through the skin, subcutaneous tissue, parietal pleura, visceral pleura, and finally reaching the hypoechoic pleural effusion (**Figure 40-13**). Aspirate to confirm that the catheter-over-the-needle is within the pleural effusion. Place the ultrasound probe aside. Continue the remainder of the procedure as described previously.

ASSESSMENT

Numerous analyses of the pleural effusion fluid are required to determine its etiology (**Table 40-2**). Large pleural effusions are more commonly associated with infections and malignancy.[26] Fluid analysis criteria have been established to separate transudates and exudates.[10,27] If the fluid fits one of the criteria in **Table 40-3**, it is an exudate. These parameters have been confirmed to have 98% sensitivity and 83% specificity in detecting exudates.[28] Color and odor can be helpful. If the fluid has a putrid odor, consider an infection. White or yellow fluid suggests an empyema or chylothorax. The fluid's white blood cell count is of limited benefit. If it is >10,000, the fluid likely represents a parapneumonic effusion. A pleural fluid hemoglobin and hematocrit can be compared to that of the blood. Bloody pleural effusions are usually associated with malignancy, pneumonia, pulmonary embolism with a lung infarction, or trauma.[29] If the fluid is grossly bloody, consider a hemothorax. If the pleural fluid's hematocrit is >50% of the serum hematocrit, a hemothorax is likely and chest tube placement should be considered. Other helpful tests include a fluid pH. If the pH is below 7.25 to 7.30, consider it the result of a parapneumonic process, rheumatologic process, esophageal rupture, or malignancy. An elevated amylase level suggests esophageal rupture, malignancy, or pancreatic disease.[30] Elevated triglyceride levels suggest a chylothorax. Cytology is important to search for an underlying malignancy. Up to 50% of patients with a pulmonic malignancy will have neoplastic cells in the pleural fluid.[3] Bacteriologic information such as Gram's stain, acid-fast, and fungal preparations are also important, although the yield can be below 30%.[16] Fluid should always be sent for aerobic and anaerobic cultures to rule out an infectious etiology for the pleural effusion. The appearance of pleural fluid on ultrasound may help identify whether the pleural fluid is a transudate or an exudate. Transudates are consistently seen as anechoic, whereas exudates may range from an anechoic to a hyperechoic.[31,32]

AFTERCARE

When done aspiring fluid, remove the catheter and apply a bandage to the puncture site. Several authors have suggested that a postprocedure chest radiograph may not be necessary.[33,34] These were small studies with methodologic errors. Omitting the postprocedure chest radiograph cannot be recommended at this time. Obtain a plain chest radiograph upon completion of the procedure to assess for a pneumothorax. An expiratory film is the best film to look for a pneumothorax, especially if it is small. Repeat a chest radiograph in 4 to 6 hours to look for a delayed pneumothorax. If no pneumothorax is present and if appropriate for the clinical condition, the patient may be discharged with good instructions and close follow-up.

TABLE 40-3 Laboratory Features of a Pleural Fluid Exudate

Fluid/serum lactate dehydrogenase (LDH) > 0.6
Fluid/serum protein > 0.5
Pleural fluid LDH > 200 IU/mL
Pleural fluid LDH > 2/3 upper limit of normal for serum

TABLE 40-4 Potential Complications Associated with a Thoracentesis

Cough
Hemothorax
Hypovolemia
Hypoxemia
Inadequate yield
Intrapleural infection
Laceration of an intercostal nerve or vessel
Laceration of the liver or spleen
Pain at the procedure site
Pneumothorax
Reexpansion pulmonary edema
Shortness of breath
Tension pneumothorax
Vasovagal reactions

The procedure site should be evaluated two to three times a day for signs of infection. These patients should be educated about the signs, symptoms, and significance of an infection. They should return to their primary physician or the Emergency Department immediately if they develop fever, chills, shortness of breath, redness or pus at the puncture site, or if any concerns arise.

COMPLICATIONS

The potential complications of a thoracentesis are listed in **Table 40-4**.[1,3,16,28,35] Complication rates range from 20% to 50%. The major complications are a 5% to 19% incidence of pneumothorax and a 1% to 7% incidence of pneumothorax requiring a chest tube.[11,36] One author recommends ultrasound-guided thoracentesis for all patients as the safest approach, although this is disputed by others.[9,36] The majority of studies report lower rates of postprocedural pneumothoraces with ultrasound-guided thoracentesis performed by an experienced operator.[9–11,15,37–41] However, others have not shown a significant difference in the incidence of postprocedural pneumothoraces with the use of ultrasound.[42,43]

The use of the proper technique and the Emergency Physician's experience are important in reducing the rate of complications.[44–46] Despite this, it is difficult to predict which patients may be at risk of developing a postprocedural pneumothorax.[47] Drainage of large volumes of fluid, greater than 1.5 to 2 L, may increase the risk of developing a pneumothorax.[48] Improper technique or tortuosity of the intercostal artery can result in intercostal artery injury.[49] Qureshi compiled methods to reduce the incidence of pneumothorax.[16] They are direct supervision of inexperienced operators, removal of small amounts of fluid, use of small-gauge needles, use of ultrasound for small effusions, and use of a needle-catheter system for a therapeutic procedure.

PNEUMOTHORAX

ANATOMY AND PATHOPHYSIOLOGY

A thoracentesis can be performed to relieve a simple pneumothorax or a tension pneumothorax. A pneumothorax can be defined by the presence of air between the visceral and parietal pleura.[25] Primary spontaneous pneumothoraces occur in otherwise healthy people without antecedent trauma. Secondary spontaneous pneumothoraces occur as a complication of underlying lung disease, most commonly chronic obstructive pulmonary disease.[1,3] A traumatic pneumothorax occurs as a result of penetrating or blunt trauma to the thoracic cavity. An iatrogenic pneumothorax is a subcategory of the traumatic pneumothorax, with the three most common etiologies being pleural biopsy, subclavian vein catheterization, and thoracentesis.

The pressure in the pleural space is negative in reference to the atmosphere. This is due to the tendency of the lung to collapse and the chest wall to expand. The alveolar pressure is greater than the pleural space pressure due to the elastic recoil of the lung. As a result, if a communication occurs between the alveolar and pleural space, the air will preferentially move into the pleural space until the pressure equalizes. The physiologic consequence is a decrease in vital capacity and PaO_2. This may be well tolerated in otherwise healthy people but not in patients with underlying cardiac and/or pulmonary disease. If a one-way valve develops such that air can only enter the pleural space from the alveolus but not return, the intrapleural pressure will eventually exceed atmospheric pressure, with a progressive increase in air occupying the pleural space. Clinical deterioration may occur due to a decreasing PaO_2 and cardiac output.[50–52] Other data point to hypoxia and hypercarbia as the cause of clinical deterioration.[18]

Ultrasound guidance may aid in locating a pneumothorax, with the best viewing window being the intercostal space. Zhang et al. showed a sensitivity and specificity of ultrasound in diagnosing a pneumothorax of 86% and 97%, respectively; whereas conventional radiography was 28% and 100%, respectively.[53] In addition, ultrasound diagnosed a pneumothorax within only 2 to 5 minutes, compared to 20 to 30 minutes for chest radiography.[53] In a similar study, ultrasound showed a sensitivity and specificity of 100% and 94% for detection of pneumothoraces, compared to 36% and 100% for chest radiography.[54]

Controversy exists to the exact management of a spontaneous pneumothorax.[55–60] Options include simple aspiration, tube thoracostomy, and simple aspiration followed by a tube thoracostomy if aspiration fails. Simple aspiration is more likely to fail with larger pneumothoraces.[58,59] Several recent reviews, including a Cochrane Collaboration, came to similar conclusions regarding simple aspiration.[55–57] These conclusions, while not definitive, were that simple aspiration is associated with a reduction in the percentage of patients requiring hospitalization compared to tube thoracostomy. There were no differences between the two procedures in early failures, immediate success rate, duration of hospitalization, one-year success rates, and the number of patients requiring a subsequent pleurodesis. Advantages of simple aspiration compared to tube thoracostomy include less equipment costs, easier to perform, simpler to perform, quicker to perform, and the potential to avoid hospitalization.

INDICATIONS

All tension pneumothoraces require needle drainage followed by tube thoracostomy. Patients usually present with respiratory distress, tachycardia, unilateral absence of breath sounds, hypotension, and neck vein engorgement. Although difficult to assess, these patients have tracheal deviation that is often limited to the thoracic cavity.

Not all simple pneumothoraces require drainage, as they may resolve spontaneously. Conservative management has shown a spontaneous resorption rate of 1.25% per day.[46] A pneumothorax should be drained if the patient complains of dyspnea, dyspnea on exertion, pain, or if the pneumothorax is estimated to be 15% or greater.

CONTRAINDICATIONS

There are no absolute or relative contraindications to relieving a tension pneumothorax, as it is a life-threatening emergency.

Contraindications to thoracentesis to relieve a simple pneumothorax are few. These include infection at the site of the procedure,

in which case an alternate site should be selected.[3] A traumatic pneumothorax or a pneumothorax associated with a hemothorax or pyothorax requires tube thoracostomy. Any pneumothorax that is expanding or expanding despite thoracentesis also requires a tube thoracostomy. Any patient on anticoagulation or with a suspected bleeding diathesis, whether known or suspected, may require reversal of the condition before the procedure.[1] A patient with minimal symptoms and a small pneumothorax may be observed before deciding to evacuate the pneumothorax.

EQUIPMENT

Pneumothorax—Tension

- Alcohol swab, povidone iodine solution, or chlorhexidine solution
- 12 to 16 gauge catheter-over-the-needle, 2 in. long

Pneumothorax—Stable

- Sterile gloves and gown
- Face mask with a face shield or goggles
- Povidone iodine or chlorhexidine solution
- Sterile gauze sponge
- Sterile towels
- Sterile basin
- Syringes for anesthesia infiltration, 5 and 10 mL
- 25 gauge needle for anesthesia infiltration of the skin
- 21 or 23 gauge needle for infiltration of subcutaneous tissue, periosteum, and pleura
- 16 or 18 gauge catheter-over-the-needle
- 14 to 18 gauge catheter-through-the-needle
- Pigtail or straight catheter kit
- Three-way stopcock
- 50 mL syringe
- Intravenous extension tubing
- Heimlich valve

Ultrasound Guidance

- Ultrasound machine
- 3.5 to 5.0 MHz phased-array ultrasound probe
- Sterile ultrasound gel
- Sterile ultrasound probe cover

Commercial kits have been developed and are available to provide the equipment needed to perform a thoracentesis. These kits are disposable, single-patient use, and contain all the required equipment. They save time in that the equipment does not have to be found and set up. Disadvantages include potentially increased cost and limited equipment in the kit.[18] Common kits include the Pharmaseal, distributed by Baxter (Jacksonville, TX); the Arrow Clark Thoracentesis Kit, distributed by Arrow (Reading, PA); and the Argyle Turkel Safety Thoracentesis Kit, distributed by Boston Scientific (Miami, FL).[3]

The TRU-CLOSE Thoracic Vent (UreSil, Skokie, IL) is an alternative device to the pigtail catheter and Heimlich valve combination. It is a one-piece unit that combines an intrapleural catheter and an external one-way antireflux valve that attaches to the chest wall by an adhesive pad. Its insertion is quicker, easier, and simpler than a traditional catheter. The low profile makes ambulation and outpatient management easier for the patient. These devices are rarely available in the Emergency Department.

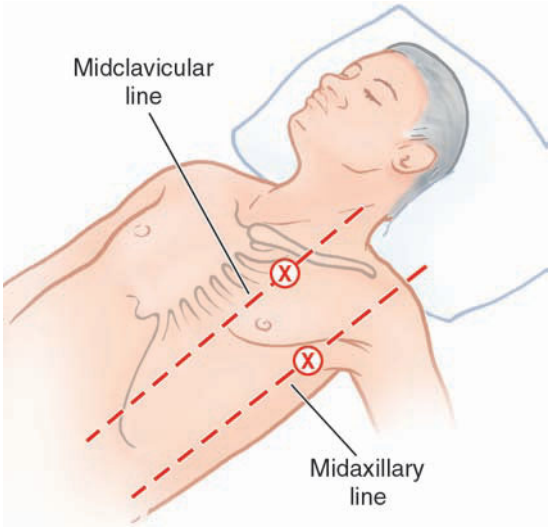

FIGURE 40-14. Relief of a tension pneumothorax. The patient should be in the supine position, with the head of the bed elevated 30° if not contraindicated. The second intercostal space in the midclavicular line is the recommended site. For pleural effusions or a debilitated patient, the midaxillary line or posterior axillary line may be used at the level of the fourth or fifth intercostal space.

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative and have a consent form signed.[1] Place the patient supine on the bed. Alternatively, the patient may be supine with the head of the bed elevated to 30° (**Figure 40-14**). Clean any dirt or debris from the skin. Identify the anatomic landmarks required to perform the procedure. Although not required, it is recommended to place the patient on the cardiac monitor, noninvasive blood pressure cuff, pulse oximetry, and supplemental oxygen. Apply povidone iodine or chlorhexidine solution to the skin surface and allow it to dry. Apply sterile drapes around the site of the procedure. Atropine should be at the bedside. It may be administered (1.0 mg subcutaneously or intramuscularly or 0.5 mg intravenously) to patients who develop symptomatic bradycardia during the procedure. The most common approach is the second intercostal space in the midclavicular line (**Figure 40-14**). An alternate site is the fourth or fifth intercostal space in the midaxillary line. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids as well as protect the patient from infection.

TENSION PNEUMOTHORAX TECHNIQUE

If the patient has a tension pneumothorax, thoracentesis is both a diagnostic and therapeutic procedure. A tension pneumothorax is a true life threat. Identify the needle insertion site by palpating the second intercostal space in the midclavicular line. If a tension pneumothorax is clinically evident, ultrasound guidance is not necessary prior to needle decompression and should not delay treatment. **Insert the catheter-over-the-needle over the superior border of the third rib to avoid the neurovascular bundle, which is located on the inferior border of the second rib.** Advance the catheter-over-the-needle into the pleural space. If time permits, a 5 to 10 mL syringe without the plunger can be attached to the catheter-over-the-needle. The syringe barrel can be used as a handle to advance the catheter-over-the-needle.

When the pleural cavity is entered, a release of pressure and a small "pop" may be felt. Stop advancing the needle. Securely hold the needle so it does not move. Advance the catheter until the hub is against the skin. Remove the needle. If the patient has a tension pneumothorax, a continuous rush of air will be heard or felt. **Needle thoracentesis for a tension pneumothorax is a temporizing measure; therefore, a tube thoracostomy should be performed immediately after this life-saving procedure.** Refer to Chapter 39 for complete details regarding this procedure.

SIMPLE PNEUMOTHORAX TECHNIQUES

A primary spontaneous pneumothorax occupying over 15% of the hemithorax is the indication for simple aspiration via a thoracentesis.[3] The same sterile preparation, location of fluid, positioning, anesthesia considerations, and ultrasound-guided technique apply to the evacuation of a simple pneumothorax as to a diagnostic thoracentesis.

Spontaneous pneumothoraces used to be drained by tube thoracostomy. Simple aspiration may be just as effective as a tube thoracostomy.[55–60] If a tube thoracostomy is required, a small bore straight or pigtail catheter can be just as effective to manage a spontaneous pneumothorax.[61–65] While an initial study recommends using small bore tubes in patients with chest trauma, further clinical information is required before this becomes standard of care.[66] The advantages of a small bore catheter include: less pain on insertion, decreased need for analgesics and sedation, and the potential to discharge the patient with outpatient management.

CATHETER-OVER-THE-NEEDLE TECHNIQUE

Two types of catheters can be used to perform this procedure. They are the catheter-over-the-needle and the catheter-through-the-needle (**Figures 40-5 & 40-6**). The catheter-over-the-needle technique is most commonly used (**Figure 40-5**). Make a small "nick" in the skin with a #11 surgical blade at the needle insertion site. Attach a 14 to 18 gauge catheter-over-the-needle to a 10 mL syringe as a handle. Insert the catheter-over-the-needle into the nick and advance it, reproducing the original anesthetized tract (**Figure 40-5A**). Apply negative pressure to the syringe as the catheter-over-the-needle is advanced. Stop advancing the catheter-over-the-needle when air is aspirated. Angle the catheter-over-the-needle superiorly. Securely hold the syringe and needle so they do not move. Advance the catheter until the hub is against the skin. Withdraw the needle and syringe as a unit while the catheter remains within the pleural cavity (**Figure 40-5B**). **When the needle is removed, quickly cover the catheter with a gloved finger. This will prevent ambient air from entering the pleural cavity.** Attach intravenous catheter extension tubing to the hub of the catheter. Place a three-way stopcock attached to a 50 mL syringe onto the extension tubing. Hold the catheter hub against the skin securely. Aspirate air into the syringe and then advance the air into the room by adjusting the three-way stopcock. Air is then withdrawn manually. This process should be continued until resistance is felt. **If no resistance is felt after 4 L of aspiration, it is presumed that expansion has not occurred and a continual leak of air exists from the lung into the pleural cavity; therefore a tube thoracostomy should be performed.** After no more air is aspirated, close the stopcock and secure it to the chest wall. The success rate for the aspiration of a pneumothorax is 64%.[67,68]

CATHETER-THROUGH-THE-NEEDLE TECHNIQUE

The second option utilizes the catheter-through-the-needle system (**Figure 40-6**), which is known as the Bardig Intracath system. It is not as popular as the catheter-over-the-needle systems. Place the needle on a tuberculin syringe. Insert the needle and advance it through the anesthetized tissues (**Figure 40-6A**). A small "nick" in the skin with a #11 surgical blade will facilitate the needle entry. Apply negative pressure to the syringe as the needle is advanced along the anesthetized tract and into the pleural cavity (**Figure 40-6A**). Stop advancing the needle when air is aspirated. Securely hold the needle so it does not move. **Remove the syringe and cover the needle hub with a gloved finger. This will prevent ambient air from entering the pleural cavity.** Angle the needle slightly superiorly and advance the catheter through the needle (**Figure 40-6B**). Withdraw the needle, leaving the catheter within the pleural cavity (**Figure 40-6C**). **Once the needle is removed, do not readvance the needle, as the catheter may shear off and fall into the pleural cavity.** Place a three-way stopcock attached to a 50 mL syringe onto the hub of the catheter. Place the needle guard on the needle. Secure the catheter by taping it to the skin. Withdraw air as previously described.

SELDINGER TECHNIQUE

Drainage can also be accomplished using a pigtail or straight catheter and the Seldinger technique (**Figure 40-15**). An alternative is to use a central venous catheter if a pigtail catheter is not available.[18,19] Attach a 16 gauge, 2 in catheter-over-the-needle to a 5 or 10 mL syringe. Insert the catheter, as described above, aimed superiorly. Securely hold the needle and syringe so it does not move. Advance the catheter to the hub. Remove the needle and syringe. **Quickly cover the catheter hub with a gloved finger.** Insert the guidewire through the catheter (**Figure 40-15A**). **Hold the guidewire securely to prevent it from falling completely into the pleural cavity.** Remove the catheter over the guidewire, leaving the guidewire in place (**Figure 40-15B**). Extend the skin incision with a #11 scalpel blade by 3 to 5 mm to allow the catheter to enter into the pleural space without "crumpling" (**Figure 40-15C**). Advance the dilator over the guidewire and into the pleural cavity to dilate the tract (**Figures 40-15C & D**). A gentle twisting motion of the dilator as it is advanced will aid in its insertion into the pleural cavity (**Figure 40-15D**). Hold the guidewire securely. Remove the dilator while leaving the guidewire in place. Insert the catheter over the guidewire and into the pleural cavity (**Figure 40-15E**). Remove the guidewire and attach a three-way stopcock to the catheter. Aspirate the air as described previously.

DRAINAGE SYSTEMS

Drainage systems for a pneumothorax vary in style but function with the same "one-way valve" principle. The simplest method is a flutter valve. It is best illustrated by the following noncommercial method. Cut a premoistened finger from a sterile glove. Tie the proximal end to the thoracentesis catheter with a silk suture and cut the distal end so that it is open to the air[1] (**Figure 40-16**). This creates a flutter valve and allows air to escape with coughing or expiration and prevents air from reentering the pleural space on inspiration.

A commercial kit often contains a Heimlich flutter valve[1] (**Figure 40-17**). **The arrow on the clear protective tube covering the Heimlich valve must point away from the patient.** Suction is usually not needed. Stable patients can be sent home with this setup. This includes patients with a primary spontaneous pneumothorax and a small apical pneumothorax with initial reexpansion and good apposition of the lung with the lateral chest wall. Up to 30% of patients with a secondary pneumothorax can be treated on an ambulatory basis. Additional requirements include good residual lung function, normal oxygen saturation, and an air leak adequately treated by thoracentesis.[35] **A contraindication to using the flutter valve is a hemothorax.** A closed underwater seal system is recommended in these cases. Refer to Chapter 39 for details regarding the use of a closed underwater seal system and the other indications for its use.

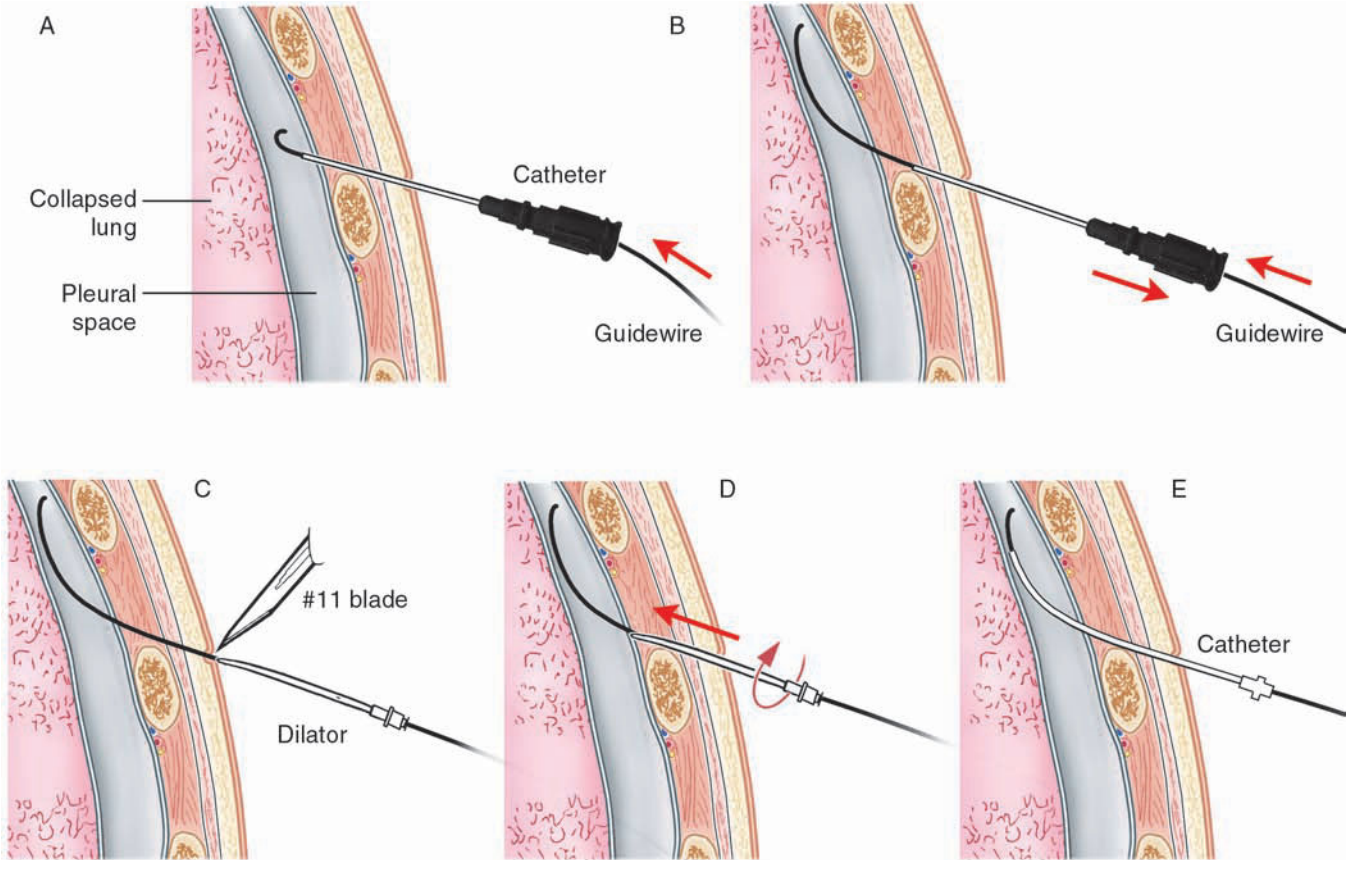

FIGURE 40-15. The Seldinger technique for inserting a catheter to aspirate a pneumothorax. A catheter-over-the-needle has been placed into the pleural cavity and aimed superiorly. The needle has been removed while the catheter remains in the pleural cavity. **A.** A guidewire is inserted through the catheter. **B.** The catheter is removed while the guidewire remains in the pleural cavity. **C.** The skin incision is enlarged with a #11 scalpel blade. A dilator is placed over the guidewire. **D.** The dilator is advanced over the guidewire and into the pleural cavity. A gentle twisting motion will help guide the dilator through the tract. **E.** The dilator has been removed while the guidewire remains inside the pleural cavity. The catheter is advanced over the guidewire and into the pleural cavity. The guidewire is then removed while the catheter remains inside the pleural cavity.

ULTRASOUND-GUIDED TECHNIQUE FOR A PNEUMOTHORAX

The same sterile preparation applies to ultrasound evaluation of a pneumothorax as for evaluation of a pleural effusion. However, a pneumothorax may be more readily identified with the patient positioned supine rather than upright. A 3.5 to 5.0 MHz phased-array probe is recommended for ultrasound-guided examination of the pleural space.[22] In general, the orientation of the probe follows the convention that the probe marker should correlate to the reference point in the left upper corner of the screen.

The key ultrasound features of a pneumothorax include: absence of inspiration–expiration related "lung slide," loss of "comet tail" artifact, and broadening of the pleural line to a thick band.[24] In the case of a unilateral pneumothorax, the hemithorax suspected of

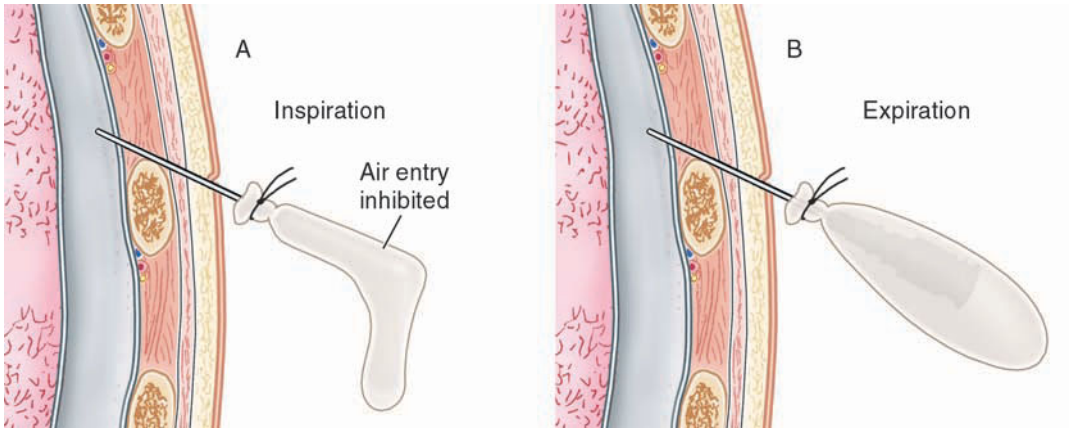

FIGURE 40-16. Use of a finger from a sterile glove as a one-way valve. Place the proximal end of the finger on the drainage system and cut the distal tip. It will act as a one-way valve.

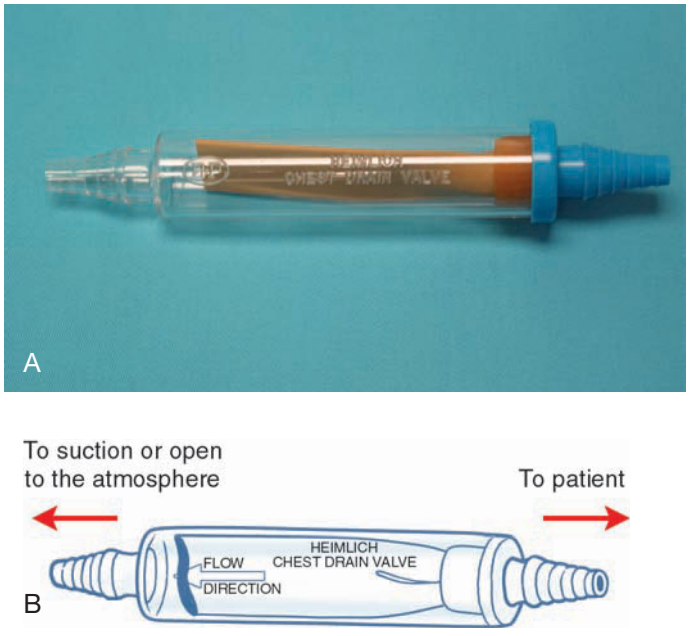

FIGURE 40-17. The Heimlich valve.

having a pneumothorax should be compared to the unaffected side, with the unaffected side showing normal "lung slide," "comet tail" artifact, and pleural line <2 mm thick.

ASSESSMENT

Relief of a tension pneumothorax will equalize the pressure between the atmosphere and the pleural space. The patient will now have a simple pneumothorax. The vital signs should begin to normalize, the pulse oximetry improves, and the respiratory distress improves. If the patient had a tension pneumothorax, they will need a tube thoracostomy followed by a chest radiograph. The patient may begin to cough when the lung reexpands. Breath sounds should be present bilaterally upon reexpansion.

If the patient does not improve clinically after needle decompression for a tension pneumothorax, there are two possibilities. First, the pleural space may not have been entered with the needle. This occurs when the patient is obese or very muscular. The procedure may then be repeated with a longer needle. Second, the patient may not have had a tension pneumothorax. Reevaluate the patient by physical examination, bedside ultrasonography, and review the chest radiograph to determine if a tension pneumothorax is present.

Obtain a chest radiograph after the relief of a simple pneumothorax. It will allow the Emergency Physician to determine the success, or lack thereof, of the procedure. Perform a tube thoracotomy if at any point the pneumothorax is not improving with a thoracentesis or if the patient's symptoms worsen.

AFTERCARE

Obtain a follow-up chest radiograph upon completion of the procedure to assess for a pneumothorax. An expiratory film should be obtained, especially if the pneumothorax was small. A chest radiograph should be repeated 4 to 6 hours after the procedure to look for a delayed pneumothorax. If no pneumothorax is present and if appropriate for their clinical condition, the patient may be discharged with good instructions and close follow-up. An alternative is placement in an observation unit and discharge within 24 hours.[69]

The procedure site should be evaluated two to three times a day for signs of infection. These patients should be educated about the signs, symptoms, and significance of an infection. They should return to their primary physician or Emergency Department immediately if they develop fever, chills, shortness of breath, redness or pus at the puncture site, or if any concerns arise.

A patient may be a candidate for outpatient management with a Heimlich valve under the following conditions: a stable primary spontaneous pneumothorax, close apposition of the lung to the lateral chest wall with initial thoracentesis or aspiration and drainage procedures, Emergency Physician satisfaction with the position of the catheter, and an air leak that is manageable with one thoracentesis. A small study has confirmed this outpatient management, whereas many Emergency Physicians have been managing patients like this for years.[70] Contraindications for outpatient management include traumatic pneumothoraces, secondary pneumothoraces, a patient with poor residual function, a large air leak requiring tube thoracostomy, a hemothorax, unacceptable residual collapse defined as poor apposition of the lateral lung to the lateral chest wall, or if the patient is not reliable.[6]

Instructions to the patient should include the following: clean the thoracentesis site with mild soap daily; apply a split dressing around the catheter and tape it to the skin; make sure that the tubing is taped firmly to the valve to prevent accidental dislodgment; the arrow on the valve should point away from the patient; the sound of air exiting the valve is expected; and showers are permitted but not a bath or swimming. If these patients experience shortness of breath, chest pain, or difficulty breathing, they should call 911 and immediately return to the Emergency Department. Instruct the patient on the removal of the Heimlich valve from the catheter if significant shortness of breath develops as they may have developed a tension pneumothorax. They should also be instructed on the signs of an infection at the chest wall insertion site.

The patient should follow-up daily for radiographic evaluation. Upon complete inflation of the lung, the thoracentesis catheter can be removed. The patient should be observed for 4 to 6 hours after catheter removal and a repeat chest radiograph obtained. The patient can be discharged if the lung is completely expanded. If not, a thoracostomy tube should be reinserted and the patient admitted.

COMPLICATIONS

Complications associated with this procedure can be numerous. Clinically, a pneumothorax can become worse. Causes include lacerating the lung with the needle, inadequate coverage of the hub of the needle or catheter with a gloved finger after entering the pleural space, and an air leak in the drainage system. It may also occur from a lung parenchymal-pleural fistula that can develop from poor lung expansion during large-volume pneumothorax drainage.[71] A tension pneumothorax can occur from a lung laceration along with inadvertent plugging of the drainage system (e.g., fluid in tube, kinking). A hemothorax is possible if the lung, intercostal artery, or mammary artery is lacerated with the needle. Less common complications include cardiac or great vessel perforation due to poor positioning of the needle upon insertion. Infection occurs about 2% of the time if sterile technique is observed. Catheter shearing is possible with the catheter-through-the-needle system if the needle guard is not placed on the needle or the catheter is withdrawn through the needle. Many of these complications can be prevented by the use of proper and careful technique.

Reexpansion hypotension has been reported following rapid evacuation of persistent unilateral pneumothoraces of at least

1 week duration. The mechanism is unclear. It is associated with reexpansion pulmonary edema that precipitates intravascular volume depletion, myocardial depletion, or large volume aspiration.[1] Reexpansion pulmonary edema may be precipitated by pneumothoraces over a few days duration before reexpansion or large volume aspiration.[72–74]

SUMMARY

A thoracentesis can help differentiate between transudates and exudates. Together with the clinical presentation, the information can be useful in diagnosing the patient's condition. It can be lifesaving if the patient has a tension pneumothorax. It offers an alternative to tube thoracostomy for patients with stable spontaneous primary pneumothoraces. Outpatient management can be considered in some cases with the addition of a Heimlich valve. Regardless of what method is used, physicians in training should be supervised until competency with this procedure is demonstrated.

41 Open Chest Wound Management

Eric F. Reichman

INTRODUCTION

Open chest wounds come in a variety of shapes and sizes. Their one commonality is an open communication between the pleural space and the external environment. The wounds have often been sealed by the soft tissues of the chest wall in the vast majority of patients with penetrating injuries to the chest. The primary concern with these patients is the diagnosis and treatment of underlying thoracic, cervical, and/or abdominal injuries. **Rarely, small perforations may produce a valve-like entry into the pleural space, enabling air to be "sucked in" during inspiration but blocking air egress during expiration. Thus air will continue to accumulate, leading to a tension pneumothorax requiring needle decompression followed by a tube thoracostomy.** Larger, more destructive wounds of the chest may also occur. These are most common in combat injuries. In civilian practice, they are often secondary to shotgun injuries. The larger wounds are also caused by high-velocity weapons, explosions, on-the-job injuries, propeller injuries, or fencepost impalements, to name a few. Clothing, wadding, shell fragments, and pieces of the chest wall may all be driven into the thoracic cavity. Such injuries are associated with physical loss of a portion of the chest wall itself, making adequate ventilation impossible.[1] These wounds are known by numerous names including open chest wounds, open pneumothoraces, sucking chest wounds, and communicating pneumothoraces. These specific open chest wounds are the focus of this chapter.

Wounds of the chest are described in the earliest of medical documents, the Edwin Smith papyrus. This document dates from the time of Imhotep (3000 B.C.). It contains descriptions of 58 cases, three of which involved chest injuries per se. One was actually an open chest wound, case number 40. The patient sustained a penetrating injury to the anterior thorax through the manubrium. Treatment consisted of binding the wound with fresh meat on the first day and, later, with grease, honey, and lint.

During Greco-Roman times, open chest wounds were universally fatal. In 362 B.C., Epaminondas was wounded by a spear to the chest at the battle of Mantinea. Once he discovered that the Thebans had been victorious, he pulled the spear out, knowing that he would die.

Galen cared for chest wounds in gladiators. Treatment consisted of a poultice and leaving the wound open. This treatment did not change until the time of Theodoric, who advised the closing of chest wounds. In 1267, he was quoted as saying, "The stitches should be placed in accordance with the size of the wound so that the natural heat cannot escape in any way nor the air outside be able to enter." His advice was not accepted by all. The Master Military Surgeon Paré left these wounds open for 2 to 3 days to allow drainage of blood, after which he would close them.

During the Battle of Crecy in 1346, firearms and firearm injuries were first introduced. In 1382, small guns were used against the Venetians. Injuries from these weapons were documented in the chronicles of these battles.

Techniques for managing chest wounds have improved with each subsequent war. The most important treatable aspect of these chest wounds was the associated open pneumothorax. The question of whether to manage such injuries open or closed remained controversial. In Rome in 1514, John de Vigo was the first surgeon to present his views on gunshot wounds of the chest. He thought them to be universally fatal and, for the most part, untreatable. William Hewson, in 1767, observed that a patient with a large open chest wound was not able to breathe but could do so easily once the injury was closed.

It took another 40 years for Baron Larrey, Napoleon's Surgeon, to confirm Hewson's observation in a wounded soldier. He gave one of the best descriptions of an open pneumothorax, shock, and air hunger in his memoirs of the Napoleonic wars:

"A soldier was brought to the hospital at the Fortress of Ibrahym Bey, immediately after a wound penetrated the thorax between the fifth and sixth true ribs. It was 8 cm in extent. A large quantity of frothy and vermillion blood escaped from it with a hissing noise at each inspiration. His extremities were cold, pulse scarcely perceptible, countenance discolored, and respiration short and laborious. In short he was every moment threatened with a fatal suffocation. After having examined the wound, the divided edges of the part, I immediately approximated the two lips of the wound and retained them by means of adhesive plaster, and a suitable bandage around the body. In adopting this plan I intended only to hide from the sight of the patient and his comrades, the distressing spectacle of the hemorrhage, which would soon prove fatal; and I therefore thought that the effusional blood into the cavity of the thorax could not increase the danger. But the wound was scarcely closed, when he breathed more freely, and felt easier. The heat of the body soon returned, and the pulse rose. In a few hours he became quite calm, and to my great surprise, grew better. He was cured in a very few days, and without difficulty."

Another famous accounting of an open chest wound was by William Beaumont in 1825. He attended Alexis St. Martin in 1822, who was shot in the lower chest. Beaumont arrived within one-half hour of the injury and noted that the wound had been caused by a short-range blast, within a yard of St. Martin's chest: "fracturing and carrying away the anterior half of the sixth rib, fracturing the fifth, lacerating the lower portion of the left lobe of the lungs, the diaphragm and perforating the stomach. The whole mass of materials forced from the musket, together with fragments of clothing and pieces of fractured ribs, were driven into the muscles and cavity of the chest."

Upon Beaumont's arrival, he found lung and stomach herniating from the wound. "After cleaning the wound from the discharges and other extraneous matter, and replacing the stomach, and the lung as far as practicable, I applied the carbonated fermenting poultice and kept the surrounding parts constantly wet with a lotion of muriate of

ammonia and vinegar." After an hour, Beaumont returned expecting to find his patient dead. To his pleasure and surprise, the patient was, in fact, improved. He had saved his life by closing his chest wound.

By the final years of World War I, the controversy of "to close or not to close" was resolved in favor of immediate wound closure. However, when closing these wounds it was important to understand the physiology of negative intrathoracic pressure. The German internist Buelau introduced closed underwater seal drainage of an empyema in 1875. In 1889, T. Holmes, a consulting Surgeon at St. George's Hospital in London, introduced intercostal drainage for large chest wounds. However, he did not advocate an underwater seal. It was not until World War II that closed tube drainage was added to the treatment of an open pneumothorax as a routine measure. Positive-pressure ventilation was introduced in the early 1900s. The most recent advancement in the treatment of these injuries came from the Scandinavians, who invented respirators in the early 1950s. Mortality from chest wounds steadily decreased in each war. It was 79% in the Crimean War, 62.5% in the Civil War, 55.7% in the Franco-Prussian War, 24.6% in World War I, 12% in World War II, and in recent civilian experience is now 4% to 7%.[2]

ANATOMY AND PATHOPHYSIOLOGY

The pathophysiology of an open pneumothorax has not much been improved upon since the days of Hewson and Larrey. The pathophysiologic changes of a sucking chest wound depend on the size of the wound and the intactness of the pleural space and lung. A defect in the chest wall is usually of no major clinical significance if the pleural space is obliterated.[3] However, most commonly, the pleural space is free and the air and/or blood moves in and out through the chest wall defect, making a "sucking" sound.

A sucking chest wound or open pneumothorax results in a mostly unidirectional flow of air through the wound and into the pleural space. During inspiration, the intrathoracic pressure is negative compared to the extrathoracic pressure. This allows air to flow through the wound and into the pleural space. During expiration, the tissues surrounding the wound come into apposition and decrease the wound diameter. This results in air becoming trapped within the pleural space. As breathing continues, this process progresses and air increasingly accumulates in the pleural space, compresses the lung, and prevents lung expansion during inspiration. The open pneumothorax can become large enough to exert tension on the hemithorax contents and the mediastinal structures.

In larger injuries, this air movement causes the ipsilateral lung to move inward and collapse on inspiration (**Figure 41-1A**). The lung may expand slightly or remain completely collapsed upon expiration, depending on the size of the chest wall defect (**Figure 41-1B**). There may also be mediastinal motion toward the noninjured lung during inspiration and toward the injured lung during expiration. This to-and-fro motion compromises the function of the healthy lung as well as the injured lung because it prevents its full expansion during inspiration. During expiration, some of the air from the noninjured lung may shift to the injured lung, and the reverse may happen during inspiration (an element of the "pendelluft" phenomenon). This entire mechanism results in a large functional dead space in the noninjured lung and loss of ventilation of the injured lung, causing severe ventilatory derangement, asphyxia, hypoxemia, and hypercarbia.[2–4]

The patient with an open pneumothorax may manifest a spectrum of presentations, ranging from asymptomatic and stable to severely dyspneic and agonal. The presentation depends on the size of the chest wall defect, the extensiveness of the injuries to the lung and other structures, the preinjury pulmonary status, and whether the pleural space is free or has adhesions. The patient may present with progressive respiratory insufficiency leading to a rapid demise if not treated. **The critical diameter of the chest wall wound has been described as two-thirds (or greater) the diameter of the trachea.[5] It is thought that at this size, air moves preferentially through the chest wall rather than through the trachea.**

Two additional "open chest wounds" deserve mention. First is the wound that fully penetrates the chest wall but seals itself and closes. It can seal from apposition if adjacent chest wall soft tissues, a hematoma, underlying pleural adhesions that do not allow air into the pleural space, or from a combination of these. This type of injury prevents air from entering the pleural space and does not significantly alter respiratory physiology except for the pain of breathing. This type of wound does not indicate that there is no underlying cardiac, intrathoracic, lung, or mediastinal injury. These types of wounds require management of hemorrhage, the application of a simple dressing, and a Surgeon for management of the wound, continued hemorrhage, and any internal injuries.

The final type of open chest wound is one that allows bidirectional airflow. Breathing results in bidirectional airflow through both the trachea and the chest wound, thus decreasing airflow through the trachea. This results in hypoventilation and hypoxemia. These patients require positive-pressure ventilation with either a bag-valve-mask device, CPAP or BiPAP machine through a face mask, or endotracheal intubation. The wound must be covered with a three-sided dressing, or an occlusive dressing after the placement

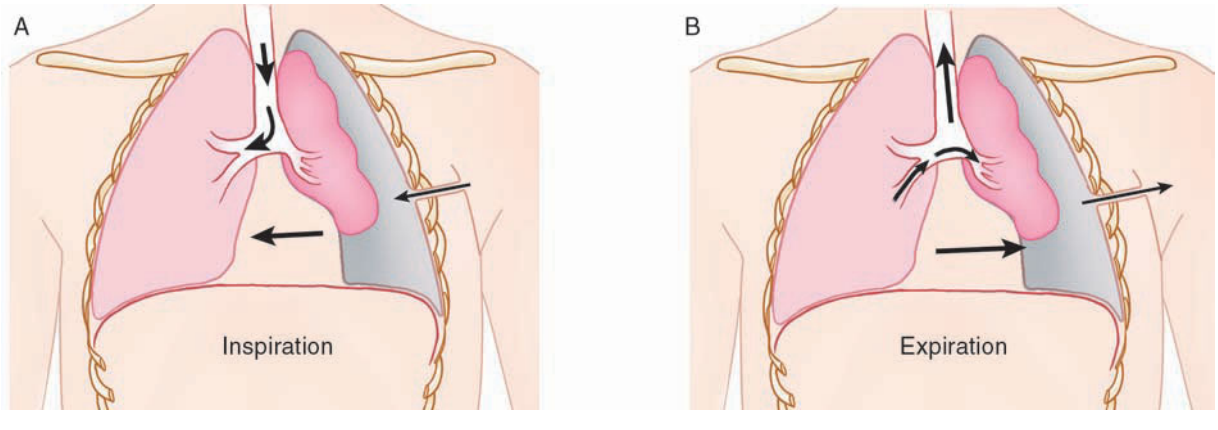

FIGURE 41-1. The effects of an open chest wound. **A.** Air moves into the pleural cavity and the lung collapses with inspiration. **B.** Air exits the pleural cavity and the lung expands slightly with expiration. The arrows represent the direction of airflow.

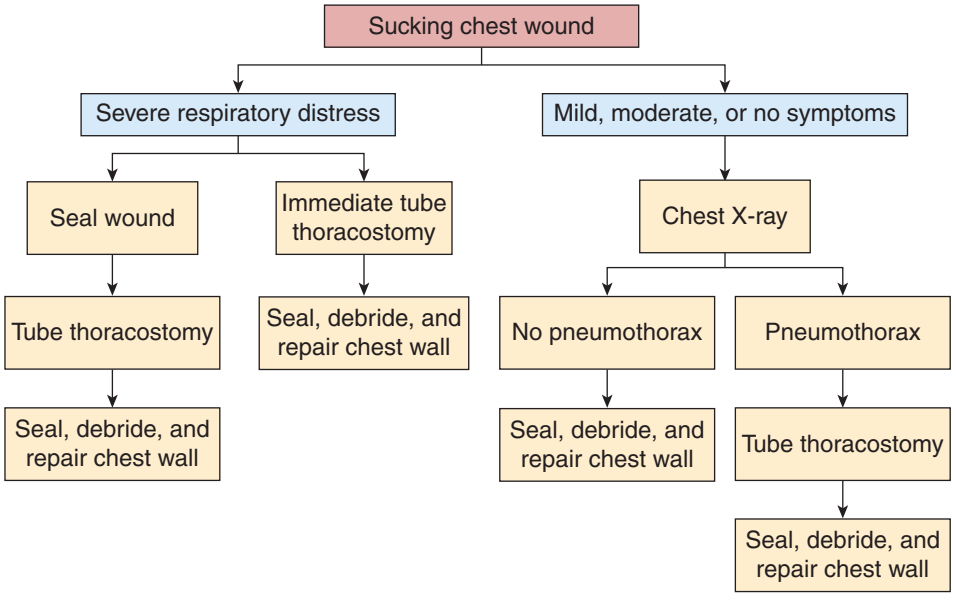

FIGURE 41-2. Algorithm for the diagnosis and treatment of an open pneumothorax. (Modified from Symbas.[3])

of a chest tube, and a Surgeon for management of the wound, continued hemorrhage, and any internal injuries.

INDICATIONS

Diagnosis of these injuries can be made easily based upon the obvious presence of the chest wall defect and the noise produced as the air moves in and out through the wound. In the symptomatic patient, all open chest wounds should be treated immediately.[3,6] Treatment techniques should be selected based on the patient's clinical condition and stability (**Figure 41-2**). **The three-sided dressing is only a temporary measure and it must be followed with the placement of a chest tube.**

Most experts agree that only the symptomatic patients should be treated in the field. An occlusive dressing should be placed over the wound and taped on only three sides. **The three-sided dressing allows air within the pleural cavity to be expelled into the atmosphere while preventing atmospheric air from entering the pleural cavity. If the wound is taped on all four sides, an open pneumothorax may quickly be converted into a tension pneumothorax.**[4,5,7–10]

In the Emergency Department, the very symptomatic patient should be treated as in the field. However, a completely occlusive dressing may be placed over the wound if a chest tube is subsequently to be placed. Continuously and closely monitor the patient for the development of a tension pneumothorax if the wound is completely sealed prior to the tube thoracostomy. **If a tension pneumothorax occurs, remove the occlusive dressing on at least one side or perform a needle thoracostomy (Chapter 39) to relieve it.**

Obtain a rapid, portable anteroposterior chest radiograph if the patient is asymptomatic, mildly symptomatic, or moderately symptomatic. If a pneumothorax is present, perform a tube thoracostomy and seal the wound. If the patient becomes severely symptomatic, the Emergency Physician should default to the other limb of the algorithm (**Figure 41-2**).

CONTRAINDICATIONS

There are no contraindications to the placement of a three-sided occlusive dressing, as this is a treatment for a life-threatening emergency. It must be properly placed to prevent the accidental conversion to a totally occlusive dressing and the progression of an open pneumothorax to a tension pneumothorax.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Petrolatum gauze
- Gauze 4 × 4 squares
- Reinforcing sterile dressings
- Tincture of benzoin
- Adhesive tape
- Sterile gloves and gown
- Face mask with an eye shield or goggles

The supplies for an occlusive dressing (i.e., petrolatum gauze) may not be readily available within or outside of the Emergency Department. Numerous substitutes for the petrolatum gauze are available. This includes a defibrillator pad. These gel-like pads are large, can be cut to size, and adhere to both dry and wet skin. Other alternatives include coating a water-soluble lubricant onto one side of a piece of aluminum foil, plastic food wrap, plastic from the packaging of sterile procedure packs, a piece cut from a plastic trash bag, or a zippered sandwich bag.

PATIENT PREPARATION

The amount and timing of patient preparation will be dictated by the location of the patient and his or her physiologic status. An informed consent is not required, as this is a noninvasive and lifesaving procedure. Such procedures should occur emergently with minimal patient preparation. If time permits, place the patient on the cardiac monitor and pulse oximeter and provide supplemental oxygen by face mask. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids.

If the patient has severe respiratory insufficiency, consider performing orotracheal intubation before or simultaneously with the application of the three-sided occlusive dressing. Positive-pressure ventilation through the endotracheal tube will expand the collapsed lung and force the intrapleural air out the wound and into the atmosphere.

Prepare the chest wall if the patient is asymptomatic, mildly symptomatic, or moderately symptomatic. Clean the wound and surrounding chest wall of any dirt and debris. Apply povidone iodine

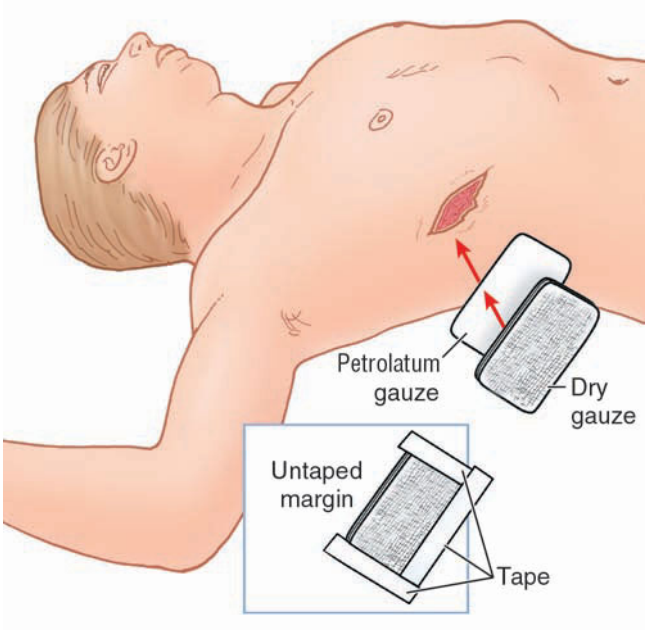

FIGURE 41-3. The three-sided occlusive dressing.

or chlorhexidine solution to the skin surrounding the wound and allow it to dry. Do not place the povidone iodine or chlorhexidine into the wound, as this has been shown to inhibit wound healing. Apply the three-sided occlusive bandage as described below. **If the patient is moderately to severely symptomatic, no preparation is required, as this wastes valuable time. Immediately apply the three-sided occlusive bandage.**

TECHNIQUE

The safest initial therapy for symptomatic sucking chest wounds is the careful application of a petrolatum gauze-based dressing taped on three sides (**Figure 41-3**). Apply three or four layers of petrolatum gauze over the wound. The dressing should extend 6 to 8 cm beyond the margins of the wound so that it will not be sucked into the pleural cavity in the spontaneously breathing patient. Cover the petrolatum gauze with dry 4 × 4 gauze squares. Apply tincture of benzoin around three sides of the dressing. Apply tape to secure the three sides of the dressing to the chest wall.

ALTERNATIVE TECHNIQUE

An alternative to the three-sided dressing is one that is totally occlusive or a four-sided dressing. There is little to no clinical evidence that a three-sided dressing is superior to a four-sided dressing. **The four-sided dressing should be placed only in the setting where rapid placement of a chest tube will be undertaken.** This occurs most commonly in the Emergency Department. It may be considered in the field when a tube thoracostomy is included in the prehospital standing medical orders.[23]

ASSESSMENT

Once the three-sided dressing has been placed, continue to closely monitor the patient for associated complications and evaluate them for underlying injuries. **Paramount among the complications is conversion of a simple pneumothorax to a tension pneumothorax. Do not be led into a false sense of security after placing the three-sided dressing. A patient can still develop a tension pneumothorax.** Periodically evaluate the three-sided dressing to ensure it is not covered with another dressing or blankets, not positioned between the patient and the bed or another object, and that it has not become occluded on all four sides. **If a tension pneumothorax occurs, remove the occlusive dressing on at least one side or perform a needle thoracostomy (Chapter 38) to relieve it.** Patients with an open chest wound have typically sustained an injury comprising great kinetic energy, whether from a blunt or penetrating event. Associated injuries will be very common. A head-to-toe secondary survey is imperative.

AFTERCARE

The aftercare of these patients consists of a tube thoracostomy (i.e., chest tube) followed by aggressive wound care, pain management, pulmonary toilet, continued monitoring, and investigation for other underlying injuries. **Once the wound is closed, the underlying pneumothorax or hemopneumothorax should be treated with the placement of a chest tube placed through an incision away from the injury site and not through the open chest wound.**

Pain will be a major problem for these patients. Trauma to the parietal pleura, bony structures, and intercostal nerves is very painful. It is imperative that these patients be able to make adequate ventilatory efforts, cough, deep breathe, perform incentive spirometry, and have aggressive pulmonary toilet. These are all necessary to prevent atelectasis, retained secretions, and pneumonia.[11] Various pain-relieving techniques may be utilized. Infiltration of long-acting local anesthetic solution may give initial relief, especially during wound debridement. Parenteral analgesics are the initial treatment modality. Advanced techniques to consider include regional nerve blocks, intercostal nerve blocks, and indwelling intrapleural or epidural catheters.

More definitive wound care should be considered once the patient is stabilized. Small, clean wounds may be managed simply with routine wound care and changes of the occlusive dressing. Local irrigation and debridement may be added if there is a limited amount of contamination. Large, grossly contaminated, and/or complex wounds are best managed in the operating room. Optimally, these wounds should be debrided and closed primarily. However, some wounds may be contaminated or complex, such that closure is not possible initially. In such cases, the wound should be debrided and left open. Large, occlusive dressings are placed along with chest tubes for removal of air, fluid, and blood. Multiple operative debridements may be required. When the wound is clean and the patient is optimized, secondary closure may be performed.[11]

Closure of large wounds may require a combination of complex techniques. These may include various skin, subcutaneous tissue, and muscle flaps.[12] Free rib grafts, pectoral muscle flaps, latissimus dorsi muscle flaps, abdominal muscle flaps, omentum flaps, skin grafts, or a myocutaneous flap can be utilized.[12–19] If using these are not possible, closure may be accomplished with a prosthetic material such as Prolene or Marlex, either temporarily or definitively.[20–22] In wounds of the lower chest, detachment of the diaphragm with reattachment at a higher level may be utilized. This converts an open chest wound to an intraabdominal wound and alleviates the ventilatory problems.

COMPLICATIONS

Complications may occur acutely or may be delayed. **Occlusion of the chest wall defect and decompensation of the patient from a simple pneumothorax being converted to a tension pneumothorax is the primary early complication. The patient must be closely monitored until a chest tube can be inserted.** A tension pneumothorax can result if the wound is completely occluded by

a blood clot, a dressing that has been sucked into the wound, soft tissue, or a bandage that is adherent on all four sides. **Immediately remove the bandage to relieve a tension pneumothorax.** Some physicians and authors remove only one side of the occlusive bandage to relieve the pneumothorax. The choice to remove part or all of the bandage is physician-dependent. If the patient is still symptomatic, ensure that the wound is not occluded by a blood clot or soft tissue.

Other complications would ensue from the failure to seek, diagnose, and treat other underlying, potentially life-threatening injuries. The patient may develop respiratory insufficiency secondary to multiple causes, some of which may be preventable with optimal care. These causes include inadequate pulmonary toilet, inadequate pain management, pulmonary contusion, pneumonia, and/or adult respiratory distress syndrome. Wound complications may include infection, fasciitis, osteomyelitis, empyema, hemothorax, and loculated hemothoraces or pneumothoraces. These wounds require frequent evaluation and aggressive care to prevent these sequelae.

SUMMARY

Open chest wounds are easily diagnosed by the evident chest wall defect and the auscultation of air moving into and out of the pleural cavity. This is a true life-threatening emergency. Treatment is dictated by the patient's clinical presentation. Lifesaving therapy should be undertaken with the simple application of a three-sided petrolatum gauze dressing. The three-sided dressing allows air within the pleural cavity to be expelled into the atmosphere while preventing atmospheric air from entering the pleural cavity. This converts the open pneumothorax to a closed pneumothorax and eliminates the major physiologic derangement. Once the patient is stabilized, more definitive care should be carried out with chest tube placement and appropriate wound care.

42 Emergency Department Thoracotomy

Kenny Banh

INTRODUCTION

An increase in urban violence combined with better triage and transport systems has resulted in the arrival of sicker trauma patients at the Emergency Department (ED). Previously, these patients might not have survived long enough to make it to the ED.[1] The majority of individuals with penetrating chest injuries arrive in the ED in stable condition and are managed without major operative procedures.[2] A subset of individuals, however, arrive in extremis and may require a thoracotomy. The purpose of the ED thoracotomy may be to control hemorrhage within the chest, to relieve a pericardial tamponade surgically or one that cannot be decompressed by a needle thoracotomy, to redistribute cardiac output to the brain and the heart, or to provide more effective cardiac massage.[3]

ANATOMY AND PATHOPHYSIOLOGY

The structures within the chest include the heart, esophagus, lungs, bronchi, pulmonary hilar vessels, and numerous other vascular structures. The heart is located in the anterior mediastinum. The aorta and esophagus are located in the posterior mediastinum. The internal mammary arteries course along the posterior aspect of the anterior chest wall just lateral to the sternum. The intercostal vessels run along the inferior aspect of the ribs. The subclavian vessels are at the very superior aspect of the thorax. They course directly under the clavicles and can be very difficult to visualize via an anterolateral thoracotomy. The azygos vein can be found coursing along the posterior right hemithorax and emptying into the superior vena cava.

The heart is covered by the tough pericardial sac. **The phrenic nerves run superiorly to inferiorly on each side of the pericardiac sac.** They can be visualized as white or yellow strands on either side of the pericardium. Once the pericardial sac is opened, the left anterior descending coronary artery can be visualized on the anterior surface of the heart. It overlies the interventricular septum. Injuries to the left of this artery usually denote left ventricular damage while injuries to the right usually denote right ventricular damage. The majority of the anterior surface of the heart is occupied by the right ventricle.

The posterior mediastinum contains the aorta. It is located posterior to the esophagus and runs lateral to the vertebral bodies. The thoracic aorta gives off the intercostal vessels. If torn during the mobilization of the aorta, the intercostal vessels can cause troublesome bleeding.

Beall et al. originally introduced the ED thoracotomy for penetrating chest wounds.[4] This procedure was subsequently used for patients with penetrating abdominal wounds and victims of blunt trauma. **In recent years, several studies have shown an abysmal survival rate associated with an ED thoracotomy in victims of blunt trauma.** When vital signs are present in the field, the survival rates for such individuals range from 0.6% to 6.0%.[5–7] Patients who undergo an ED thoracotomy for penetrating abdominal injuries have survival rates of approximately 5%.[8] In these cases, the ED thoracotomy is performed for resuscitation purposes.

Patients presenting to the ED with penetrating chest trauma who present without signs of life in the field have a poor prognosis. Survival for these patients ranges from 0% to 9%.[9,10] If the patient sustains penetrating chest trauma and has signs of life in the field, survival averages 14%, with a range of 0% to 36%.[1] The reason for the wide range probably lies in the small numbers of patients in the studies and the varying definitions of "signs of life."

The best survival for penetrating chest injury and an ED thoracotomy is in patients with stab wounds resulting in cardiac tamponade. The use of bedside ED ultrasonography allows better identification of these patients. The survival for this entity ranges from 21% to 71%, averaging 31%.[6,11–14] It should be noted that 90% of patients who survive an ED thoracotomy for penetrating chest injuries have good neurologic outcomes.[11] This must be contrasted with a 50% incidence of good neurologic outcome in survivors of blunt trauma who receive a thoracotomy.[15]

INDICATIONS

Signs of life, if present at the scene or at any time during the transport or resuscitation and a short transport time, should prompt an ED thoracotomy in patients with penetrating chest trauma.[13,16] These signs include a palpable pulse, a blood pressure, pupil reactivity, any purposeful movement, an organized cardiac rhythm, or any respiratory effort. **Thus, the patient must have signs of life on presentation or have lost them en route to the ED if a thoracotomy is to be considered.** A thoracotomy should be performed to control hemorrhage within the thoracic cavity, to decompress a pericardial tamponade, to cross-clamp the aorta and redistribute the cardiac output to the brain and heart, and to provide open cardiac massage. Patients who are in shock or rapidly deteriorating clinically after penetrating chest trauma and are not responding to aggressive fluid resuscitation are also candidates

for an ED thoracotomy. It is also indicated to cross-clamp the aorta when the patient is exsanguinating from injuries below the level of the diaphragm.[17]

CONTRAINDICATIONS

There are a few well-supported contraindications to performing an ED thoracotomy. **A thoracotomy should not be performed in patients with penetrating chest trauma who have no vital signs in the field.**[18,19] In the absence of field vitals, the survival rates are at the lower end of the range. The few that survive have severe neurologic impairment. Outside of patients that collapse in the ED, **victims of blunt trauma with or without field vitals should not routinely undergo an ED thoracotomy.**[20] It is also contraindicated when prehospital CPR exceeds 10 minutes without a return of spontaneous circulation after blunt trauma, when prehospital CPR exceeds 15 minutes without a return of spontaneous circulation after penetrating trauma, and when the patient presents to the ED in asystole without a pericardial tamponade.[18,19] **An ED thoracotomy should not be performed regardless of the indications if a Trauma Surgeon, or other qualified Surgeon, is not immediately available to take the patient to the Operating Room for definitive management.** Do not perform an ED thoracotomy with the anticipation of transferring the patient to another facility if they can be resuscitated.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile towels
- Sterile gloves and gown
- Face mask with an eye shield or goggles
- Sandbags or towels
- #3 scalpel handle
- #10 scalpel blade
- US Army retractors, 1 set
- Curved Mayo scissors, 8¾ and 6¾ in.
- Curved Metzenbaum scissors, 5½ in.
- Toothed forceps
- Satinsky vascular clamp
- Finochietto rib retractor, 12 in spread
- Suction source
- Suction tubing
- Yankauer suction catheter
- 2-0 silk suture on a large curved needle
- Hemostats, needle driver, 10 in
- Gauze 4 × 4 squares
- Sternal saw, hand-operated
- Lebsche knife (sternal osteotome) and mallet

All hospitals and EDs have preprepared, prepackaged, and sterile thoracotomy trays. Review the equipment available on the trays at your institution to become familiar with their contents before the tray is required emergently.

PATIENT PREPARATION

The patient should already be supine, intubated, and ventilated. Abduct the left upper extremity 180° (**Figure 42-1**). The extremity should be held in position by an assistant or with the use of a soft restraint. Place sandbags or towels under the patient's left scapula. This will elevate the torso off the bed to allow for more complete access. Apply povidone iodine or chlorhexidine solution to the patient's left chest. Apply sterile drapes over the chest to demarcate a surgical field.

An ED thoracotomy is primarily performed on patients who are unresponsive. As such, there is no immediate need for analgesics, sedatives, or local anesthetic solution. If the patient is resuscitated, they will experience significant postprocedural pain. **Parenteral analgesics and sedatives should be available and administered if the patient survives and there are no contraindications.**

Set up the required equipment. Open the prepackaged, sterile thoracotomy tray on a bedside table. The tray should contain all the equipment required for the procedure. Sterile technique should be observed and followed by all involved personnel, who should be fully capped, gowned, masked, and gloved. This will protect the healthcare personnel from exposure to the patient's blood and body fluids as well as minimizing the risk of infection if the patient survives.

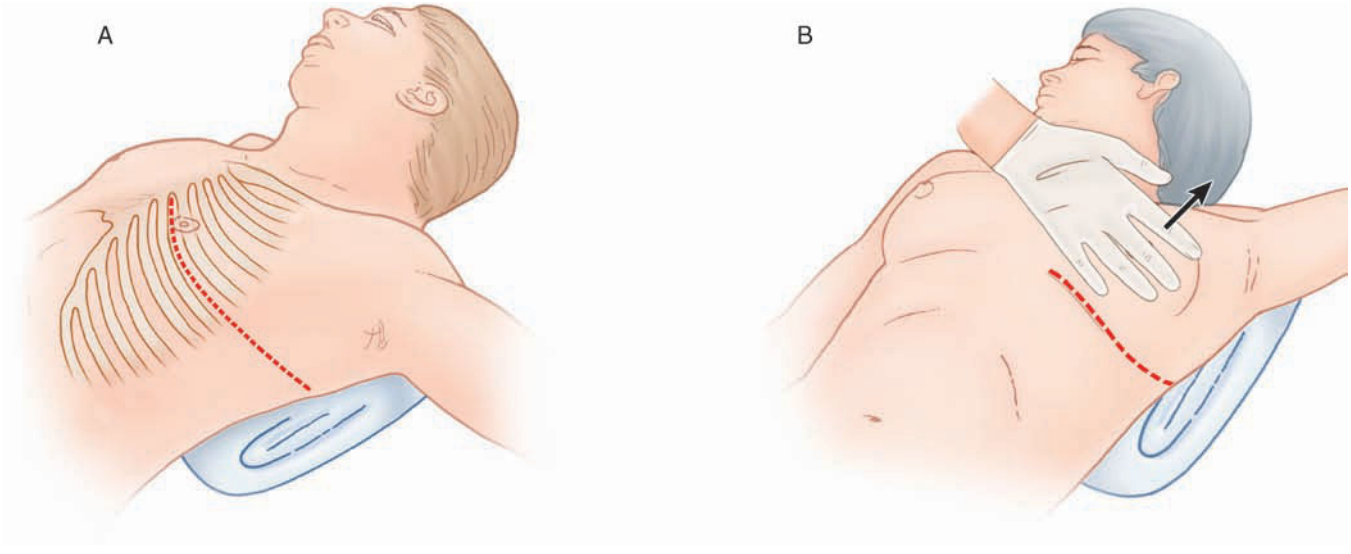

FIGURE 42-1. Patient positioning. Place a sandbag or towel under the left shoulder and abduct the left arm 180°. Identify the fifth intercostal space in the male (**A**) or the inframammary line in the female (**B**).

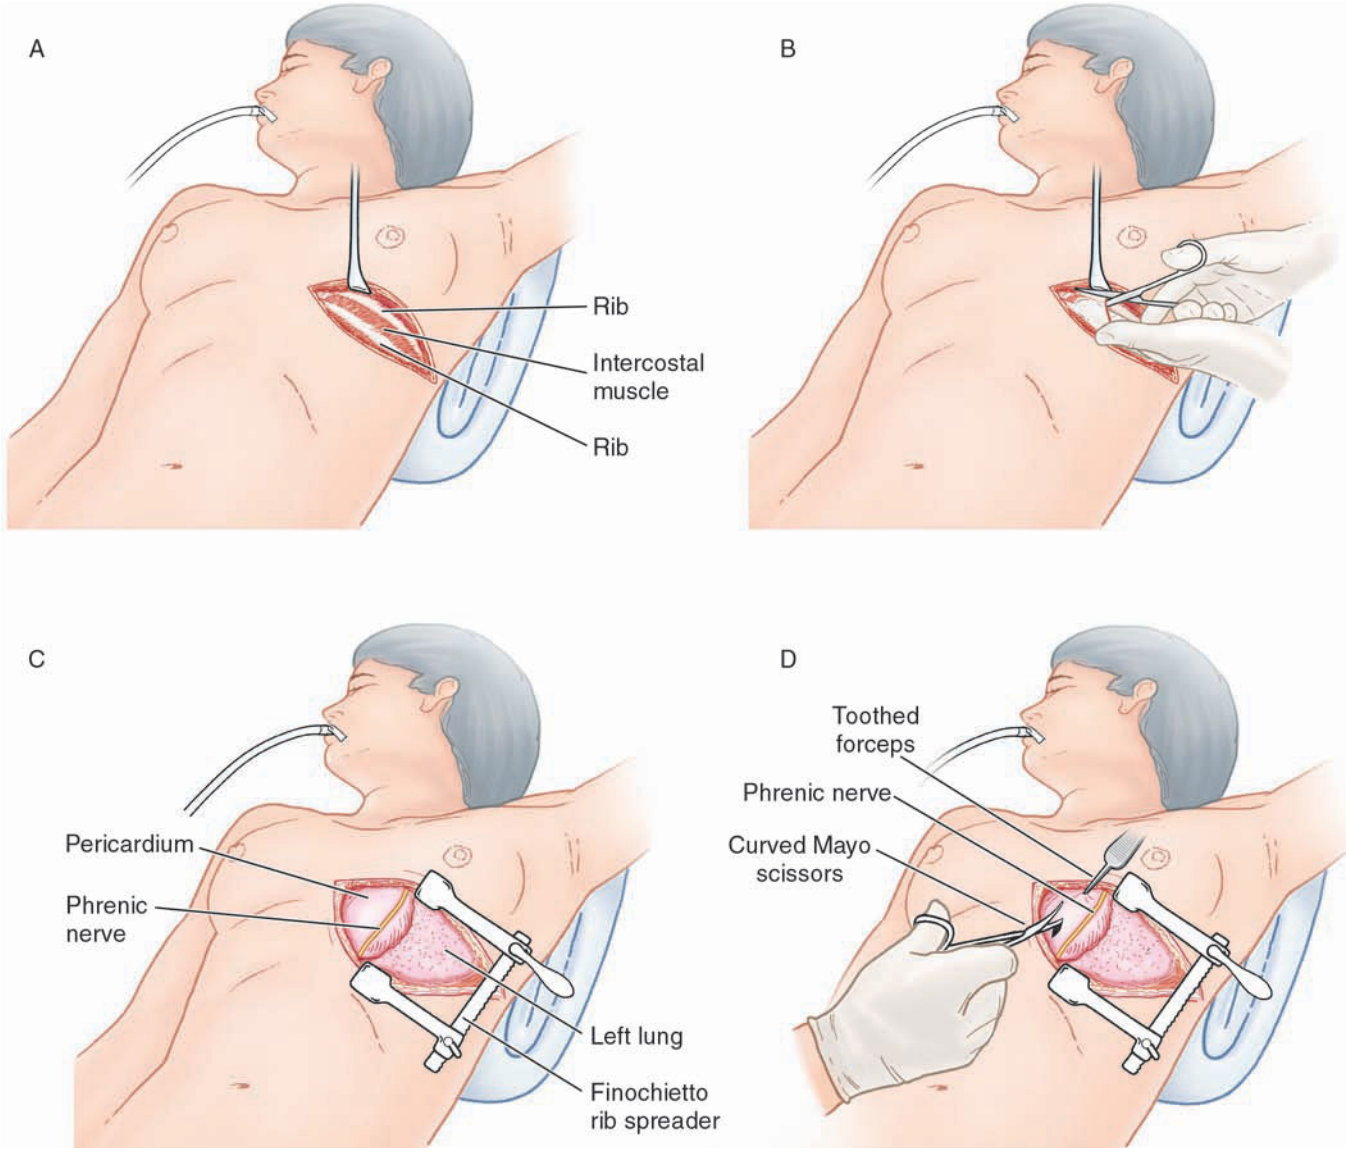

FIGURE 42-2. ED thoracotomy. **A.** The initial incision is made through the skin, subcutaneous tissue, and superficial muscles. **B.** The intercostal muscles are incised with Mayo scissors. **C.** The Finochietto rib spreader is inserted and opened. **D.** The pericardium is grasped and opened.

TECHNIQUES

LEFT-SIDED THORACOTOMY

Apply the scalpel blade to the handle. Identify the site to be used to make the initial skin incision. This is the left fourth or fifth intercostal space, corresponding to the intercostal space below the nipple in a male and below the inframammary fold in a female (**Figure 42-1**). **Using one stroke of the scalpel, make an incision extending from the sternum to the posterior axillary line or the gurney (Figure 42-2A).** Carry the incision through the skin, subcutaneous tissues, and superficial chest musculature down to and through most of the intercostal muscles (**Figure 42-2A**). An Army retractor may be used to open and separate the edges of the incision. This step is based on physician preference and is not required.

Discontinue mechanical ventilation. Consider advancing the endotracheal tube into the right mainstem bronchus. This will allow the left lung to deflate and minimize injury upon entering the left thoracic cavity while still ventilating the right lung. Alternatively, temporarily discontinue mechanical ventilation. Puncture through the intercostal muscles in the anterior axillary line with the curved Mayo scissors. Carefully extend the puncture 2 to 3 cm using the curved Mayo scissors. Insert the nondominant index and middle fingers through the incision and separate the lung from the chest wall. Advance the fingers and Mayo scissors simultaneously, superiorly then inferiorly to cut the intercostal muscles along the entire inner space (**Figure 42-2B**). Resume mechanical ventilation.

Insert the Finochietto retractor with the arm and crank positioned near the gurney (**Figure 42-2C**). Turn the crank to open the arms of the rib spreader. Clear any blood from the left hemithorax and inspect for any brisk bleeding. If extensive bleeding is observed, it must be controlled. Use digital pressure or hemostats to initially control intercostal artery or other bleeding vessels. Subsequently place 2-0 silk stitches to tie off the bleeding vessels. For subclavian vessels, digital control must be followed by rapid transport to the operating room, since these vessels are difficult to control through an anterolateral thoracotomy.

OPENING THE PERICARDIUM

Move the left lung superiorly and laterally to expose the pericardial sac. **A pericardiotomy should be routinely performed if blood is seen within the pericardial sac, if the heart cannot be visualized through the pericardium, or if there is no other obvious injury within the chest and a potential cardiac injury may exist. Many Emergency Physicians and Trauma Surgeons will routinely open the pericardium when they are performing a thoracotomy, as a pericardial tamponade is difficult to detect visually and a potential cardiac injury may exist.**

Open the pericardial sac anterior to the phrenic nerve. Grasp and elevate the pericardium with a toothed forceps anterior to the phrenic nerve, which appears as a white or yellow strand along the lateral aspect of the pericardium (Figure 42-2D). Make an incision in the pericardium near the apex of the heart using a curved Mayo scissors. Note the color of the fluid that is expressed from the pericardial sac. It should normally be straw-colored without any hint of red. Carefully insert one of the jaws of the Mayo scissors into the pericardial sac. **Extend the incision with the Mayo scissors parallel to the phrenic nerve, from the apex of the heart to the root of the aorta.** Deliver the heart from the pericardium and inspect it for any injury. Internal cardiac massage may be performed for asystole, bradycardia, and/or hypotension. The technique is described in Chapter 43. Any cardiac wounds identified should be temporarily plugged or closed as described in Chapter 44.

RIGHT-SIDED THORACOTOMY

If there is a high index of suspicion of injury in the right hemithorax with minimal or no injury found in the left hemithorax, the thoracotomy must be extended to the right side. If possible, extend the incision through the sternum using a curved Mayo scissors and continue it to the right posterior axillary line (**Figure 42-3**). Remove the Finochietto rib spreaders from the left side and apply them to the patient's right fifth intercostal space. Examine the right hemithorax for injury. When the sternum is cut, the internal mammary arteries on both sides will be lacerated. Apply hemostats to the transected vessels to obtain hemostasis. They may later be tied off if the patient is resuscitated.

Occasionally, the large curved Mayo scissors cannot transect the calcified sternum. Perform a right-sided thoracotomy similar to that on the left. If further access is required, cut the sternum with a hand-held sternal saw or a Lebsche knife (**Figure 42-4**). Pass one end of the sternal saw from the left fifth intercostal space, behind the sternum, and out of the right fifth intercostal space (**Figure 42-4A**). Place an index finger through the loop on each end of the sternal saw. Move the hands toward and away from the patient in a to-and-fro motion until the sternum is transected. Alternatively, a Lebsche knife can be used to transect the sternum. Place the hooked portion of the knife under the sternum with the sharp blade against the lateral border of the sternum (**Figure 42-4B**). Lift up the handle of the Lebsche knife to lock it against the posterior surface of the sternum. This will prevent the tip of the Lebsche knife from cutting the heart. Hit the flat knob on the back of the Lebsche knife with a mallet to drive the knife through the sternum (**Figure 42-4B**).

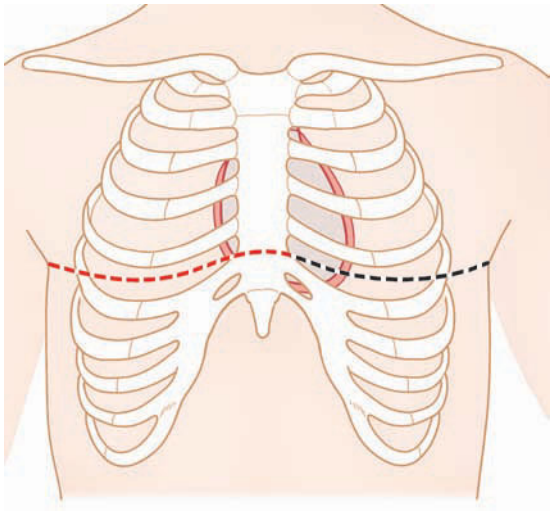

FIGURE 42-3. The left-sided incision is continued across the sternum and the right fifth intercostal space to perform a right-sided thoracotomy.

ASSESSMENT

Any bleeding should be controlled with the application of pressure, hemostats, and/or sutures. Any injuries to the heart (Chapter 44) or the hilum and great vessels (Chapter 45) should be managed. Cross-clamping of the proximal aorta will prevent further exsanguination from more distal injuries (Chapter 46). Open cardiac massage can be performed while the resuscitative efforts continue (Chapter 43).

AFTERCARE

If the patient is resuscitated in the ED, they should be immediately transported to the Operating Room for definitive care as soon as the Anesthesiologist and Surgeon are available. Continue the administration of fluids, packed red blood cells, platelets, plasma, and inotropic agents as necessary until the patient is hemodynamically stable. Administer broad spectrum antibiotics intravenously if the patient is resuscitated and survives. Administer parenteral analgesics and/or sedation if not contraindicated.

COMPLICATIONS

The ED thoracotomy has many potential and serious complications. Fortunately, this procedure is often being performed as a last effort at resuscitation of a "dead patient." The complications are, therefore, not significant when the alternative to this procedure is death.

The ED thoracotomy is rarely ever performed under truly sterile conditions. Time is often of the essence in performing this procedure. Povidone iodine or chlorhexidine solution and sterile drapes are rarely applied before an emergent ED thoracotomy. If applied, the povidone iodine or chlorhexidine solution does not have time to dry before the skin incision is made. Parenteral antibiotics should be administered if the patient is resuscitated.

The complications of the thoracotomy include vascular and organ injury. Lacerations of the internal mammary or intercostal arteries can be ligated with silk suture. There is also the possibility of inadvertent laceration of the lung or the myocardium during the initial incision. By temporarily halting mechanical ventilation while performing the thoracotomy, injury to the underlying lung can often be prevented. These injuries will need repair at the appropriate time.

A pericardiotomy can result in significant complications. The left phrenic nerve may be transected. The myocardium or a coronary artery can be lacerated. The heart may be fixed by adhesions to the pericardium from prior pericardial disease or pericarditis. Attempting to remove the heart from the pericardium can result in avulsion of the atrial or ventricular myocardium. Performance of the pericardiotomy adds another delay in initiating cardiac compressions.

Care should be taken to prevent injury to any of the healthcare providers. Universal precautions should be followed by all

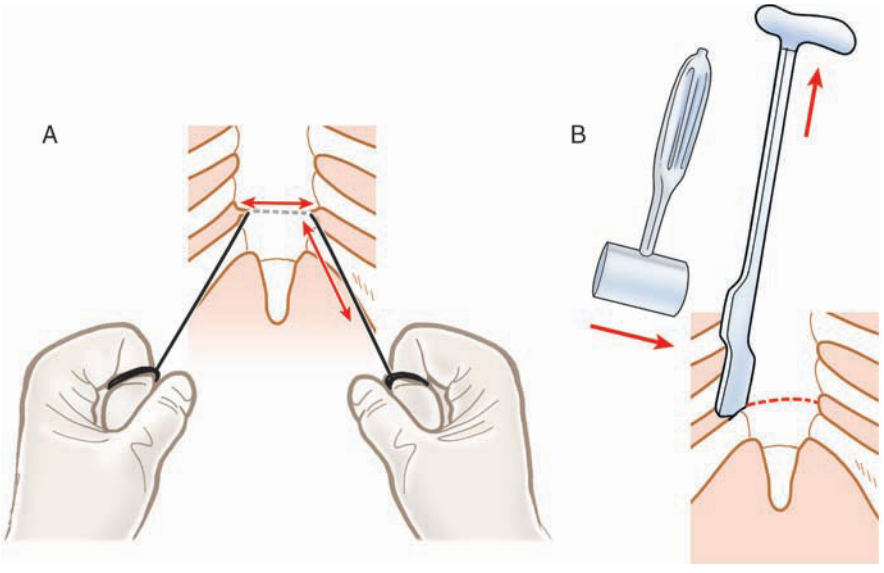

FIGURE 42-4. Cutting the sternum. **A.** The sternal saw is moved to-and-fro while maintaining upward pressure. **B.** The Lebsche knife is hooked under the sternum and lifted upward to secure it in place. The mallet strikes the Lebsche knife and drives it through the sternum.

personnel. The use of gloves, goggles, masks, and gowns will protect against exposure to the patient's blood. All needles, scalpels, and scissors should be returned to the bedside tray immediately after use and not left on the patient or the bed. Use extreme caution when placing your hands inside the patient's hemithorax. Fractured ribs from the trauma or the Finochietto rib spreader can easily penetrate gloves and skin. The costs associated with an occupational exposure associated with an ED thoracotomy are quire significant.[21] This is especially true if the healthcare provider develops hepatitis C or HIV.[21]

SUMMARY

An ED thoracotomy is a lifesaving procedure when used on patients in extremis secondary to penetrating chest or abdominal trauma. To be considered for this procedure, the patient must have signs of life when brought to the ED, must have lost them en route, or have lost them on the scene. This procedure should rarely be used in patients with blunt trauma. The Emergency Physician must have the appropriate surgical backup before performing a thoracotomy, since this procedure does not provide definitive therapy.

43 Open Cardiac Massage

Eric F. Reichman

INTRODUCTION

The purpose of cardiopulmonary resuscitation (CPR) during cardiac arrest or hypovolemic shock is to provide adequate cardiac output. This can be done using either closed or open chest cardiac massage. Open cardiac massage may on rare occasions be performed in the Emergency Department. It is performed on patients who have had an emergent thoracotomy after penetrating chest trauma and have inadequate cardiac activity. It may also be performed, in rare instances, after a thoracotomy to decompress a pericardial tamponade in a medical patient. Open cardiac massage is considered a heroic procedure in the Emergency Department that can be lifesaving if performed on the appropriate patient.[1–11]

Open cardiac massage was routinely performed before the introduction of closed chest CPR. This technique was primarily performed in hospitals by Surgeons. Most of the patients were surgical and open cardiac massage had a high success rate. After the development of closed chest CPR in the early 1960s, there was a dramatic decline in open cardiac massage in the mid-to-late 1960s and 1970s. The exceptions were cardiac arrests due to trauma or in the Operating Room.

ANATOMY AND PATHOPHYSIOLOGY

The efficacy of cardiac massage can be established by measuring the cardiac output, coronary perfusion pressure, and cerebral perfusion pressure. Del Guercio et al. showed that a higher cardiac index can be achieved with open than with closed cardiac massage.[1] A minimal coronary perfusion pressure of 15 mmHg must be maintained for return of spontaneous circulation. While not all patients with this pressure will have a return of spontaneous circulation, a pressure of less than 15 mmHg predicts a uniformly fatal outcome.[2] While closed chest CPR generated only 1 to 9 mmHg of pressure, Boczar et al. found that their patients all had a coronary perfusion pressure of almost 20 mmHg throughout open chest massage.[3] Open chest CPR produces improved cerebral perfusion and better neurologic recovery.[4,10] Open cardiac massage can generate near normal cerebral blood flow and improve cardiac perfusion pressure.

INDICATIONS

Open cardiac massage is indicated if absent or inadequate cardiac activity is noted after a thoracotomy for penetrating trauma, a thoracotomy to decompress pericardial tamponade (spontaneous, postsurgical, or from an aortic dissection), or a cardiac arrest after recent chest surgery.[7,9,11] Other possible indications include abnormal chest wall anatomy that prevents closed chest CPR, hypothermic cardiac arrest, refractory ventricular fibrillation, massive air embolism, and if standard CPR is not effective.

CONTRAINDICATIONS

The only absolute contraindication to performing open cardiac massage is the presence of a palpable pulse. Open cardiac massage is ineffective if the patient has a pericardial tamponade. Perform a pericardiotomy and remove any clots from the pericardial sac. The

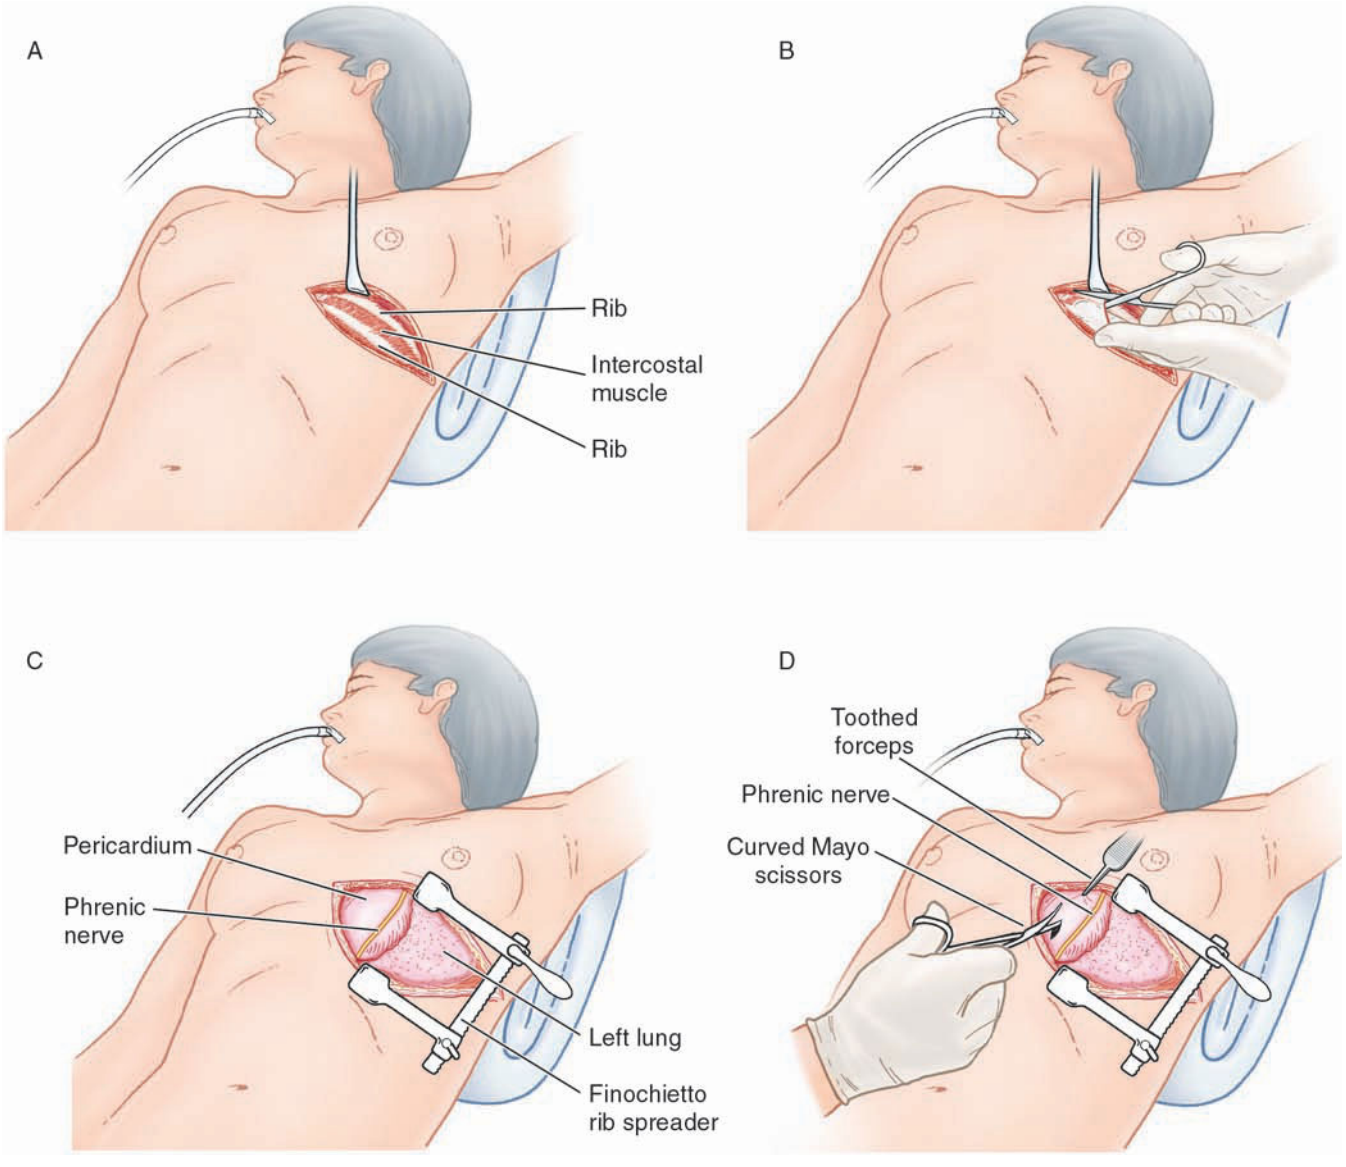

FIGURE 43-1. The anterolateral thoracotomy.

heart may then begin to beat spontaneously. If not, repair any lacerations to the myocardium prior to performing cardiac compressions.

EQUIPMENT

No equipment is required to perform open cardiac massage other than that needed to perform the thoracotomy and pericardiotomy (Chapter 42).

PATIENT PREPARATION

The preparation and positioning of the patient is exactly the same as that for a thoracotomy. A thoracotomy must first be performed (**Figure 43-1**). Refer to Chapter 42 for the complete details of a thoracotomy. A pericardiotomy should be performed only if absolutely necessary—that is, if blood is seen within the pericardial sac or cardiac tamponade is suspected. Remove any blood and clots from the pericardial sac, deliver the heart from the pericardial sac, and repair any myocardial lacerations.

An intact pericardium is preferable if open cardiac massage is to be performed. It prevents the fingertips from inadvertently rupturing the atria or ventricles should the heart be grasped incorrectly. The pressure from open cardiac massage is distributed over a larger area if the pericardium remains intact. The heart will move within the pericardial sac, prevent the fingers from compressing one spot for a prolonged time, and may decrease the chance of myocardial rupture.

TECHNIQUES

Several important principles must be kept in mind prior to performing open cardiac massage. The heart must be angled not more than 20° to 30° into the left hemithorax (Figure 43-2A). Angulation of more than 30° may crimp the pulmonary veins and vena cava closed and thus minimize cardiac output. The compressive forces should be applied perpendicular to the interventricular septum. Your hands should be placed directly behind and in front of the heart. The left anterior descending artery can be used as a landmark, as it runs above the interventricular septum. Do not place the fingers over the coronary arteries so that their flow is occluded. The fingertips should never be used to compress the heart, as they may rupture the

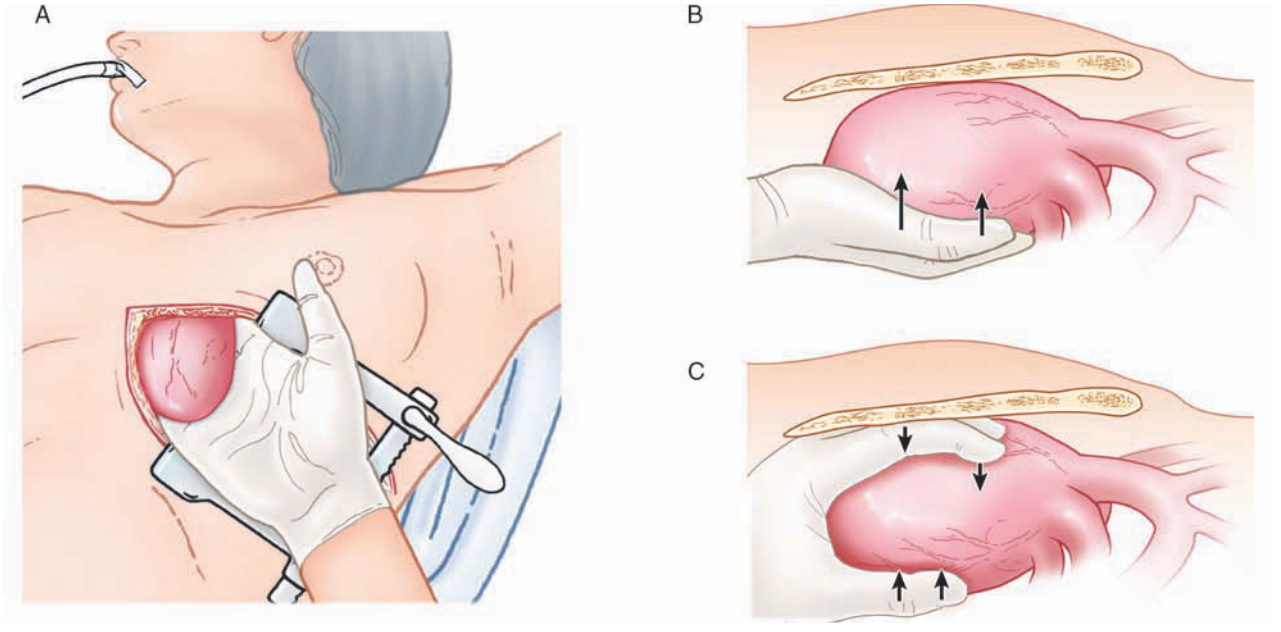

FIGURE 43-2. One-handed open cardiac massage. **A.** The dominant hand angles the heart 20° to 30° into the left hemithorax. **B.** One-handed cardiac massage with sternal compression. **C.** The one-handed compression technique.

myocardium. Use only the palm, volar surfaces of the fingers, and pads of the fingers to perform cardiac compressions. The fingers should always be held tightly together to form a flat surface. This allows the force of compression to be spread out and not concentrated over one finger. Each compression of the heart must be followed by complete relaxation of the heart. It is during this relaxation phase (i.e., diastole) that the cardiac chambers fill with blood and the coronary arteries perfuse the myocardium.

Three techniques have been described to perform open cardiac massage (**Figures 43-2 & 43-3**). These include one-handed massage with sternal compression, one-handed compression, and two-handed compression. Two-handed compression has been shown to be consistently superior to the other two techniques in generating cardiac output.[5]

ONE-HANDED MASSAGE WITH STERNAL COMPRESSIONS

Tightly adduct the fingers of the dominant hand to make a flat surface. Insert the hand into the thoracotomy incision and against the posterior surface of the heart (**Figures 43-2A & B**). Angle the heart 20° to 30° into the left hemithorax. Compress the heart against the sternum, beginning with the heel of the hand, then the palm, then fingers in sequence. This method is difficult to perform in children because of the plasticity of the sternum.[6]

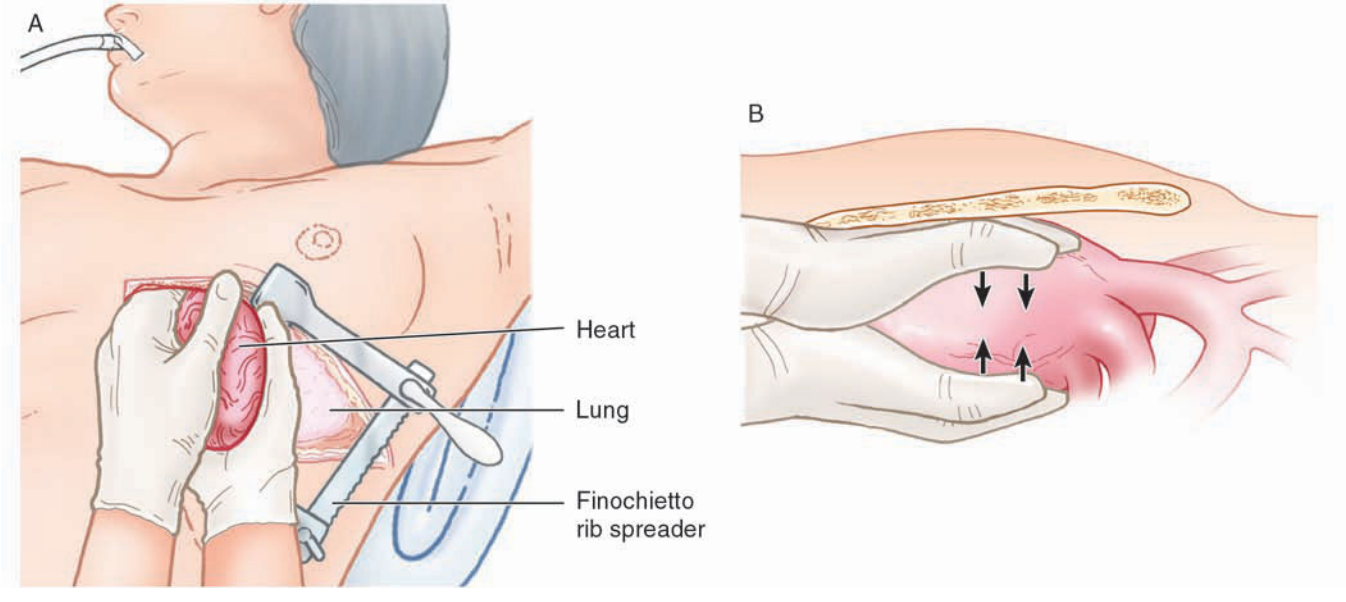

FIGURE 43-3. Two-handed open cardiac massage. **A.** The hands are positioned on the anterior and posterior surfaces of the heart. **B.** Compressions begin at the cardiac apex with the palms and progress toward the base of the heart with the fingers.

ONE-HANDED COMPRESSIONS

Tightly adduct the fingers of the dominant hand to make a flat surface. Insert the hand into the thoracotomy incision and against the anterior surface of the heart (**Figure 43-2C**). Place the thumb against the posterior surface of the heart. The apex of the heart will lie in the palm of the hand (**Figure 43-2C**). Angle the heart 20° to 30° into the left hemithorax. Appose the thumb and fingers to compress the heart. This is not the preferred method, as the thumb can place significant pressure on the left ventricle and possibly cause it to rupture.

TWO-HANDED COMPRESSIONS

This is the technique of choice in children. The child's sternum, the costochondral tissues, and the ribs are mostly cartilage. Thus, the sternum is very pliable. This makes the one-handed massage with sternal compression technique not very effective. The one-handed compression technique can rupture the thin myocardial walls.

Tightly adduct the fingers and cup the left hand. Insert the left hand into the thoracotomy incision and against the anterior surface of the heart (**Figure 43-3A**). Tightly adduct the fingers of the right hand to make a flat surface. Insert the right hand into the thoracotomy incision and against the posterior surface of the heart (**Figure 43-3A**). Angle the heart 20° to 30° into the left hemithorax. Appose the hands to compress the heart (**Figure 43-3B**). Compressions should ideally begin with the heel of the hands and progress toward the fingers.

ASSESSMENT

Compressions should begin at a rate appropriate for the patient's age as specified by the American Heart Association (Pediatric Advanced Life Support and Advanced Cardiac Life Support). Ideally, compress the heart at a rate of at least 100 times a minute if possible. This compression rate is based on consensus and not clinical research. Assess the effectiveness of the cardiac compressions by noting a palpable carotid pulse. A radial or femoral arterial line can be placed to monitor the effectiveness of the compressions. The arterial line allows for repeated blood and blood gas sampling. The arterial line will also allow the Emergency Physician to ensure that the heart is completely relaxed between compressions.

AFTERCARE

If a spontaneous cardiac rhythm and a peripheral pulse return, cover the thoracotomy incision with sterile saline-moistened gauze and a simple dressing. Administer intravenous antibiotics whose spectrum covers skin flora. The patient must be taken emergently to the Operating Room by a Trauma Surgeon or Cardiothoracic Surgeon for definitive treatment and closure of the chest wall.

COMPLICATIONS

The major complication of open cardiac massage is myocardial rupture or perforation. This can occur from compression of the heart against a jagged and fractured rib or sternum. Incorrect technique with too vigorous a massage can result in perforation of the ischemic myocardium by the fingertips. Other complications include decreased cardiac output with compressions if the heart is angled more than 30° into the left hemithorax and kinks shut the vena cava or pulmonary veins. Infection is possible if the patient survives. Parenteral antibiotics should be administered to prevent infection and sepsis. The complications associated with the thoracotomy and the pericardiotomy are discussed in Chapter 42. The quality of life of survivors can be poor to normal.[8]

SUMMARY

Open cardiac massage is a more efficient way of maintaining circulation than closed chest massage. Cardiac compressions can be performed with one or two hands, depending on physician preference. The two-handed technique is preferred, as it generates greater cardiac output than the one-handed techniques. Once a cardiac rhythm and blood pressure are restored, definitive treatment for injuries must be provided expeditiously by a Surgeon in the Operating Room.

44 Cardiac Wound Repair

Eric F. Reichman

INTRODUCTION

Wounds of the heart are highly lethal. Traumatic cardiac penetration carries a 70% to 80% fatality rate.[1] Major factors determining survivability include whether or not cardiac standstill has occurred as well as the amount of tissue destruction sustained from the injury.[2]

Penetrating wounds can be caused by knives, bullets, ice picks, and (infrequently) rib or sternal fragments. **Regardless of the offending agent, repair must be done as expeditiously as possible.** The right ventricle is the most frequently injured chamber. However, injury to the heart may occur at more than one site. This is especially true with gunshot wounds.

The treatment goal in the Emergency Department is temporary hemostasis. Many different techniques of cardiorrhaphy have been described. We will limit our discussion to five possible approaches to dealing with these injuries (i.e., digital or Foley catheter occlusion, vascular clamps, staples, and sutures).

ANATOMY AND PATHOPHYSIOLOGY

The heart is contained within the pericardial sac. Numerous portions of the heart are exposed behind the anterior chest wall (**Figure 36-2**). This includes the right ventricle, left ventricle, right atrium, left atrium, aorta, pulmonary artery, and inferior vena cava. These structures are vulnerable to injury behind the anterior chest wall.[3,4] The surface areas that each of these structures contributes to the anterior cardiac silhouette are as follows: 55% right ventricle, 20% left ventricle, 10% right atrium, 10% aorta and pulmonary artery, 4% inferior vena cava, and 1% left atrium.[5] These numbers also reflect, roughly, the anatomic incidence of injury with cardiac trauma.[5] Traumatic injury to any of these structures can result in a pericardial effusion and cardiac tamponade.

INDICATIONS

Any penetrating injury to the heart requires immediate and temporary repair to prevent the patient from exsanguinating. A bluish hue behind the pericardium or a tense pericardial sac after penetrating trauma suggests an underlying cardiac injury. A pericardiotomy should be performed, any blood and clot removed from the pericardial sac, and the heart explored for the site of injury. The indications to perform a thoracotomy are described in Chapter 42.

CONTRAINDICATIONS

The only absolute contraindication to performing a cardiorrhaphy is if the patient has obvious signs of death. It should not be performed if the patient has not had any vital signs for over 15 minutes, as anoxic brain injury is irreversible. It is also contraindicated in

FIGURE 44-1. Examples of several atraumatic vascular clamps.

patients with penetrating chest trauma who do not meet the criteria for performing an anterolateral thoracotomy (Chapter 42).

EQUIPMENT

- Sterile gloves and gown
- Face mask with an eye shield or goggles
- Silk suture, 4-0 and 5-0 (or Prolene)
- 2-0 silk, on a semicircular atraumatic needle
- 10 in. needle driver
- Foley catheter, sizes 14 to 20 French
- Satinsky, or other, atraumatic vascular clamp (**Figure 44-1**)
- Allis clamps
- Defibrillator with internal cardiac paddles
- Mayo scissors
- Metzenbaum scissors, curved
- Teflon pledgets
- Sterile saline
- 20 mL syringe
- Standard skin stapler, 6 mm wide staples
- Laparotomy pads
- Gauze 4 × 4 squares
- Hemostats

PATIENT PREPARATION

No preparation is required other than that of performing a thoracotomy and a pericardiotomy (Chapter 42). The patient should be intubated, ventilated with 100% oxygen, and fully monitored (i.e., telemetry, a noninvasive blood pressure cuff, and pulse oximetry). Instruct a nurse to administer intravenous broad spectrum antibiotics that cover skin flora, gram-positive organisms, and gram-negative organisms. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids. While time is of the essence and this is an emergent procedure, aseptic technique should be followed.

TECHNIQUES

Bleeding from a cardiac wound should ideally be stopped by placing a finger over the wound and immediately transporting the patient to the Operating Room for definitive repair. Unfortunately,

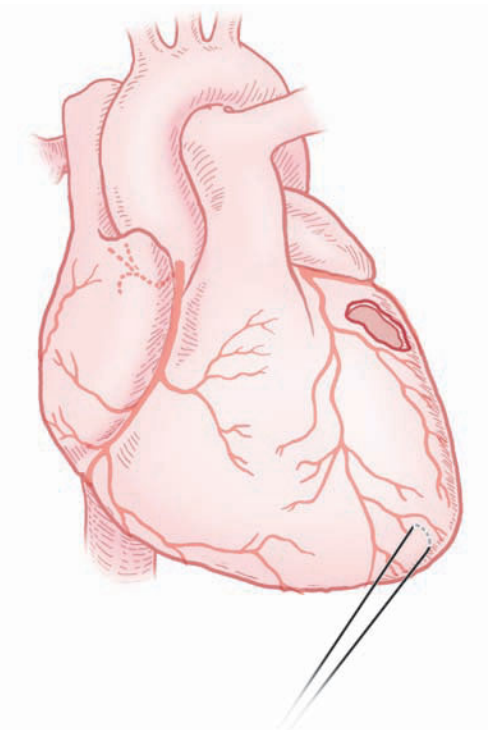

FIGURE 44-2. The apical traction suture known as Beck's suture may be placed to control the heart.

the Anesthesiologist, Surgeon, and/or Operating Room may not be immediately available. If the Emergency Physician performs a thoracotomy, they should be versed in methods of temporary cardiac wound repair. Several techniques are available to control hemorrhage from a cardiac wound.

CONTROL OF THE HEART

It is extremely difficult to maintain a finger over a cardiac wound or to stitch a cardiac wound if the heart is beating. An apical traction suture known as Beck's suture can be placed to control the heart (**Figure 44-2**). The apex of the heart is the ideal site because it is often away from most lacerations, is a thick portion of the heart, and is away from any major coronary arteries. Place a 2-0 silk suture through the apex of the heart and remove the needle from the suture. The ends of the suture can be grasped by hand or with a hemostat to elevate and control the heart while it is beating.

SAUERBRUCH MANEUVER

Large cardiac wounds and wounds with significant bleeding are difficult to repair, as the blood obscures the surgical field. Experienced Surgeons may temporarily clamp the inferior and superior vena cava to maintain a bloodless field. **Clamping the vena cava should not be performed by an Emergency Physician, as it is time-consuming and can injure other structures.** A quicker and safer alternative is the Sauerbruch maneuver, or grip, to partially occlude venous inflow through the inferior and superior vena cava (**Figure 44-3**). This technique will stabilize the heart for wound repair and allow the bleeding site to be identified and repaired.

Insert the nondominant hand into the pericardial cavity and toward the vena cava. Place the middle finger behind the vena cava and the index finger in front of the vena cava (**Figure 44-3**). The thumb should be resting on the anterior surface of the heart. The ring and little fingers should be resting on the posterior surface of the heart. Use the thumb and the ring and little fingers to cradle

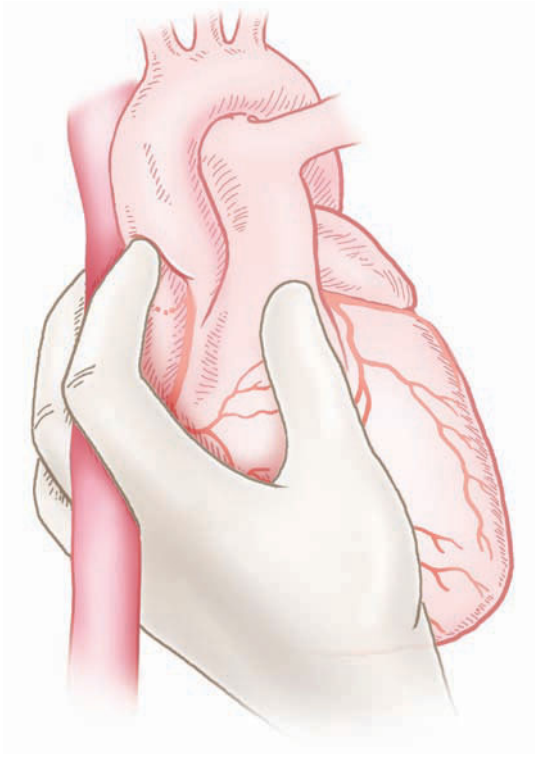

FIGURE 44-3. The Sauerbruch maneuver to partially occlude venous inflow from the superior and inferior vena cava.

the heart while apposing the middle and index fingers to partially occlude the vena cava. This technique can be used to control hemorrhage from the heart, great vessels, or hilum. **While effective at controlling hemorrhage, this technique will significantly reduce cardiac output and result in cardiac arrest. The grip should be released every 30 to 60 seconds to ensure coronary artery perfusion.**

DIGITAL OCCLUSION

Digital occlusion of small cardiac wounds can provide excellent hemostasis while awaiting definitive repair. Once a finger is placed on or over the defect, it must remain there until the appropriate materials to perform cardiorrhaphy are available. **Do not place a finger into the defect as this may increase the size of the wound.** Unfortunately, the fingertip often slips off the wound if the heart is beating. The fingertip interferes with visualization and repair of the wound. It also places the healthcare worker at risk for a needle-stick injury while attempting to repair the wound.

FOLEY CATHETER TECHNIQUE

A Foley catheter may be used to provide temporary hemostasis. As with digital occlusion, this is only a temporizing measure. Inflate the cuff of the Foley catheter with sterile saline to check its integrity and look for leaks. **Deflate the cuff. Place a hemostat on the Foley catheter 3 to 4 cm proximal to the cuff. This will prevent air from being drawn through the catheter and causing an air embolism.**

Identify the location of the cardiac wound (**Figure 44-4A**). Insert the Foley catheter through the cardiac wound until the balloon is

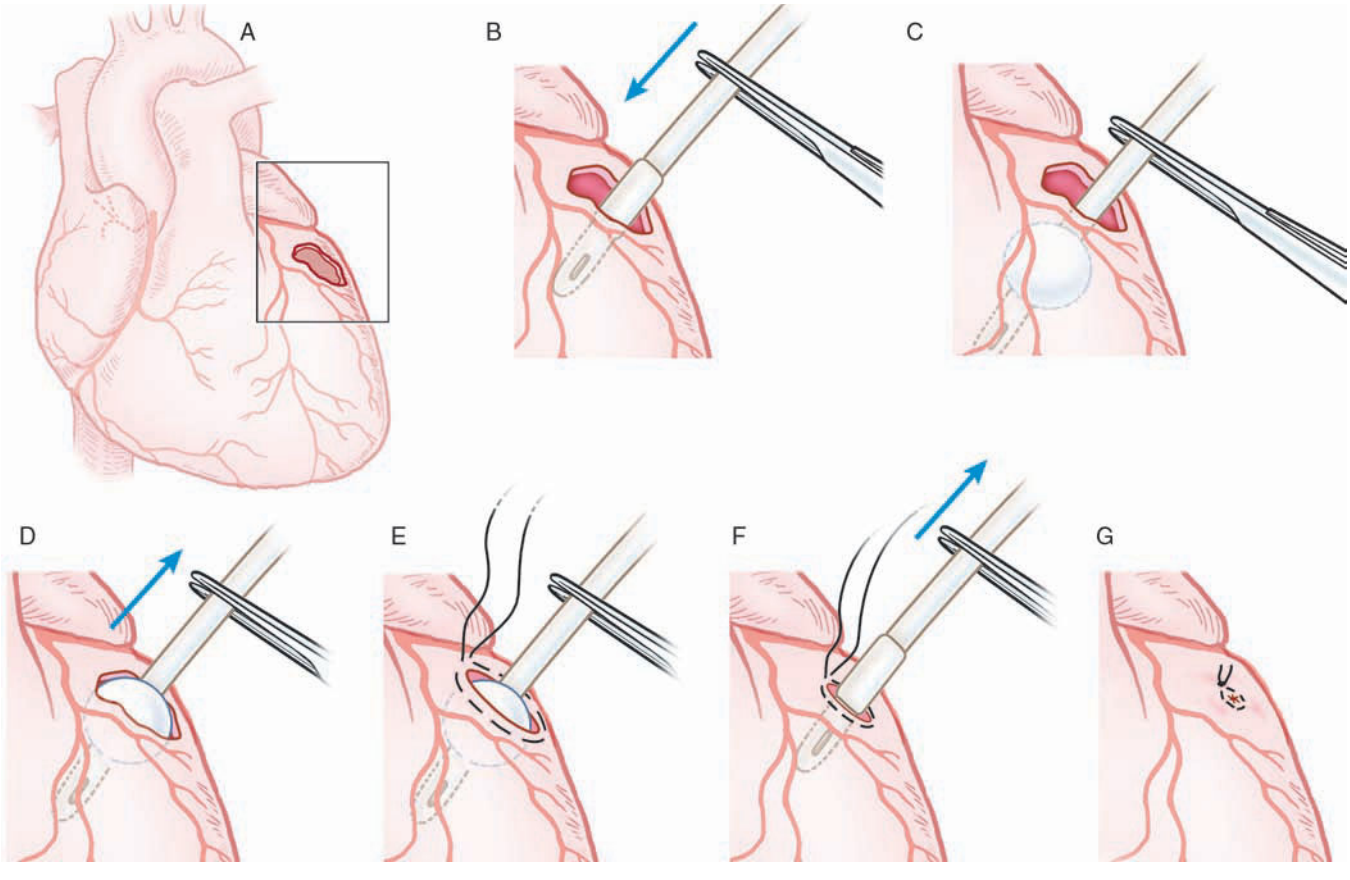

FIGURE 44-4. The Foley catheter technique to occlude and repair a cardiac wound. **A.** The cardiac wound is identified. **B.** The Foley catheter is inserted through the wound. **C.** The cuff is inflated. **D.** Gentle traction is applied to occlude the wound with the cuff. **E.** A purse-string suture is placed around the wound. **F.** The cuff is deflated and the Foley catheter is removed. **G.** The purse-string suture is tightened and tied to occlude the wound.

within the cardiac chamber (**Figure 44-4B**). Release the hemostat, inflate the cuff with 10 to 20 mL of sterile saline, and reclamp the Foley catheter (**Figure 44-4C**). **This step should be done quickly to prevent air from being drawn through the Foley catheter.**

Apply gentle traction to the catheter (Figure 44-4D). Apply just enough traction to mostly occlude the wound and slow the bleeding. A small amount of bleeding is adequate and acceptable to visualize the wound and perform a temporary repair. Do not try to provide complete hemostasis. This will result in excessive traction on the Foley catheter causing the cuff to pull through the wound, enlarge the wound, and further lacerate the myocardium.

Repair the cardiac wound. Place a purse-string suture around the wound (**Figure 44-4E**). **Use caution when placing the suture so that the needle does not pierce and rupture the cuff of the Foley catheter.** The Foley catheter may be advanced into the cardiac chamber temporarily while the suture is being placed. This will prevent the needle from piercing the cuff. **Do not advance the cuff too far into the heart and for too long a time period. The cuff may occlude blood flow through the valves and result in cardiac arrest.** After the purse-string suture is placed, deflate the cuff and quickly remove the Foley catheter (**Figure 44-4F**). Tie the ends of the suture to close the cardiac wound (**Figure 44-4G**). Place additional knots to secure the suture.

The Foley catheter technique is simple and effective. It avoids the problems associated with digital occlusion. The catheter may be placed in posterior cardiac wounds that are difficult to visualize and where it is hard to maintain digital occlusion. The Foley catheter does not interfere with visualization of the wound, wound repair, or the simultaneous performance of cardiac massage. Intravenous catheter tubing may be inserted into the lumen of the Foley catheter to infuse crystalloid solutions or red blood cells directly into the heart and central circulation. This technique is especially valuable in repairing wounds at the junction of the right atrium and vena cava.

CLAMP TECHNIQUE

Atrial wounds can bleed profusely and are difficult to control. The thin walls do not allow digital occlusion to be effective. The atrial wound can be grasped and compressed between the thumb and index finger. An atraumatic Satinsky vascular clamp can be placed around the wound to provide hemostasis (**Figure 44-5**). The wound may then be repaired with 4-0 or 5-0 interrupted silk sutures.

Allis clamps may be substituted if an atraumatic vascular clamp is not available. Place an Allis clamp on each of the opposing edges of the atrial wound. Apply upward traction, then cross the Allis clamps to approximate the wound edges. The wound may now be sutured closed. The Allis clamps do not provide as bloodless a field as does the atraumatic vascular clamp.

STAPLE TECHNIQUE

Skin staplers provide a quick and easy method to repair cardiac wounds. Careful approximation and stapling of the wound will rapidly close the defect and aid in controlling massive blood loss. Staples may be used to close small, large, or multiple lacerations. Its use avoids the potential complication of a needle stick to the Emergency Physician.

Cardiac wounds are closed similarly to skin lacerations (**Figure 44-6**). Obtain a standard skin stapler with 6 mm wide staples. These are readily available in Emergency Departments for wound closure. Use the nondominant hand to appose the wound edges. Grasp the stapler with the dominant hand. Place staples at 5 mm intervals until the wound is closed.

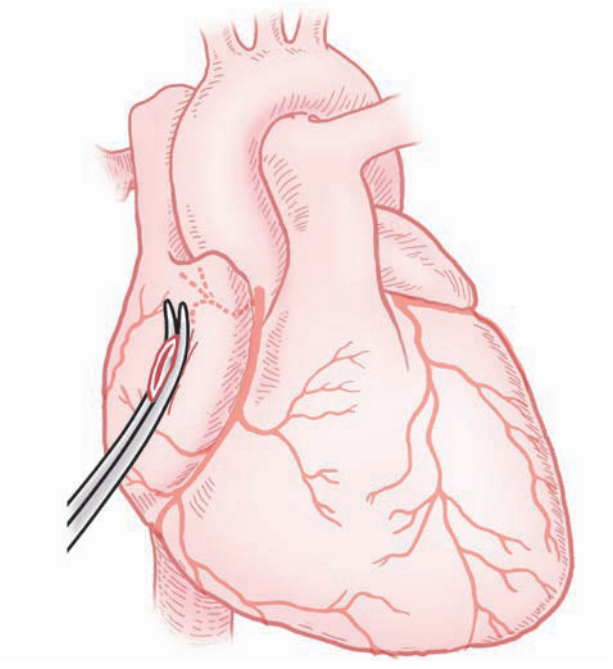

FIGURE 44-5. A Satinsky vascular clamp provides hemostasis for atrial wounds.

SUTURE TECHNIQUES

Suturing of cardiac wounds is more time consuming than the other methods previously described. It requires technical proficiency and understanding of the heart's surface anatomy. Place horizontal mattress sutures using 2-0 or 3-0 silk or Prolene suture material (**Figure 44-7**). **Do not tie the sutures tightly. It is easy to inadvertently tear through the myocardium.** Use teflon pledgets to reinforce the repair and prevent cutting through the heart tissue (**Figures 44-7A & B**). This is especially important when the wound edges are irregular or tattered. Use care to avoid injury to the coronary vessels, which may lie in close proximity to a cardiac wound. Ensure that the sutures are placed adjacent to and underneath the coronary vessels (**Figure 44-7C**).

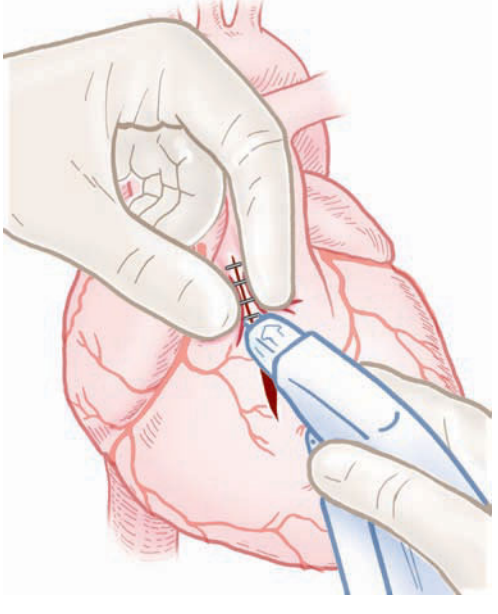

FIGURE 44-6. The cardiac stapling technique provides temporary hemostasis.

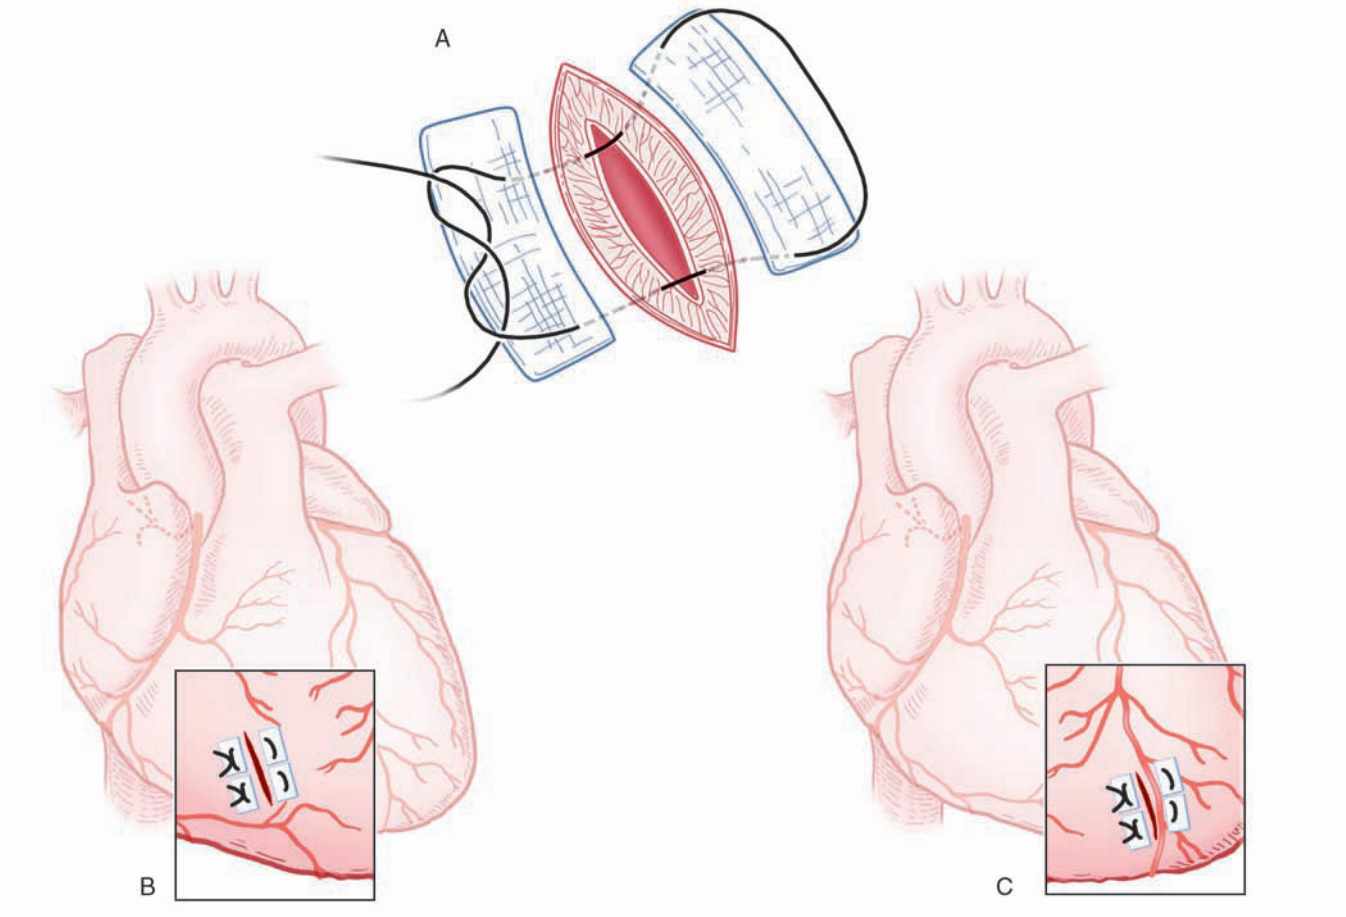

FIGURE 44-7. Horizontal mattress sutures used to close cardiac wounds. **A.** Teflon pledgets are placed on either side of the wound to prevent the suture from pulling through the myocardium. **B.** Wounds are closed with multiple horizontal mattress sutures. **C.** When suturing near a coronary artery, ensure that the sutures pass completely below the artery.

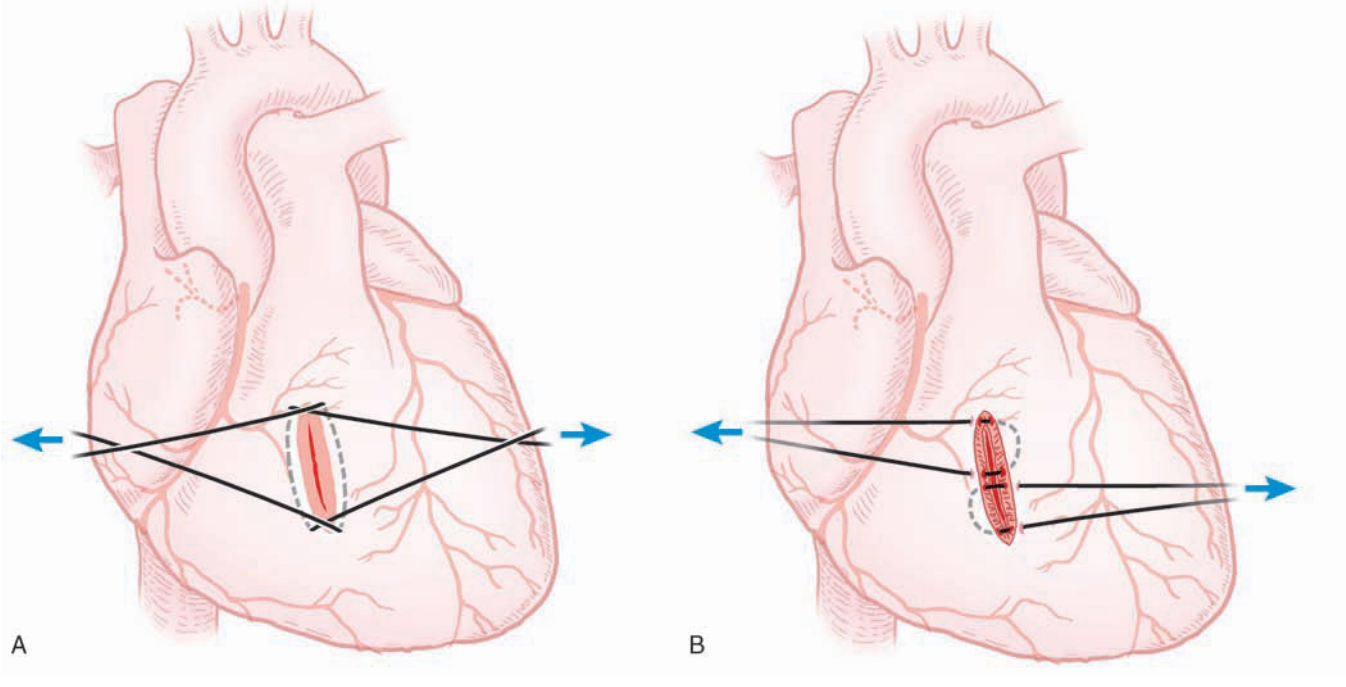

FIGURE 44-8. Incomplete horizontal mattress stitches may be placed on each side of a large wound. Tension applied to the sutures will appose the wound edges (*arrows*).

FIGURE 44-9. The internal cardiac paddles inserted into the handles.

Large cardiac wounds are difficult to repair. They bleed profusely. The digital occlusion and Foley catheter techniques are ineffective on large wounds. The wound edges are difficult to grasp and appose so that they can be repaired with a skin stapler. Place an incomplete horizontal mattress stitch on each side of the wound (**Figure 44-8**). Grasp the free ends of the sutures and cross them across the wound to appose the wound edges. Instruct an assistant to hold the suture ends while the cardiac wound is repaired with 2-0 or 3-0 silk, Prolene, or staples. The incomplete mattress sutures may then be removed or tied to each other.

FIBRILLATION

The myocardium can be deliberately placed in fibrillation to halt myocardial contractions and repair large ventricular wounds. **This should be performed only if other techniques of cardiac wound repair are unsuccessful.** Choose the proper size internal cardiac paddles. The paddle size for an infant is 2 cm, for a child is 4 cm, and for an adolescent or adult is 6 cm. Insert the sterile paddles into the sterile handles (**Figure 44-9**). Pass the cables exiting the base of the handles to an assistant to insert into the defibrillator machine ports. Instruct the assistant to turn on the defibrillator.

Place the internal cardiac paddles on the anterior and posterior surfaces of the heart (**Figure 44-10**). While the paddles can be placed directly on the heart, it is recommended by some to place sterile saline-moistened gauze squares between the paddles and the heart to aid in conduction. Apply 20 Joules (J) of energy through the paddles to fibrillate the adolescent or adult heart. Begin with 5 J of energy to fibrillate the infant or child heart. Proceed upward incrementally as required to a maximum of 20 J to fibrillate the infant or child heart. **Quickly repair the cardiac wound.**

Perform intermittent cardiac massage while repairing the fibrillating myocardium to maintain cardiac output. Do not allow the heart to fibrillate for more than 3 minutes. Defibrillate the heart with the internal paddles using 20 J of energy for the adult and adolescent heart. Repeat the defibrillation with 20 J of energy until the heart begins beating. **In general, do not use more than 20 J to defibrillate the adult or adolescent heart with the internal cardiac paddles as myocardial necrosis can occur.** It may be occasionally necessary increase the energy in the adolescent or adult to 40 J then 60 J if multiple attempts at 20 J are ineffective. Begin with 5 J of energy to defibrillate the infant or child heart. Proceed upward incrementally as required to a maximum of 20 J to defibrillate the infant or child heart.

AFTERCARE

If the patient is resuscitated, cover the thoracotomy wound with saline-moistened gauze and a simple dressing. Administer broad spectrum antibiotics if not done previously. Immediately transport the patient to the Operating Room for definitive repair of the cardiac wound and any other injuries by a Trauma or Cardiovascular Surgeon.

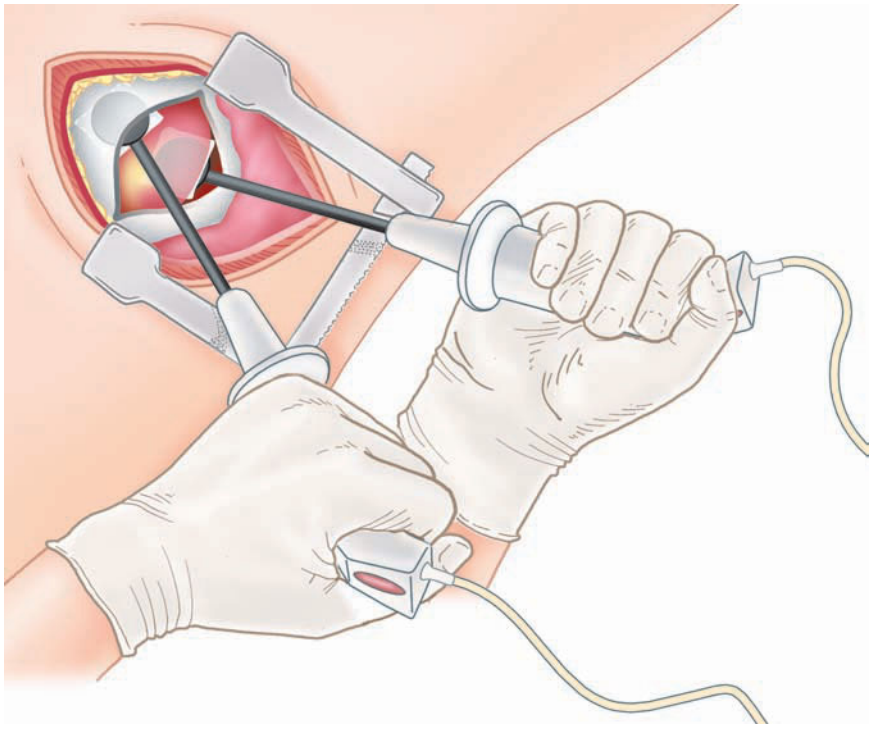

FIGURE 44-10. Application of the internal cardiac paddles. Sterile saline-moistened gauze can be placed between the paddles and the heart to increase conductivity.

COMPLICATIONS

The complications associated with digital pressure include further destruction of tissue. If pulled too tightly, Foley catheters can become dislodged and restart troublesome bleeding. They can also enlarge a cardiac wound if the cuff pulls through the wound. A drop in cardiac output can result if the cuff obstructs the cardiac valves, impinges on the chordae tendineae, or occupies too much space within the cardiac chamber. Decrease the cuff size by withdrawing some of the saline from the cuff. Suturing is probably associated with the greatest rate of complications. Tearing of the myocardium is a frequently encountered problem. The suture should be tied just tight enough to stop the bleeding. Care should be exercised to avoid ligation of the major coronary vessels and their branches. Dysrhythmias can result from occlusion of venous inflow (Sauerbruch maneuver) or injury to the coronary vasculature. If the patient is resuscitated, administer broad-spectrum antibiotics to prevent any potential infectious complication.

SUMMARY

Injuries to the heart can be devastating. The role of the Emergency Physician is to rapidly and temporarily control bleeding and ensure the transport of the patient to the Operating Room for definitive repair. If there is a delay in transporting the patient to the operating room, the Emergency Physician must be versed in the techniques used to repair cardiac wounds and resuscitate the patient.

45 Hilum and Great Vessel Wound Management

Eric F. Reichman

INTRODUCTION

Injuries to the thoracic great vessels can be a significant cause of morbidity and mortality. Large vessels in the hilum of the lung include the pulmonary artery and vein. The great vessels also include the vena cava, aorta, innominate artery, subclavian artery, and subclavian vein. The mortality from injuries to the subclavian artery is approximately 5% if patients who are moribund on admission to the Emergency Department are excluded.[1] However, the mortality from injury to the vena cava and the pulmonary vessels is over 60%.[2] While over 85% of patients with penetrating injuries to the thorax are stable, the remainder present in varying levels of hypovolemic shock. They may have bled externally or into the chest. Each hemithorax can hold up to one-half of an individual's blood volume. In these cases, an Emergency Department thoracotomy may be performed for hypovolemic shock.

ANATOMY AND PATHOPHYSIOLOGY

Injury to the thoracic great vessels may be due to blunt trauma, diagnostic procedures, iatrogenic causes, or penetrating trauma. Crush injuries, deceleration injuries, motor vehicle versus pedestrian collisions, and penetrating thoracic injuries may all signify an injury to a thoracic great vessel. The vessels that are most commonly injured include the aorta, innominate artery, pulmonary vein, and venae cavae.

The portable anteroposterior chest radiograph is the initial radiographic screening. It may reveal loss of the aortic knob contour, left-sided pleural effusions, mediastinal widening, nasogastric tube deviation, or tracheal deviation, all of which suggest injury to a great vessel. Other findings suggestive of such an injury include depression of the left mainstem bronchus, left apical capping, narrowing of the carinal angle, sternal fractures, opacification of the aortopulmonary window, and widening of the paraspinous stripe.

Numerous physical examination findings are suggestive of a thoracic great vessel injury. Asymmetric pulses or unequal blood pressures between the extremities are quick and simple to evaluate. Hypotension may be due to internal or external hemorrhage. Steering wheel contusions, sternal fractures, thoracic spine fractures, and a left-sided flail chest signify potential intrathoracic injury. A thoracic outlet hematoma or a hoarse voice can occur from injury to the aorta or one of its major branches. Paraplegia may be due to hypotension or an aortic disruption.

INDICATIONS

Attempts should be made to control any laceration or rupture of the thoracic great vessels.

CONTRAINDICATIONS

There are no absolute contraindications to temporarily controlling any hemorrhage from a thoracic great vessel after performing a thoracotomy (Chapter 42). The thoracotomy should not be performed if the patient has obvious signs of death, no vital signs in the field, or no vital signs for over 15 minutes. A pericardial tamponade or cardiac injury may require management prior to managing a great vessel injury.

EQUIPMENT

- 3-0 Prolene suture
- Foley catheters, sizes 14 to 20 French
- 10 in. needle driver
- Satinsky, or other, atraumatic vascular clamp (**Figure 45-1**)
- Sterile saline
- 20 mL syringe
- Laparotomy pads
- Gauze 4 × 4 squares
- Umbilical clamp
- Hemostats

FIGURE 45-1. Examples of several atraumatic vascular clamps.

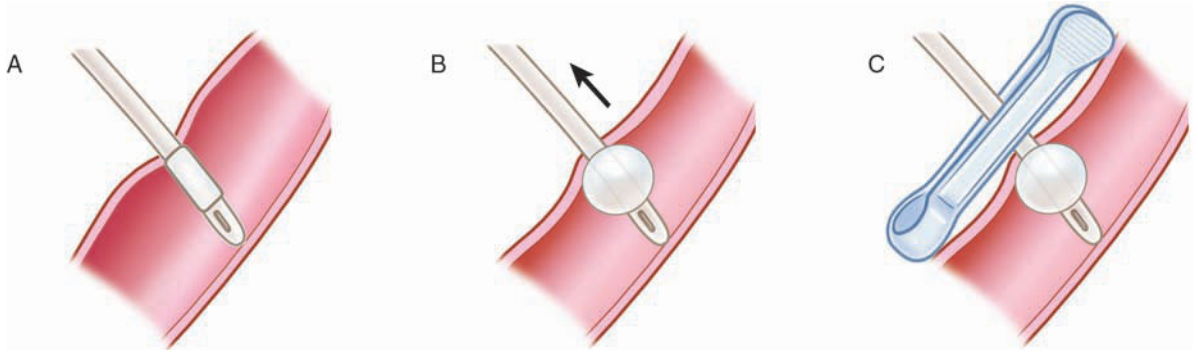

FIGURE 45-2. The Foley catheter technique to occlude an injury to a great vessel. **A.** The catheter is inserted through the wound and into the vessel. **B.** The cuff is inflated and gentle traction (*arrow*) is applied to occlude the wound with the cuff. **C.** An umbilical clamp is placed to prevent the catheter from migrating inward.

PATIENT PREPARATION

There is no preparation required other than performing an anterolateral thoracotomy (Chapter 42). The patient should be intubated, ventilated with 100% oxygen, and fully monitored (i.e., telemetry, a noninvasive blood pressure cuff, and pulse oximetry). Instruct a nurse to administer intravenous broad-spectrum antibiotics that cover skin flora, gram-positive organisms, and gram-negative organisms. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids. While time is of the essence and this is an emergent procedure, aseptic technique should be followed.

TECHNIQUES

DIGITAL OCCLUSION

Digital pressure may be used to control small lacerations of the thoracic vena cava. It will provide adequate hemostasis while repairing the wound. **Place a fingertip over the defect.** Do not place a finger in the defect. Place horizontal mattress sutures using 3-0 Prolene to close the defect. Unfortunately, the fingertip interferes with visualization of the wound and places the Emergency Physician at risk for a needlestick injury. The fingertip will have to be intermittently removed to place the sutures.

Digital pressure and rapid transport to the operating room is the most practical method of dealing with injuries to the subclavian vessels. These vessels are extremely difficult to control through a traditional anterolateral thoracotomy incision. If digital pressure is ineffective, pack the apex of the thoracic cavity with laparotomy pads or gauze squares and apply compression from below.

FOLEY CATHETER TECHNIQUE

By inserting a Foley catheter into the vessel, inflating the cuff, and placing it under gentle traction, one may occlude a wound to a great vessel (**Figure 45-2**). As with digital occlusion, this is only a temporizing measure. Inflate the cuff of the Foley catheter with sterile saline to check its integrity and look for leaks. Deflate the cuff. **Place a hemostat on the Foley catheter proximal to the cuff. This will prevent air from being drawn through the catheter and causing an air embolism.**

Identify the location of the vascular injury. Insert the catheter through the wound until the cuff is within the vessel (**Figure 45-2A**). Open the hemostat, inflate the cuff with 5 to 10 mL of sterile saline, and reclamp the Foley catheter. **This step should be completed quickly to prevent air from being drawn through the catheter. Do not overinflate the cuff so that it occludes flow through the vessel. Apply gentle traction to the catheter (Figure 45-2B). Apply just enough traction to mostly occlude the wound and slow the bleeding. Do not try to provide complete hemostasis.** This will result in excessive traction on the catheter, causing the cuff to pull through the wound, enlarge the wound, and further injure the vessel. Place an umbilical clamp or a hemostat on the catheter just outside the vessel to prevent it from migrating into the vessel (**Figure 45-2C**).

The Foley catheter technique is simple and effective. It avoids the problems associated with digital occlusion. It does not interfere with visualization of the wound or the simultaneous performance of cardiac massage. Intravenous catheter tubing may be inserted into the lumen of the Foley catheter to infuse crystalloid solutions or red blood cells directly into the heart and central circulation.

CROSS-CLAMPING TECHNIQUE

Injuries to the thoracic great vessels can bleed profusely and are difficult to control. Digital occlusion is often ineffective. An atraumatic Satinsky vascular clamp can be placed to partially occlude the great vessel and isolate the injury (**Figure 45-3**). This will provide temporary hemostasis until definitive repair in the Operating Room.

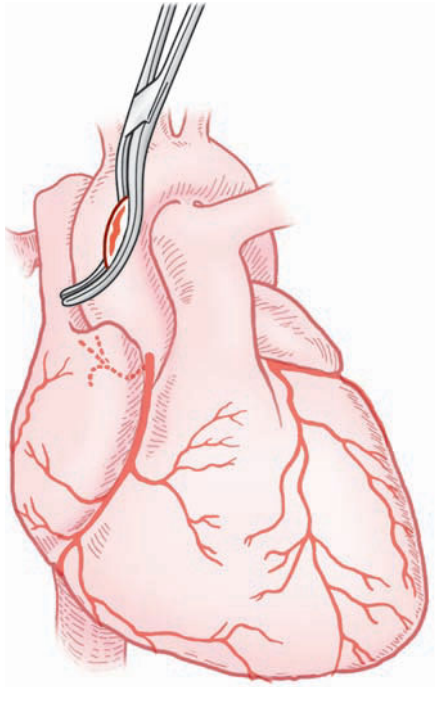

FIGURE 45-3. A Satinsky vascular clamp may be used to partially occlude the great vessel and isolate the injury.

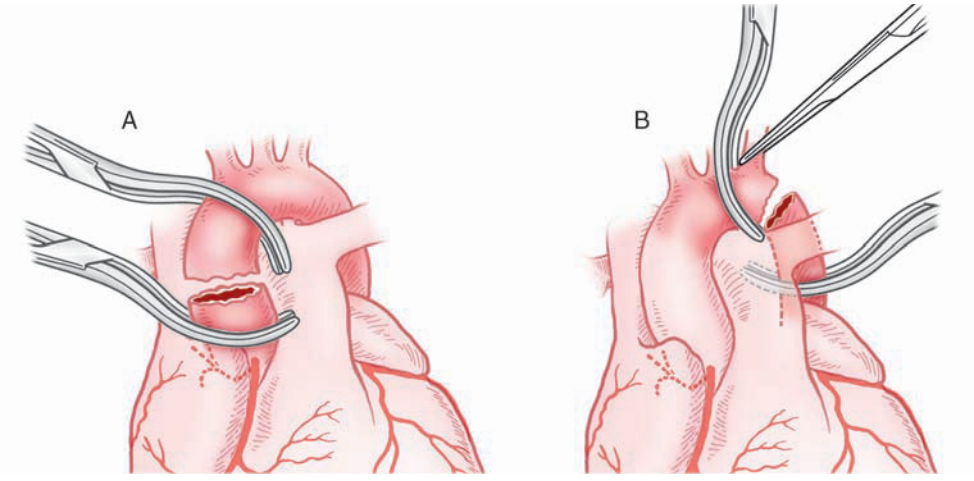

FIGURE 45-4. Cross-clamping of vascular injuries. **A.** Cross-clamp the great vessels to provide temporary hemostasis. **B.** Distal vessels must also be cross-clamped to prevent backbleeding.

Large wounds and complete transections are difficult to manage. Injuries to the pulmonary vasculature in the region of the hilum are most expeditiously controlled by placing an atraumatic vascular clamp across the respective hilum.[3] Grasp the hilum between the thumb and the forefinger. Place the clamp carefully around the entire hilum. Take care not to injure the pulmonary parenchyma or the vessels any further. Vascular injuries may be controlled by placing a cross-clamp proximal to the injury and occluding the backbleeding with additional clamps (**Figure 45-4**). These patients should be immediately transported to the Operating Room to be placed on bypass and repair the injuries. **It is not recommended for the Emergency Physician to suture great vessel injuries in an attempt to repair them.**

AFTERCARE

If the patient is resuscitated, cover the thoracotomy wound with saline-moistened gauze and a simple dressing. Administer broad-spectrum antibiotics if not done previously. Immediately transport the patient to the Operating Room for definitive repair of the great vessel injury and any other injuries by a Trauma or Cardiovascular Surgeon.

COMPLICATIONS

The complications associated with digital pressure include extending the injury if the procedure is not performed carefully. Inaccurate digital control can lead to unnecessary loss of blood during transport of the patient to the operating room. Foley catheters, if pulled too tightly, can become dislodged and restart troublesome bleeding. They can also enlarge a wound if the cuff pulls through the wound. The cuff may obstruct flow through the vessel and compromise cardiac output. Decrease the cuff size by withdrawing some of the saline from the cuff. An overly rough mobilization and clamping can increase the size of the injury and cause massive bleeding. Cross-clamping of the aorta and/or pulmonary artery will obstruct peripheral blood flow. The vessel must be repaired or the patient placed on bypass to prevent anoxia and permanent neurologic dysfunction.

SUMMARY

Injuries to the thoracic great vessels carry a high mortality as bleeding occurs unimpeded into the pleural space. The survival of the patient depends on their presenting condition as well as the speed and accuracy with which the intrathoracic hemorrhage is controlled.

46 Thoracic Aortic Occlusion

Eric F. Reichman

INTRODUCTION

Temporary thoracic aortic occlusion should be performed during an Emergency Department thoracotomy for hypovolemic shock. It preserves cerebral and coronary artery perfusion pressure.[1] The blood flow to the viscera below the cross clamp, however, falls to less than 10% of baseline flow.[2] This can be advantageous since it stops distal hemorrhage, but it can later result in the undesired metabolic consequences of acidosis, hyperkalemia, and multiple organ system failure.[3,4]

ANATOMY AND PATHOPHYSIOLOGY

The aorta begins at the left ventricle and gives rise to the arteries of the body, directly or indirectly (**Figure 46-1**). It leaves the ventricle and is directed upward as the ascending aorta. It arches to the left and backward at the level of the sternal angle to become the aortic arch. The arch gives rise to the brachiocephalic trunk, left common carotid artery, and left subclavian artery. The aortic arch is directed inferiorly after giving rise to the left subclavian artery and is known as the descending aorta. The descending aorta is subdivided into the thoracic portion above the diaphragm and the abdominal portion below the diaphragm. It descends through the posterior mediastinum, lying first against the left side of the fifth thoracic vertebral body. As it descends, it gradually approaches the midline of the 12th thoracic vertebral body, at which point it passes through the diaphragm.

The esophagus is a thin, muscular tube measuring approximately 2.0 to 2.5 cm in diameter. It descends along the vertebral bodies. It travels forward, away from the vertebral bodies, and to the right at the level of the ninth thoracic vertebral body. It traverses the diaphragm at the level of the 10th thoracic vertebral body. It lies posterior and medial to the descending thoracic aorta throughout most of its course. It migrates as it travels distally, so that its lower part lies in front of the aorta just above the diaphragm (**Figure 46-1**).

INDICATIONS

The primary reason to occlude the descending thoracic aorta is to temporarily direct blood flow from below the diaphragm to preserve flow to the brain and heart. The descending thoracic aorta

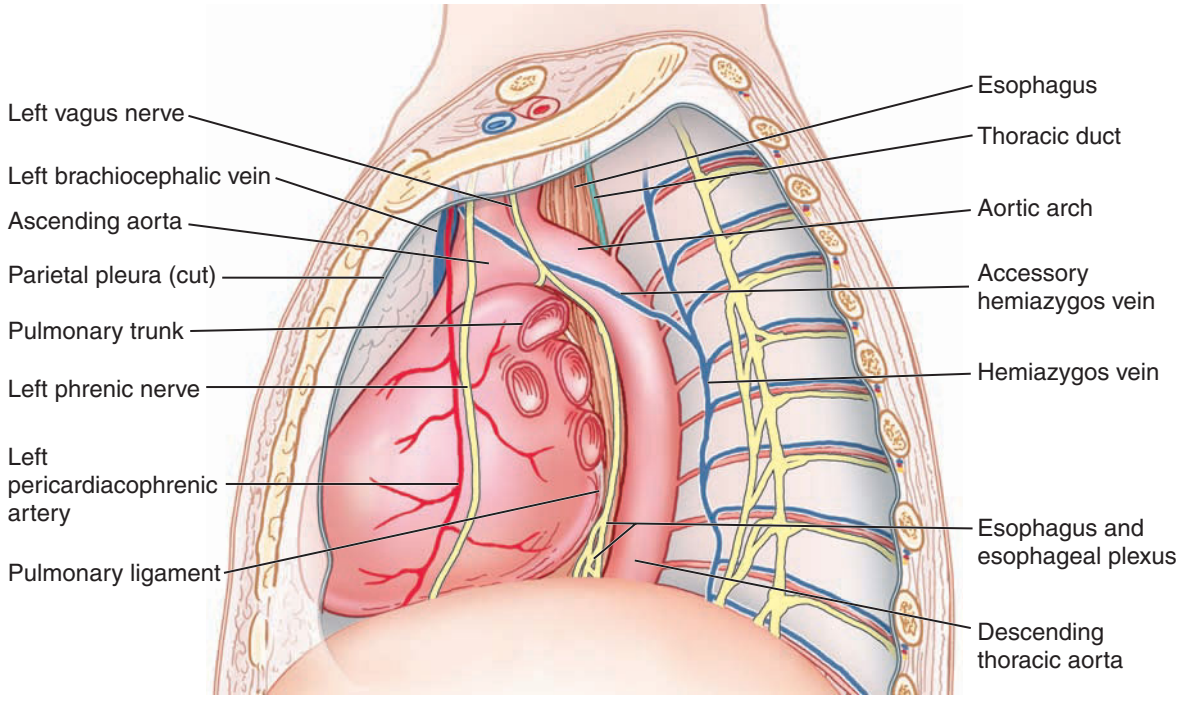

FIGURE 46-1. Anatomy of the aorta and surrounding structures of the mediastinum and left hemithorax. The mediastinal pleura has been removed to visualize the underlying structures.

may be occluded in patients with penetrating thoracic or abdominal trauma in which hypovolemic shock and clinical deterioration are not responsive to aggressive fluid resuscitation and blood transfusion. These patients should have the appropriate indications to perform an anterolateral thoracotomy (Chapter 42). The thoracic aorta may also be occluded immediately prior to laparotomy if the patient has a tense abdomen filled with blood. The abdominal incision will decompress the abdomen and result in hypotension, decreased coronary and cerebral perfusion pressure, exsanguination, and death. Uncontrollable hemorrhage below the diaphragm can be controlled by temporarily occluding the descending thoracic aorta.

CONTRAINDICATIONS

There are no absolute contraindications to temporarily occluding the descending thoracic aorta after performing an anterolateral thoracotomy. The thoracotomy should not be performed if the patient has obvious signs of death, no vital signs in the field, or no vital signs for over 15 minutes.

EQUIPMENT

- Satinsky, or other, atraumatic vascular clamp (**Figure 46-2**)
- Metzenbaum scissors
- DeBakey or large Kelly clamp
- Nasogastric tube
- Aortic compressor, Conn or homemade
- Gauze 4 × 4 squares

PATIENT PREPARATION

No preparation is required other than that of performing a thoracotomy and a pericardiotomy (Chapter 42). The patient should be intubated, ventilated with 100% oxygen, and fully monitored (i.e., telemetry, a noninvasive blood pressure cuff, and pulse oximetry). Insert a nasogastric tube. Instruct a nurse to administer intravenous broad-spectrum antibiotics that cover skin flora, gram-positive organisms, and gram-negative organisms. The Emergency Physician should wear full personal protective equipment to protect themselves from contact with the patient's blood and body fluids. While time is of the essence and this is an emergent procedure, aseptic technique should be followed.

TECHNIQUE

Identify the aorta by palpation. It is often easier to identify and isolate the aorta just above the diaphragm. In this location, the aorta is slightly separated from the adjacent esophagus. Elevate the left lung with the nondominant hand superiorly and medially. Instruct an assistant to maintain the lung out of the way. Place the dominant

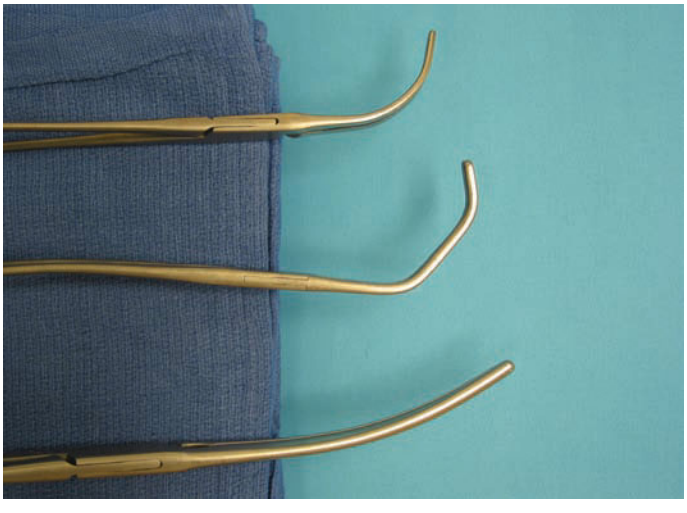

FIGURE 46-2. Examples of several atraumatic vascular clamps.

hand through the thoracotomy incision and into the posteroinferior recess of the thoracic cavity. Advance the hand along the diaphragm and toward the midline. The fingers will first encounter the vertebral bodies. The next palpable structure is the aorta. It lies anterior to the vertebral bodies. The aorta may be difficult to palpate if it is collapsed in the patient with hypovolemic shock. In the elderly, the aorta may be significantly calcified, which helps to identify it despite hypovolemia. The aorta is covered by the mediastinal pleura. Place the thumb and index finger of the nondominant hand over the aorta just above the diaphragm.

Isolate the aorta. Bluntly dissect open the mediastinal pleura overlying the aorta with a DeBakey clamp or a large curved Kelly clamp. **Never use a scalpel to open the mediastinal pleura, as it may lacerate the aorta.** Some physicians may prefer to use a Metzenbaum scissors to dissect and open the mediastinal pleura. Identify the aorta by palpation. Bluntly separate the aorta from the esophagus with the dominant hand. It may be extremely difficult to separate the aorta from the esophagus in the patient with hypotension, hypovolemia, and/or shock. Place a nasogastric tube if this has not been done previously. The nasogastric tube will be palpable within the esophagus and can be used to identify the esophagus. Hook the dominant index finger around the aorta. **Use the finger to separate the aorta from the vertebral bodies. The dissection should not be extensive. It should free approximately 3 to 4 cm of the descending thoracic aorta.**

DIRECT COMPRESSION

Direct compression of the aorta is fast and simple, it does not interfere with the operative field, and it causes less damage than the application of a clamp. Digital compression is often ineffective. Aortic compression devices have a unique shape to occlude the aorta atraumatically by compressing it against the vertebral bodies. It may be applied before or after the aorta is isolated. Homemade compression devices may use rubber tubing to occlude the aorta[5] (**Figure 46-3A**). The Conn compressor is commercially available and uses a metal plate to occlude the aorta (**Figure 46-3B**). Place the distal end of the compression device against the distal descending thoracic aorta (**Figure 46-3C**). Apply downward pressure to occlude the aorta. The degree of occlusion can be controlled by increasing or decreasing the pressure applied to the aorta.

CROSS-CLAMPING

The descending thoracic aorta is most commonly occluded with an atraumatic or Satinsky vascular clamp. Aortic compression devices are rarely available in Emergency Departments or on thoracotomy trays. The aorta must first be separated and isolated from the esophagus, as described above. Place an index finger behind the descending thoracic aorta to elevate it away from the underlying esophagus (**Figure 46-4A**). Place the Satinsky or other atraumatic vascular clamp over the aorta. One jaw should be posterior to the aorta and adjacent to the index finger while the other jaw is anterior to the aorta. Clamp the aorta and remove the index finger (**Figure 46-4B**).

It is imperative not to clamp the esophagus. Do not clamp the aorta before it is dissected from the esophagus. Esophageal injury can lead to perforation, ischemia, and sepsis if the patient is resuscitated. Ideally, the clamp should be placed under direct visualization of the aorta. Unfortunately, this is not always practical. The index finger under the aorta can confirm the proper isolation of the aorta and the proper position of the jaws of the clamp before the aorta is occluded.

AFTERCARE

If—after the thoracotomy, open cardiac massage, and aortic cross-clamping—there is return of a cardiac rhythm and a carotid pulse, the patient must be taken immediately to the Operating Room for definitive treatment. Cover the thoracotomy wound with saline-moistened gauze and a simple dressing. The patient's blood pressure in the upper extremity should be monitored every 30 to 60 seconds after the aorta is occluded. An elevated blood pressure can result in a hemorrhagic stroke or left ventricular failure. Elevated blood pressure will require intermittent release of the aortic occlusion and/or pharmacologic management. Parenteral broad-spectrum antibiotics should be administered to prevent infection if not done previously.

COMPLICATIONS

Intercostal arteries arising from the thoracic aorta can be damaged during mobilization of the aorta. This will result in troublesome bleeding that requires operative control. The aorta, vena cava, or the esophagus can be damaged by the clamp. Aortic cross-clamping can

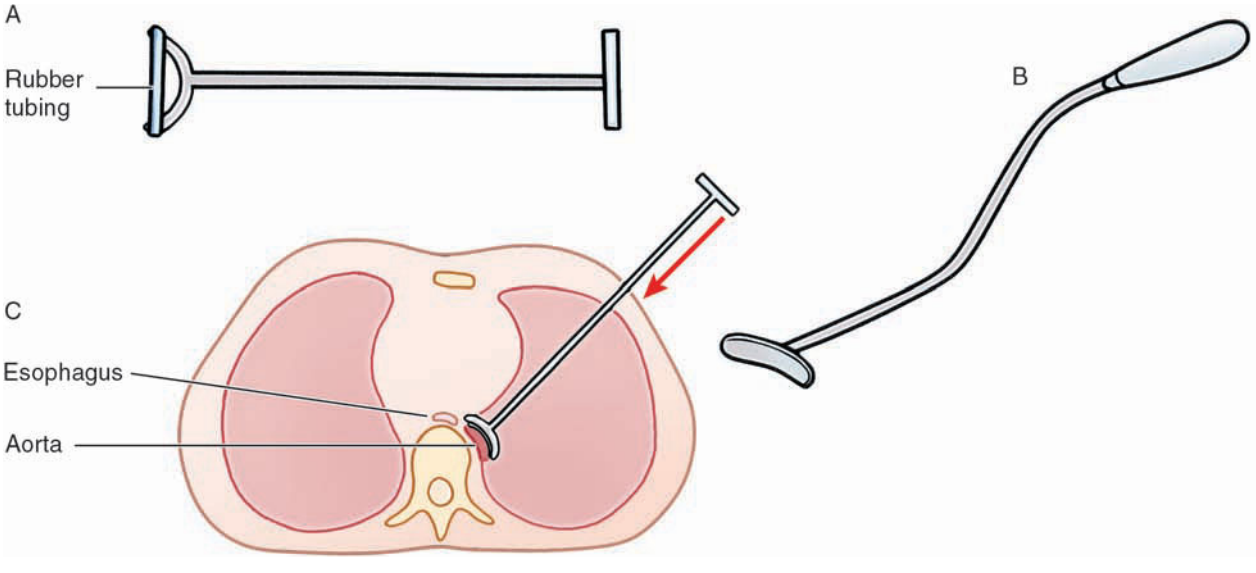

FIGURE 46-3. Aortic compression. **A.** The homemade aortic compression device.[5] **B.** The commercially available Conn compressor. **C.** The aorta is compressed between the distal end of the compression device and the thoracic vertebral body.

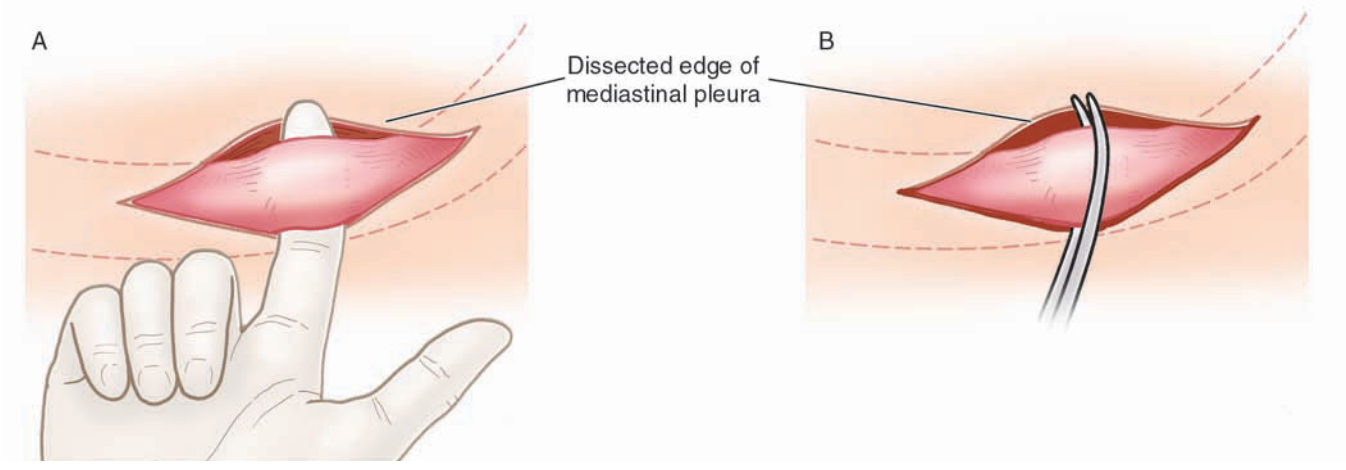

FIGURE 46-4. Aortic cross-clamping. **A.** The mediastinal pleura has been bluntly opened and the aorta isolated from the esophagus. **B.** The Satinsky, or other atraumatic, vascular clamp is placed across the aorta to occlude distal blood flow.

precipitate hypertension, stroke, and left-sided heart failure. If the patient is successfully resuscitated, this should be dealt with by periodically releasing the clamp. Lack of blood flow through the artery of Adamkiewicz will cause ischemia of the distal spinal cord. There is a 5% incidence of paraplegia when the blood supply to the distal aorta and spinal cord is disrupted. This incidence increases dramatically when the spinal cord is ischemic for more than 30 minutes.[6]

Aortic cross-clamping causes visceral ischemia. The gut loses its barrier function and becomes a cytokine-generating organ, which leads to a systemic inflammatory response and multiple organ failure. Renal and liver failure can result from a lack of blood flow.

The organs distal to the aortic clamp become severely ischemic and receive only 10% of the basal cardiac output. The anaerobic metabolism in these organs generates lactic acid. When the aortic clamp is released, acid and potassium are released into the central circulation and can cause a cardiac arrest. Thus, bicarbonate must be given at this time and the cardiac rhythm monitored carefully.

SUMMARY

Aortic cross-clamping is a useful adjunct to open cardiac massage in hypovolemic shock. It can help salvage patients by increasing coronary and cerebral perfusion. It may be performed as a lifesaving and temporizing measure until the patient can be taken to the Operating Room for definitive management.

SECTION 4

Vascular Procedures

47 General Principles of Intravenous Access

Daniel Belmont

INTRODUCTION

The practice of Emergency Medicine frequently requires access to a patient's venous circulation. Venous access allows sampling of blood as well as administration of medications, nutritional support, and blood products. Devices such as cardiac pacing wires and pulmonary artery catheters can be introduced into the patient's central venous circulatory system.

Percutaneous, as opposed to surgical, venous access is usually rapid, safe, and well tolerated. An understanding of the various techniques available, the venous anatomy, and the indications for the procedure allows the Emergency Physician to choose the appropriate site and method of venous access.

ANATOMY AND PATHOPHYSIOLOGY

Veins, like arteries, have a three-layered wall composed of an internal endothelium surrounded by a layer of muscle then a layer of connective tissue (**Figure 47-1**).[1] The muscular layer of a vein is much smaller than that of an artery. While veins can dilate and constrict somewhat on their own, they do so mostly in response to the pressure within them. Veins with high pressures become engorged and are easier to access. The use of venous tourniquets, dependent positioning, "pumping" via muscle contraction, and the local application of heat or nitroglycerin ointment all contribute to venous engorgement.[2] These maneuvers can be used to aid in the identification of a peripheral vein.[3]

The connective tissue surrounding veins can be a help or a hindrance during attempts at peripheral venous access. Deficient connective tissue permits the vein to "roll" from side to side and evade the needle. Tough connective tissue can impede the entry of a flexible catheter through the soft tissues and into the vein. This tissue also serves to stabilize the vein and prevent its collapse.

Venous valves are an important aspect of peripheral venous anatomy (**Figure 47-2**).[1] They encourage unidirectional flow of blood back toward the heart. Venous valves prevent blood from pooling in the dependent portions of the extremities due to gravitational forces. Valves can impede the passage of a catheter through and into a vein. Forcing a catheter past venous valves may damage them and contribute to later venous insufficiency. Valves are more numerous at the points where tributaries join larger veins and in the lower extremities. Valves are almost totally absent within the large central veins, the veins of the head, and the veins of the neck.

Veins can be subdivided into central veins and peripheral veins. The important central veins with regard to venous access are the internal jugular, subclavian, and femoral veins. Central veins are usually larger than peripheral veins and have fewer tributaries.

Superficial peripheral veins are generally visible beneath the surface of the skin of the extremities and neck. They are often tortuous and continually merge and divide. Peripheral veins are easiest

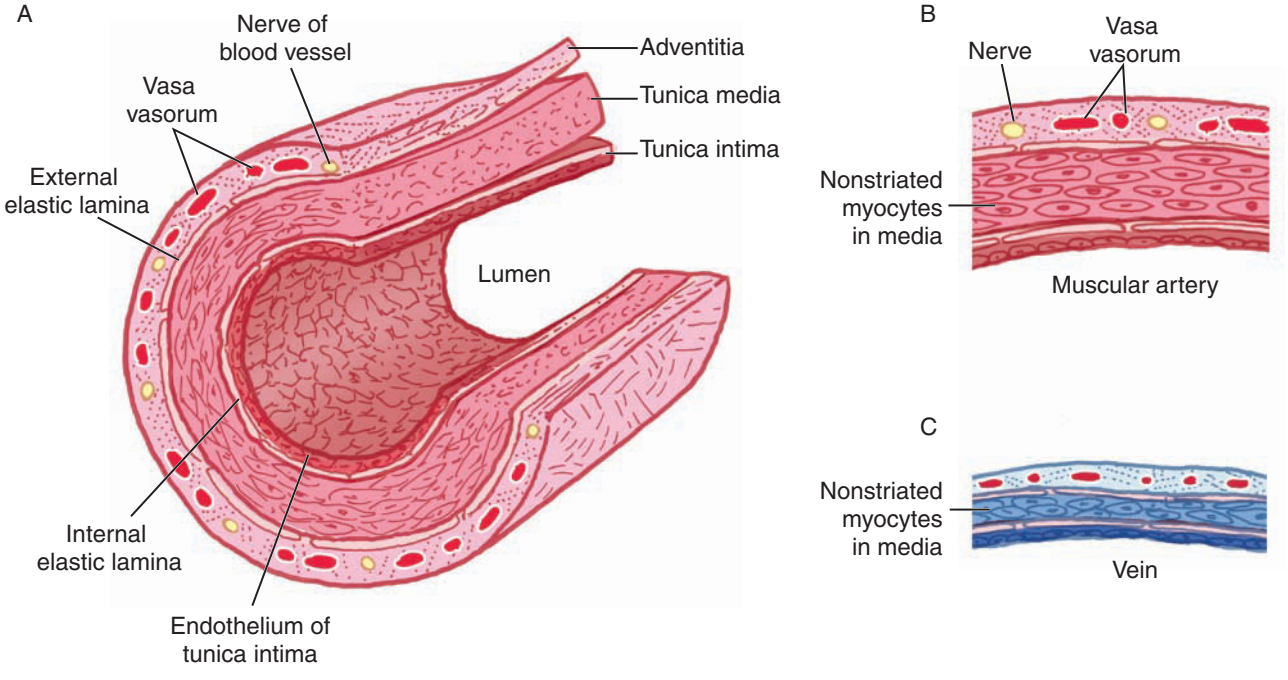

FIGURE 47-1. Comparative anatomy of an artery and a vein. **A.** The generic blood vessel. **B.** A muscular artery. **C.** A vein. Note the vein's thinner wall with fewer myocytes and elastic fibers. This is indicative of the lower pressure within veins compared to arteries.

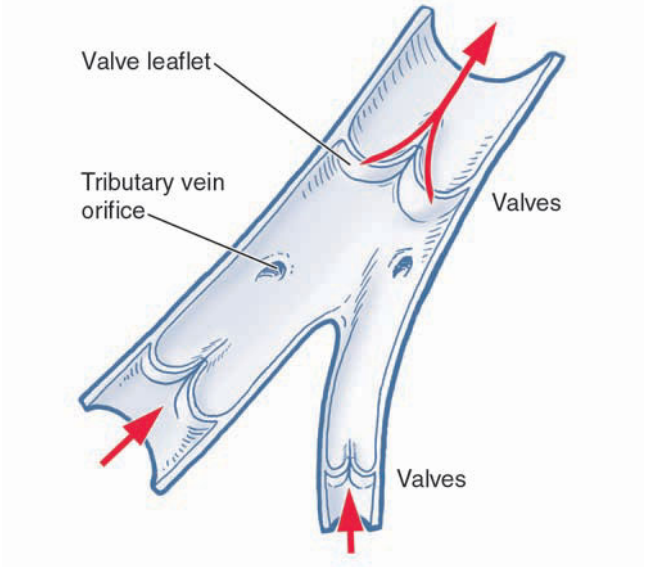

FIGURE 47-2. Venous valves. Cross-section of converging veins demonstrating the valve leaflets that only permit forward flow, proximally, toward the right heart. The arrows represent the directional flow of blood.

to access at the apex of the "Y" formed when two tributaries merge into a larger vein or where the vein is straight and free of branches (and hence valves) for approximately 2 cm proximal to the site of puncture (**Figure 47-3**). These sites tend to be anchored and "roll" less than other sites. The superficial veins of the upper extremity are preferred to those of the lower extremity for peripheral venous

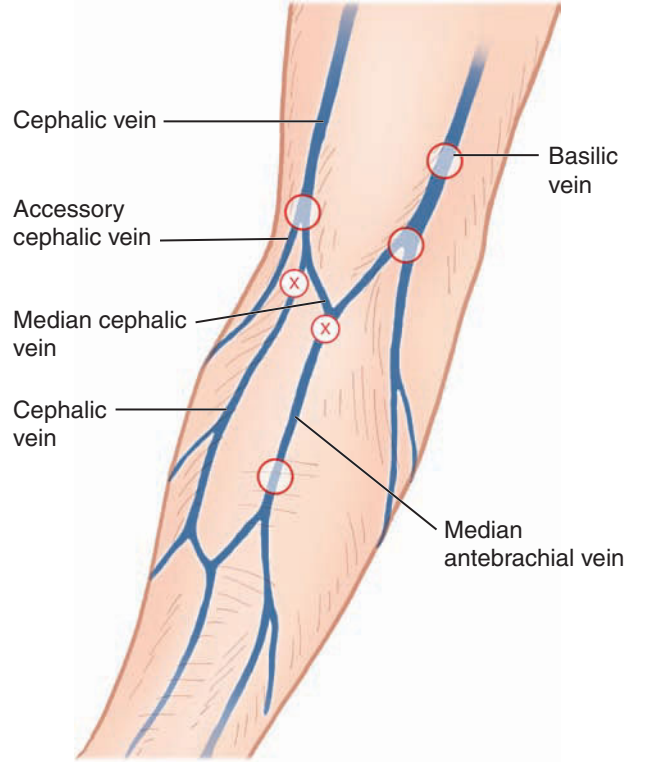

FIGURE 47-3. Preferred venous access sites. Preferred sites (*open circles*) are at the apex of converging veins or in the middle of a long straight vein. Sites just distal to branching or convergence of veins (red ⊗) are best avoided due to the presence of valves and the difficulty in threading a cannula.

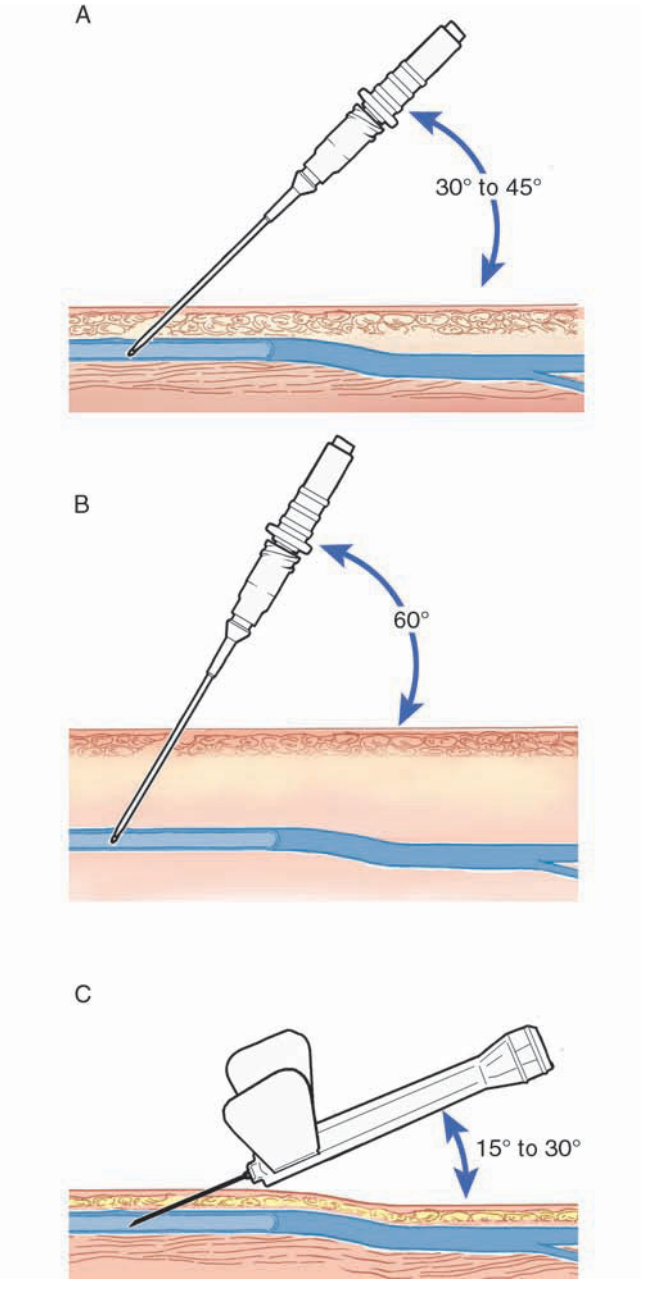

FIGURE 47-4. The angle between the needle and the skin must be varied based upon the depth and diameter of the target vein. **A.** A shallow angle must be used for small and superficial veins. **B.** A steeper angle must be used for deeper veins. **C.** A butterfly-type needle permits the shallowest angle of entry for very small and superficial veins.

access. Indwelling catheters in the upper extremity interfere less with patient mobility and the risk of phlebitis is lower.[1]

The depth of the vein beneath the epidermis will affect the ease with which it may be accessed. Very superficial veins are often small, fragile, and easily passed "through and through" with a needle, resulting in a hematoma. The deeper veins are often not visible and must be located by surface landmarks and palpation. The angle of insertion of the needle must be varied depending on the depth of the vein being punctured (**Figure 47-4**). A shallow angle of approximately 30° to 45° should be used for most small and superficial veins (**Figure 47-4A**). A more obtuse angle of approximately 60° should be used to access deeper veins

(**Figure 47-4B**). This steeper angle allows the vein to be penetrated within a reasonable horizontal distance from the skin puncture site. Very small and superficial veins should be entered at a very acute angle of approximately 15° to 30° (**Figure 47-4C**).

INDICATIONS

Venous puncture (venipuncture) with a needle is indicated only for the sampling of venous blood. Medications may be administered as a one-time dose via this technique. The risk of medication extravasation with this technique is high, and it has therefore fallen out of favor.

Venous cannulation is indicated for repeated sampling of venous blood. It is also performed for the administration of intravenous medications, fluid solutions, blood products, and nutritional support. The specific indications for peripheral venous access, central venous access, and the various techniques of venous cannulation are discussed below and in Chapters 48 and 49.

CONTRAINDICATIONS

Veins should not be accessed through infected skin. A vein proximal to a running venous infusion should not be used for venous blood sampling. The blood sample will be tainted or diluted by the infused solution. The hole in the vein may allow blood, infused solutions, and medications to extravasate into the surrounding tissues.

Venipuncture and venous cannulation of veins in an extremity with an arteriovenous fistula should be avoided. Veins in the upper extremity that may be needed for arteriovenous fistula construction for hemodialysis in the near future should not be punctured unless absolutely necessary. Scarring of the vein may complicate later surgical procedures.

CATHETER MATERIALS

Indwelling catheters are made of flexible polymers that are less likely to break or erode through the blood vessel wall than more rigid materials such as steel or glass. Polymer resins, Teflon, and polyurethane are commonly used materials. Latex-containing products should be avoided due to the risk of allergic reactions. Polyurethane catheters may be weakened by alcohol-based solutions.[1] Thus, such solutions should not be infused through polyurethane catheters.

All catheters are potentially thrombogenic. They should be left in place only as long as needed. Catheters impregnated with antiseptics, such as chlorhexidine and silver sulfadiazine, are commercially available and may decrease the incidence of catheter-related sepsis.[4] Chlorhexidine has been associated with immediate hypersensitivity reactions, most commonly in persons of Japanese descent.[5] Silver sulfadiazine has not been proven safe to use in sulfa-sensitive patients. Catheters are also available that, when immersed briefly in an antibiotic solution prior to insertion, allow an antibiotic to bind to the catheter surfaces. These catheters may reduce the risk of infection with organisms susceptible to the chosen antibiotic.

FLUID-FLOW CONSIDERATIONS

Both the diameter and the length of the infusion device will affect the flow rate through the catheter. Viscous fluids (e.g., blood products and albumin) will infuse more slowly than less viscous fluids (e.g., saline). These relationships can be seen in the solution of Poiseuille's equation for ideal fluid flow through a cylindrical tube:

$$\text{Flow rate} \propto \frac{(\pi \times \text{catheter radius}^4 \times \text{pressure gradient along the tube})}{(8 \times \text{tube length} \times \text{dynamic fluid viscosity})}$$

The pressure gradient and resistance to flow are inversely proportional to the length of the tubing. **Changes in catheter diameter will have the most effect on flow rates.** The flow rate increases to the fourth power as the catheter's internal radius increases. Flow rates can be maximized by using the largest internal diameter (i.e., smallest gauge) catheter that will fit inside the chosen vein. Large-bore venous catheters are preferred for the highest-volume rapid fluid resuscitations, particularly of viscous blood products. Flow rates decrease as the catheter length increases. **Use of the shortest possible catheter to access the chosen vein will permit the highest fluid infusion rates.** External pressure applied to the bag of infusion solution will linearly increase the flow rate.

LOCATING A PERIPHERAL VEIN

Identifying a peripheral vein can sometimes be quite difficult. Dilating a vein (venodilation) can make a vein larger, easier to identify, and easier to access. These techniques are easy to perform.

Several venodilation techniques do not require any special equipment. Place the extremity in a dependent position.[15] This position allows gravity to decrease venous return and dilate the veins.[16] Gently tap the skin in the area to dilate the underlying veins.[15,16] The exact mechanism of how this works is not known. It may be due to the release of chemical mediators, stimulation of nerve fibers, or a combination of both. Instruct the patient to open and close their hand. The muscular contractions of the forearm muscles increase arterial inflow distally while venous outflow is inhibited by the tourniquet.[15,17–19] Try to "milk" the veins in a distal direction. Apply your fingers over the skin, press downward, and then move the fingers distally to "milk" or back-flow the blood and dilate the distal veins.[15] Apply a warm compress, heat pack, warm towel, or submerge the extremity in warm water to dilate the veins. Be careful to not use too hot of a temperature to prevent burning the patient.

Several commercially available devices can be used to produce venodilation. The Esmarch Bandage is a tourniquet system used to exsanguinate a limb prior to surgery. Apply it to the upper extremity starting proximally and wrap it distally, the reverse of applying it to exsanguinate the extremity. It will result in blood pooling in the distal veins and subsequent venodilation. The Rhys-Davies Exsanguinator can also be placed proximal to distal to pool blood distally and cause venodilation.[20] This device is usually not available in the Emergency Department. A vacuum device was developed to aid in obtaining venous access.[21,22] It was cumbersome and is also not available in the Emergency Department.

Topically applied pharmaceuticals can be used to dilate the dorsal hand veins.[23–25] Topical nitroglycerine ointment has been used for many years. Apply 1 in. of the ointment and rub it into the skin on the dorsal hand. Use gloves while applying the ointment to prevent the side effects of a headache or hypotension to the healthcare provider. Allow the ointment to sit for 2 minutes then completely wipe it off the skin. Clean any residual nitroglycerine ointment from the skin with an alcohol swab. Identify a vein by palpation. Topical nifedipine is an alternative, but not currently available in the United States.

In recent years, numerous commercial devices have become available to visualize veins. The VeinViewer (Christie Medical Holdings Inc., Memphis, TN) uses polarized near-infrared light from light-emitting diodes to penetrate the skin and subcutaneous tissues.[26–28] The device projects the underlying blood-filled veins onto the skin using a visible green light. The AccuVein AV300 (AccuVein LLC, Cold Spring Harbor, NY) and the Veinlite (TransLite, Sugar Land, TX) are similar devices, but handheld. The Venoscope (Venoscope LLC, Lafayette, LA) is a handheld device

that is also available in a neonatal version. The major drawback of these devices is their cost.

ANESTHESIA

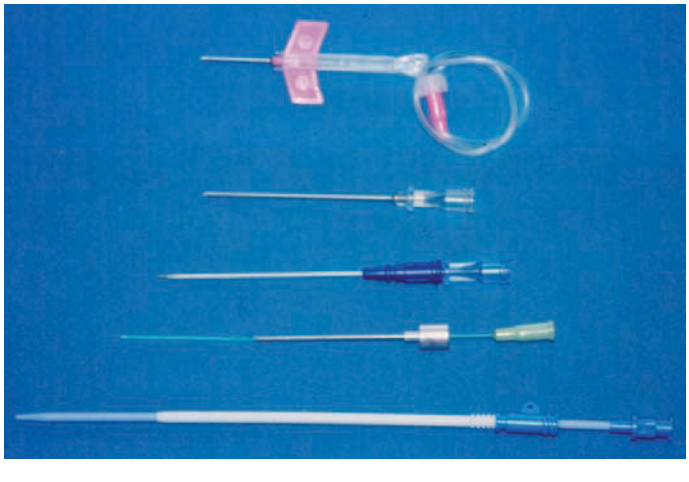
The use of anesthesia prior to venipuncture or venous cannulation is much appreciated by the patient, especially if the patient is a child. The injection of local anesthetic solution will decrease the pain of venous access. Unfortunately, the pain of injection can be just as uncomfortable as the venous access procedure. The application of a topical anesthetic, such as ELA-Max (Ferndale Laboratories, Ferndale, MI) or EMLA (Astra Zenica, Wilmington, DE), that is designed to enhance transdermal absorption requires approximately 30 to 60 minutes to adequately anesthetize the skin and subcutaneous tissues. This time delay limits their use in the Emergency Department. Refer to Chapters 123 and 124 for a more complete discussion of topical anesthetics.

Numerous alternative anesthesia methods can be considered. These are rarely available or used in the Emergency Department. Local anesthetic absorption through the skin can be enhanced to decrease the time it takes to provide anesthesia. These methods include using sound energy (sonophoresis), electrical energy (iontophoresis), and epidermal tape stripping.[29–31] A portable, handheld laser used prior to the application of topical anesthesia for 5 minutes effectively reduces the pain of venous access.[32,37] Topical vapocoolant spray will briefly anesthetize the skin long enough to allow for venous access.[33–35] Local anesthetic patches that are heat activated to increase transdermal absorption of the local anesthetic agent in approximately 20 minutes have been found to be effective.[36] Needleless jet injections of local anesthetics effectively anesthetize the skin and subcutaneous tissues.[38–40] One study questioned if the anesthesia was due to the local anesthetic agent or the jet injection procedure itself as the placebo group was just as effective in terms of anesthesia.[39] The main advantages of these techniques, compared to injectable anesthetics, are the lack of pain during the application and the lack of tissue distortion making identification of the vein difficult.

VENIPUNCTURE

Five types of devices are used for vascular access (**Figure 47-5**). There are numerous variations of these devices. The butterfly needle and hollow needle are used for venipuncture. Blood may be withdrawn using a butterfly-type needle (**Figure 47-6**) or a standard hypodermic needle. The butterfly needle, attached to a short length of plastic tubing, allows for greater control while accessing small and superficial veins. It is often too short to reach deeper veins. Versions with an integral sheath to minimize accidental needlestick injuries are available (**Figure 47-7A**).

Venous blood sampling can be accomplished by one of several methods. Blood may be allowed to drip from the open end of the butterfly extension tubing into small-volume collection tubes for pediatric patients. Some form of suction is used to withdraw the blood more rapidly in older children and adults. A syringe or a vacuum tube may be used (**Figure 47-8**). Vacuum tubes reduce the risk



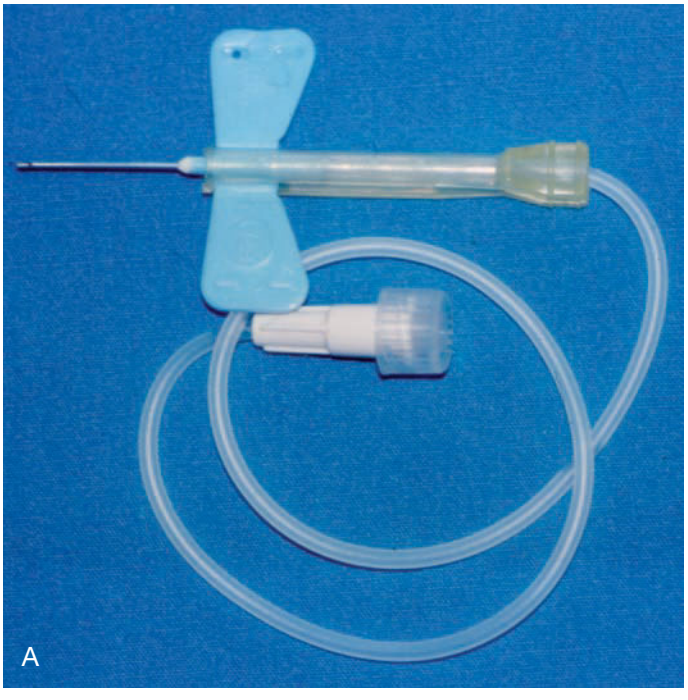


FIGURE 47-5. Venous access devices. *From top to bottom:* butterfly needle with extension tubing, hollow needle, catheter-over-the-needle, catheter-through-the-needle, and the wire-guided catheter.

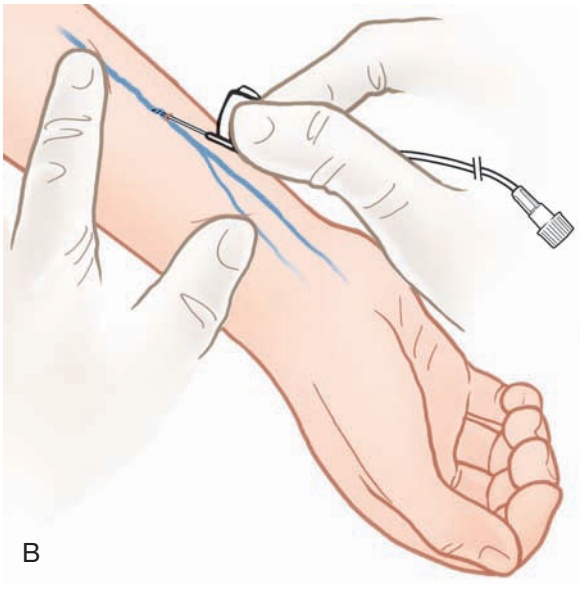

FIGURE 47-6. The butterfly-type needle. **A.** Butterfly needle with attached extension tubing. **B.** The wings of the catheter are folded together and used to direct the needle into the superficial vein. The needle may be secured within the vein and used as an infusion cannula or removed after blood samples are collected.

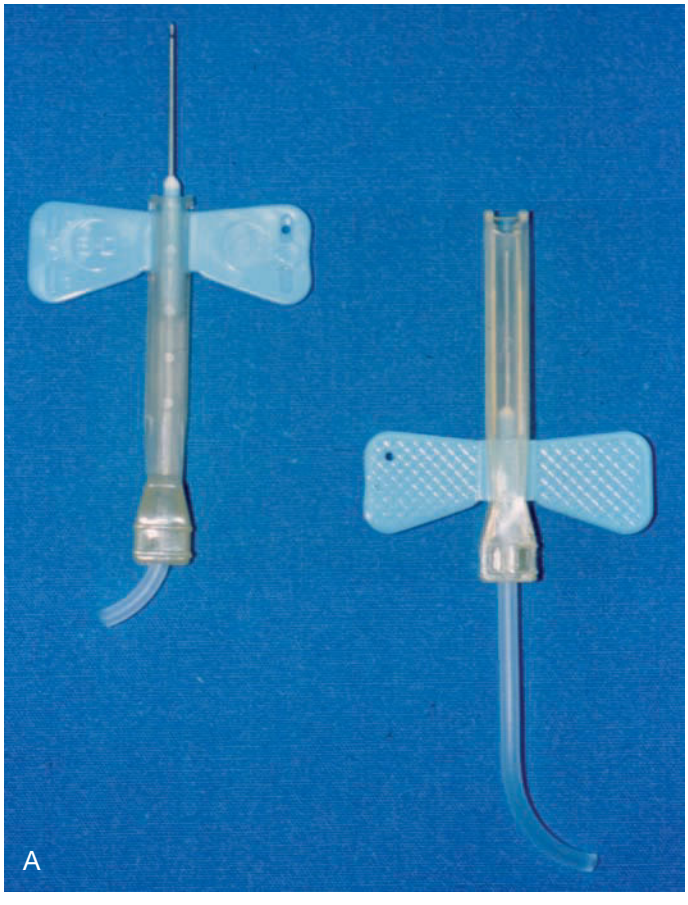

FIGURE 47-7. Needle stick prevention devices. **A.** Butterfly needle with an integral needle sheath. The left figure demonstrates the sheath retracted and the needle exposed. The right figure demonstrates the needle safely sheathed. **B.** The spring-loaded catheter-over-the-needle system. The top figure demonstrates the catheter-over-the-needle. The bottom figure demonstrates the needle inside the safety handle.

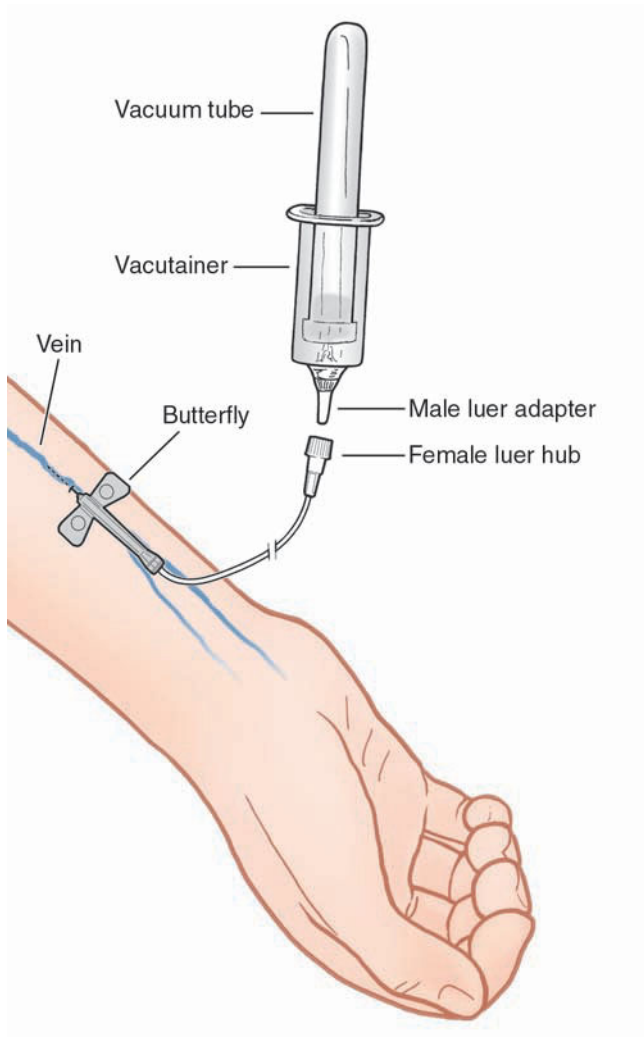

FIGURE 47-8. The Vacutainer. Once the needle is inserted into the vein, a Vacutainer adapter is connected to the female Luer hub. Specimens can be collected into different types of vacuum tubes without the risk of an accidental needle stick. However, the suction applied by the vacuum tube, unlike a syringe, cannot be controlled and may cause hemolysis and/or a small vein to collapse.

of needlestick injuries. The amount of suction provided is fixed and may result in hemolysis of the specimen and cause small veins to collapse. Syringe aspiration allows greater control over the amount of suction applied. Large syringes can be difficult to manipulate while maintaining the tip of the needle within the vein. Use a 5 to 10 mL syringe, as larger syringes result in hemolysis of the specimen and collapse of the vein. Use caution, as the needle used to transfer the specimen from the syringe to the laboratory tubes can cause a needlestick injury.

VENOUS CANNULATION TECHNIQUES

There are four main techniques of vein cannulation.[6–8] The first is the needle-only technique using a butterfly-type needle. This is seldom used today. The catheter-over-the-needle technique is the one most commonly used for peripheral venous cannulation. The catheter-through-the-needle technique is occasionally used but not very popular. The Seldinger wire-guided technique is most commonly used for central venous access. The major advantages and disadvantages of each technique are summarized in **Table 47-1**.

Identify the vein to be cannulated and the site of the skin puncture. Clean the area of any dirt and debris. Cleanse the skin with isopropyl alcohol, chlorhexidine solution, or povidone iodine solution and allow it to dry. Apply a tourniquet to the extremity, proximal to the venous cannulation site, to engorge the vein. Additional engorgement of the vein or the use of a device to locate a vein, both described previously, can aid in the identification of a peripheral vein. **Do not attempt cannulation if the vein cannot be seen, palpated, or otherwise visualized (e.g., ultrasound) in the engorged state.** Place a small subcutaneous wheal of local anesthetic solution, or some other previously mentioned alternative, at the skin puncture site to provide some comfort to the patient. The next step is to cannulate the vein by one of the methods described below.

NEEDLE-ONLY TECHNIQUE

This technique is used occasionally for short-term venous access in young children and elderly patients with fragile veins. This system is

TABLE 47-1 Features of Venous Catheterization Techniques

	Butterfly needle	Catheter-over-the-needle	Catheter-through-the-needle	Seldinger
Diameter of vein punctured compared to catheter diameter	Same	Slightly smaller	Larger	Smaller
Catheter length compared to needle	Same	Slightly shorter	Longer, up to 61 cm (24 in)	Unlimited
Speed of insertion	Rapid	Rapid	Slower	Slowest
Risk of extravasation	Highest	Low, higher with shorter catheters	Low	Very low
Security of catheter with patient movement	Lowest	Fair to good	Good	Excellent when sutured
Best choice for	Peripheral venous sampling	Peripheral venous infusion	Central venous access	Central venous access
Can change catheter without new venous puncture?	No	Can use small wire and Seldinger technique	No	Yes

prone to malposition and infiltration. The tip of the needle can easily lacerate the vein if the needle is not secure and allowed to move.

Grasp and fold the wings of the butterfly needle with the dominant index finger and thumb (**Figure 47-6B**). Briskly insert the needle, with the bevel facing upward, through the skin and into the vein.[14] A flash of blood will be seen in the tubing when the tip of the needle enters the vein. Carefully advance the needle an additional 3 to 5 mm into the vein. Attach a 5 mL syringe to the extension tubing and aspirate blood. The flow of blood into the syringe confirms proper intravascular placement of the needle. Remove the tourniquet from the extremity. Securely tape the wings of the butterfly needle to the patient's skin. Remove the 5 mL syringe, attach intravenous tubing to the catheter, and begin the intravenous infusion.

CATHETER-OVER-THE-NEEDLE TECHNIQUE

The catheter-over-the-needle systems are the ones most commonly used for venous access. The infusion catheter fits closely over a hypodermic needle. The needle and the catheter are advanced as a unit into the vein. These devices are inexpensive (about $1-4 each), come in a variety of diameters (12- to 24-gauge) and lengths, and are widely available. Versions designed to minimize accidental needlestick injuries are available and their use is encouraged (**Figure 47-7B**).[9]

Insert the catheter-over-the-needle, with the bevel facing upward, through the skin and into the vein (**Figure 47-9A**).[14] A flash of blood in the hub of the needle confirms that the tip of the needle is within the vein. Advance the unit an additional 2 to 3 mm to ensure that

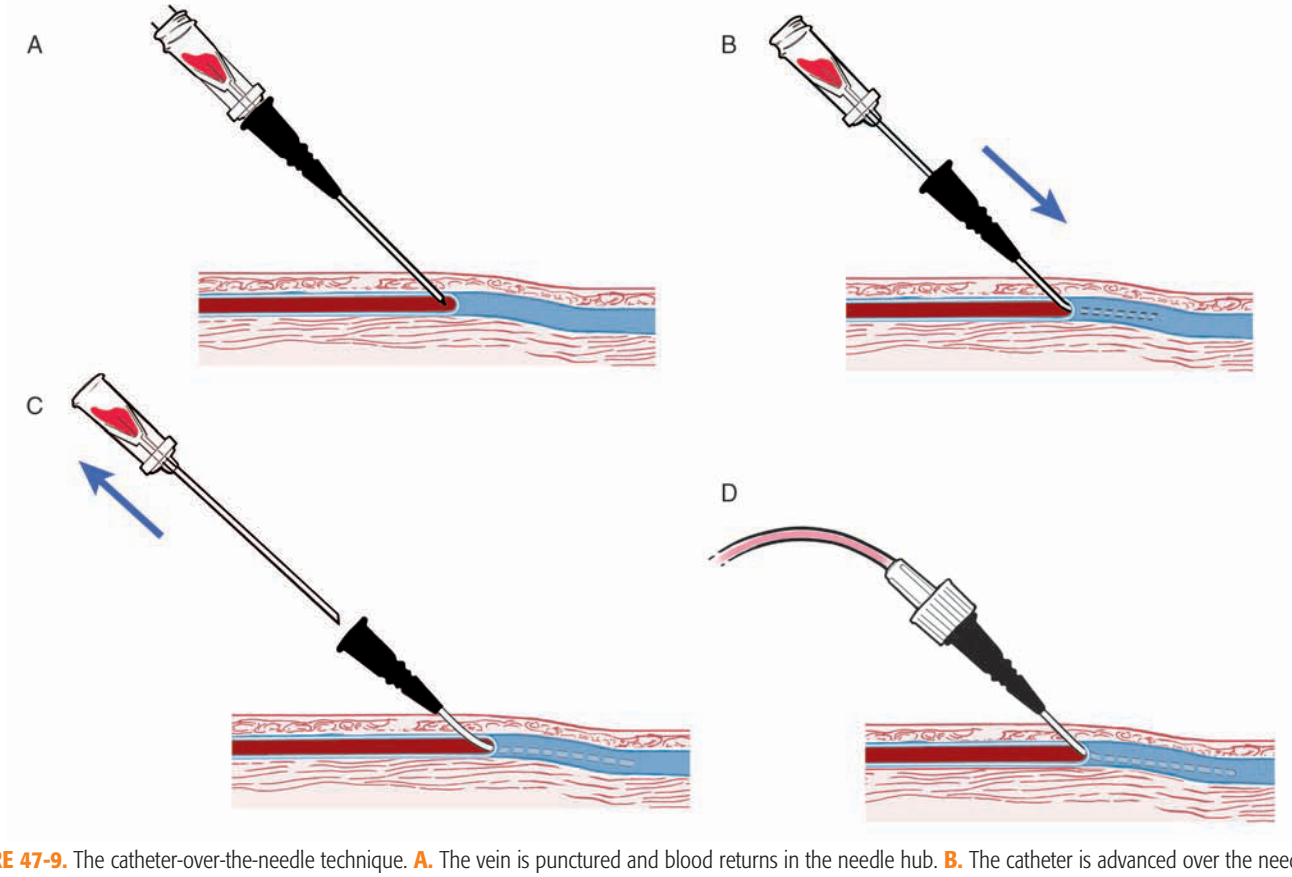

FIGURE 47-9. The catheter-over-the-needle technique. **A.** The vein is punctured and blood returns in the needle hub. **B.** The catheter is advanced over the needle and into the vein. **C.** The needle is removed. **D.** Intravenous extension tubing is attached to the catheter.

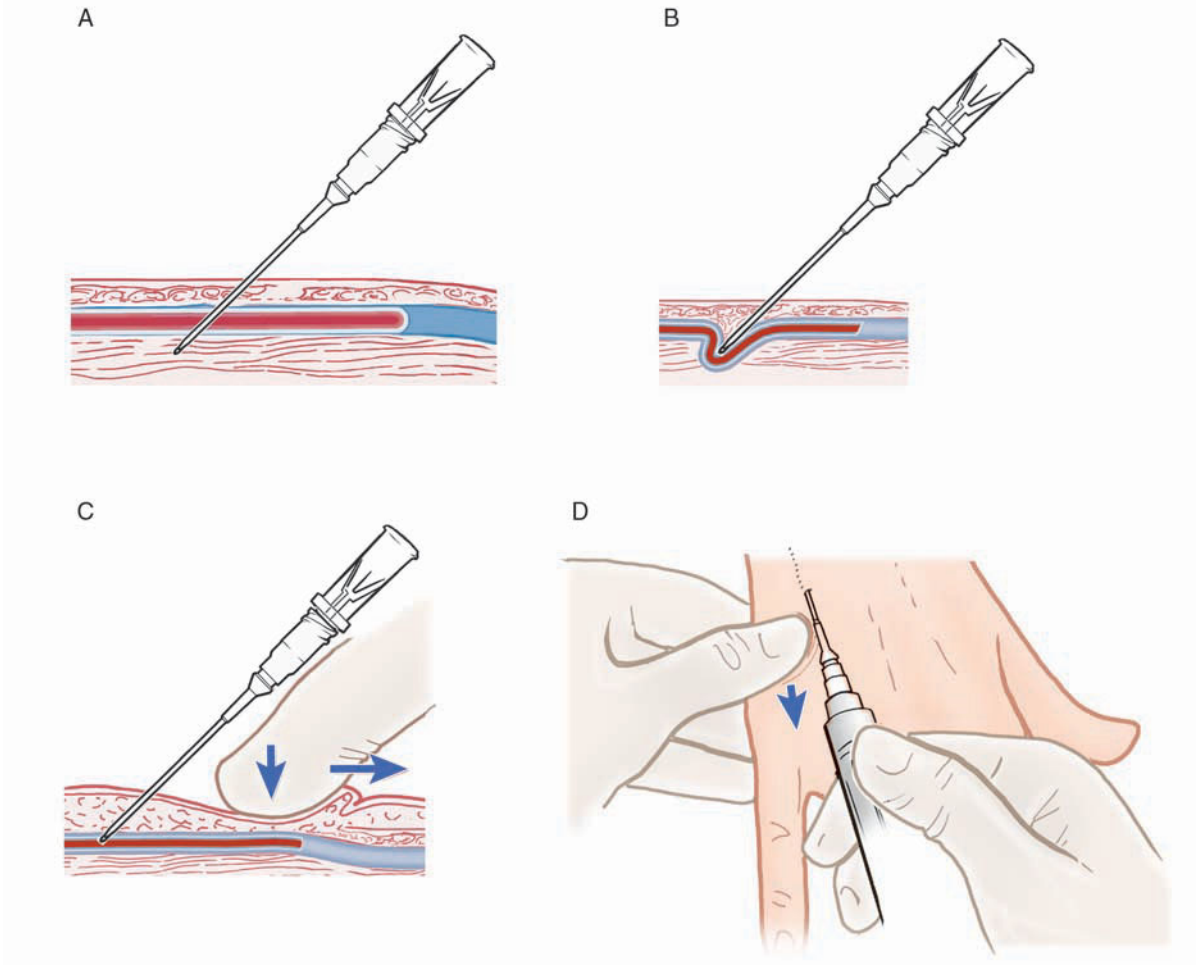

FIGURE 47-10. Pitfalls of the catheter-over-the-needle technique. **A.** Through-and-through puncture of the vein. **B.** The catheter can push the vein off the needle and prevent cannulation. **C.** Push a finger into the skin distal to the puncture site and pull back (*arrow*) to keep the vein straight and prevent it from moving. **D.** The nondominant thumb is used to pull the skin and stabilize the vein.

the catheter is within the vein. Hold the hub of the needle securely. Advance the catheter over the needle until its hub is against the skin (**Figure 47-9B**). Apply pressure, with the nondominant index finger, over the skin above the catheter to prevent blood from exiting the catheter. Remove the tourniquet from the extremity. Securely hold the hub of the catheter against the skin. Withdraw the needle (**Figure 47-9C**). Attach intravenous tubing to the hub of the catheter and begin the infusion (**Figure 47-9D**). Secure the catheter to the skin with tape.

Placement of these catheters is usually quick and simple. Several considerations should always be kept in mind when using the catheter-over-the-needle technique. Intravascular placement of the system is indicated by a flash of blood in the hub of the needle. If the patient's venous pressure is very low or if the needle is long and narrow, both sides of the vessel may be traversed (i.e., through-and-through) before the practitioner realizes that the needle was within the vein (**Figure 47-10A**). If the tip of the needle has withdrawn from the vein, the catheter will not advance. If the catheter is advanced when the tip of the needle but not the catheter is within the vein, the catheter will not advance. The catheter will push the vein off the needle (**Figure 47-10B**). Place a finger just distal to the puncture site. Depress the skin and pull it distally to prevent the vein from "rolling" as the catheter-over-the-needle is inserted into the vein (**Figures 47-10C & D**).

CATHETER-THROUGH-THE-NEEDLE TECHNIQUE

As opposed to the over-the-needle approach, this technique eliminates the need for a needle that is as long as the catheter and eliminates the possibility of pushing the vein off the end of the needle when the catheter is advanced.[10] This system is used most commonly for central, rather than peripheral, venous access. Catheters up to 61 cm (24 in) long are available and allow central venous access from the antecubital vein or the femoral vein. Select a catheter size that is appropriate for the patient and the site of entry. Packaged with each catheter are a needle and a needle guard. The needle will have an inner diameter that is slightly larger than the outer diameter of the catheter. The needle guard has a beveled channel in which the needle can reside. The needle guard hinges closed over the needle to hold it securely and prevent the needle from shearing the catheter. Holes in the corners of the needle guard allow it to be sewn to the patient's skin.

Place the needle on a tuberculin syringe. Insert the needle, with the bevel facing upward, through the skin and into the vein while applying negative pressure to the syringe (**Figure 47-11A**).[14] A flash of blood in the syringe confirms that the tip of the needle is within the vein. Advance the needle an additional 2 mm to ensure that the tip of the needle is completely within the vein. Grasp and hold the needle securely with the nondominant hand. Remove the syringe

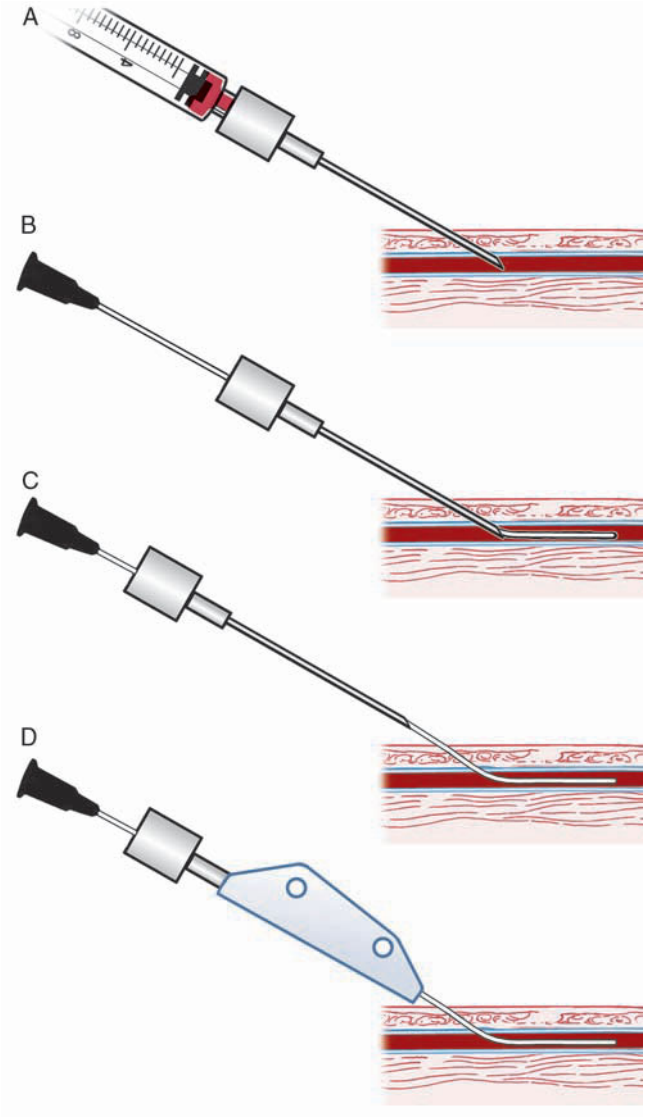

FIGURE 47-11. The catheter-through-the-needle technique.[9,11] **A.** The vein is punctured with the needle. **B.** The syringe has been removed. The catheter is inserted through the needle and into the vein. **C.** The needle is withdrawn over the catheter and completely outside the skin. **D.** The needle guard is attached to secure the needle and prevent it from shearing the catheter.

with the dominant hand. Immediately place the nondominant thumb over the needle hub to prevent air from entering the vein. Remove the tourniquet from the extremity.

Insert the catheter through the hub of the needle (**Figure 47-11B**). Advance the catheter through the needle until the desired length of catheter is within the vein. **If the catheter will not advance, remove the catheter and needle as a unit. Never withdraw the catheter through the needle. The sharp bevel of the needle may cut the catheter as it is being withdrawn and result in a catheter embolism in the central venous circulation.**

Withdraw the needle over the catheter (**Figure 47-11C**). **Do not allow the catheter to be withdrawn through the needle.** Continue to withdraw the needle until the tip is completely outside the skin. Apply the needle guard over the needle (**Figure 47-11D**). Attach intravenous tubing to the hub of the catheter and begin infusing fluids through the catheter. Secure the catheter and needle guard to the skin with tape and/or sutures.

The main disadvantage of this technique is the possibility of the needle tip shearing off the catheter, causing a catheter embolism in the venous circulation. **This can be prevented by not withdrawing the catheter through the needle and applying the needle guard immediately after the needle is withdrawn from the skin.** The contaminated needle must be handled to some extent, creating a potential risk for a needlestick injury. The needle used for the venipuncture must be larger in diameter than the catheter. This limits the practical diameter of the catheter. The needle punctures a hole in the vessel larger than the catheter and increases the risk of hematoma formation.

SELDINGER TECHNIQUE

First described by Seldinger in 1953, this technique allows for the placement of a catheter over a wire rather than directly over a needle.[11,12] The wire used must be longer than the catheter. The needle used to insert the wire can be short and of a smaller gauge than the catheter. If desired, the catheter type may be changed later without the need for a new venous puncture. Materials needed for catheter insertion are commercially available in a prefabricated kit (Teleflex Medical, Cleveland, OH; Cook Medical Inc., Bloomington, IN).

The Seldinger technique is most commonly used for central venous catheter insertion. It can be used for peripheral venous access if a short, thin guidewire is available. Ultrasound may be a useful adjunct with this technique.[13] Please refer to Chapter 50 regarding ultrasound-guided vascular access for a complete discussion. All-in-one arterial line kits are commercially available. They are intended for peripheral arterial line placement but can also be used to place catheters in peripheral veins, the brachial veins, and the external jugular veins.

The Seldinger technique for venous catheter insertion is described briefly here. Refer to Chapter 49 (central venous access techniques) for a more complete discussion. Choose the puncture site. Prepare the patient for the procedure. Clean and prepare the puncture site as previously described. The vein may first be located with a small "finder" needle if there is doubt about its exact location. Insert a 25 or 27 gauge needle attached to a 5 mL syringe, with the bevel facing upward, through the skin. Advance the needle while applying negative pressure to the syringe. A flash of blood signifies that the tip of the needle is within the vein. Note the depth and location of the vein based on the depth and direction of the "finder" needle.

Insert the thin-walled introducer needle while applying negative pressure to the syringe. The introducer needle has a tapered hub on the proximal end to guide the wire into the needle lumen. Avoid using a standard hypodermic needle, as it does not allow for the passage of the guidewire. A flash of blood in the needle hub signifies that the tip of the needle is within the vein (**Figure 47-12A**). Advance the needle an additional 1 to 2 mm into the vein. Hold the needle securely in place and remove the syringe.

Occlude the needle hub with a sterile gloved finger. This will prevent air from entering the venous system. Insert the guidewire through the hub of the needle (**Figure 47-12B**). Advance it to the desired depth, ensuring that it is at least several centimeters beyond the beveled end of the needle. **To prevent loss of the wire into the venous circulation, never let go of the guidewire with both hands at the same time.** Hold the guidewire securely in place. Remove the needle over the guidewire (**Figure 47-12C**). Make a small nick in the skin adjacent to the guidewire with a #11 scalpel blade (**Figure 47-12D**). **Direct the sharp edge of the scalpel blade away from the guidewire to prevent nicking the guidewire.**

Place the dilator over the guidewire. Advance the dilator over the guidewire to enlarge the subcutaneous passage for the catheter. Continue to advance the dilator until its hub is against the skin. Withdraw the dilator over the guidewire while leaving the guidewire in place. Advance the catheter over the guidewire until its hub

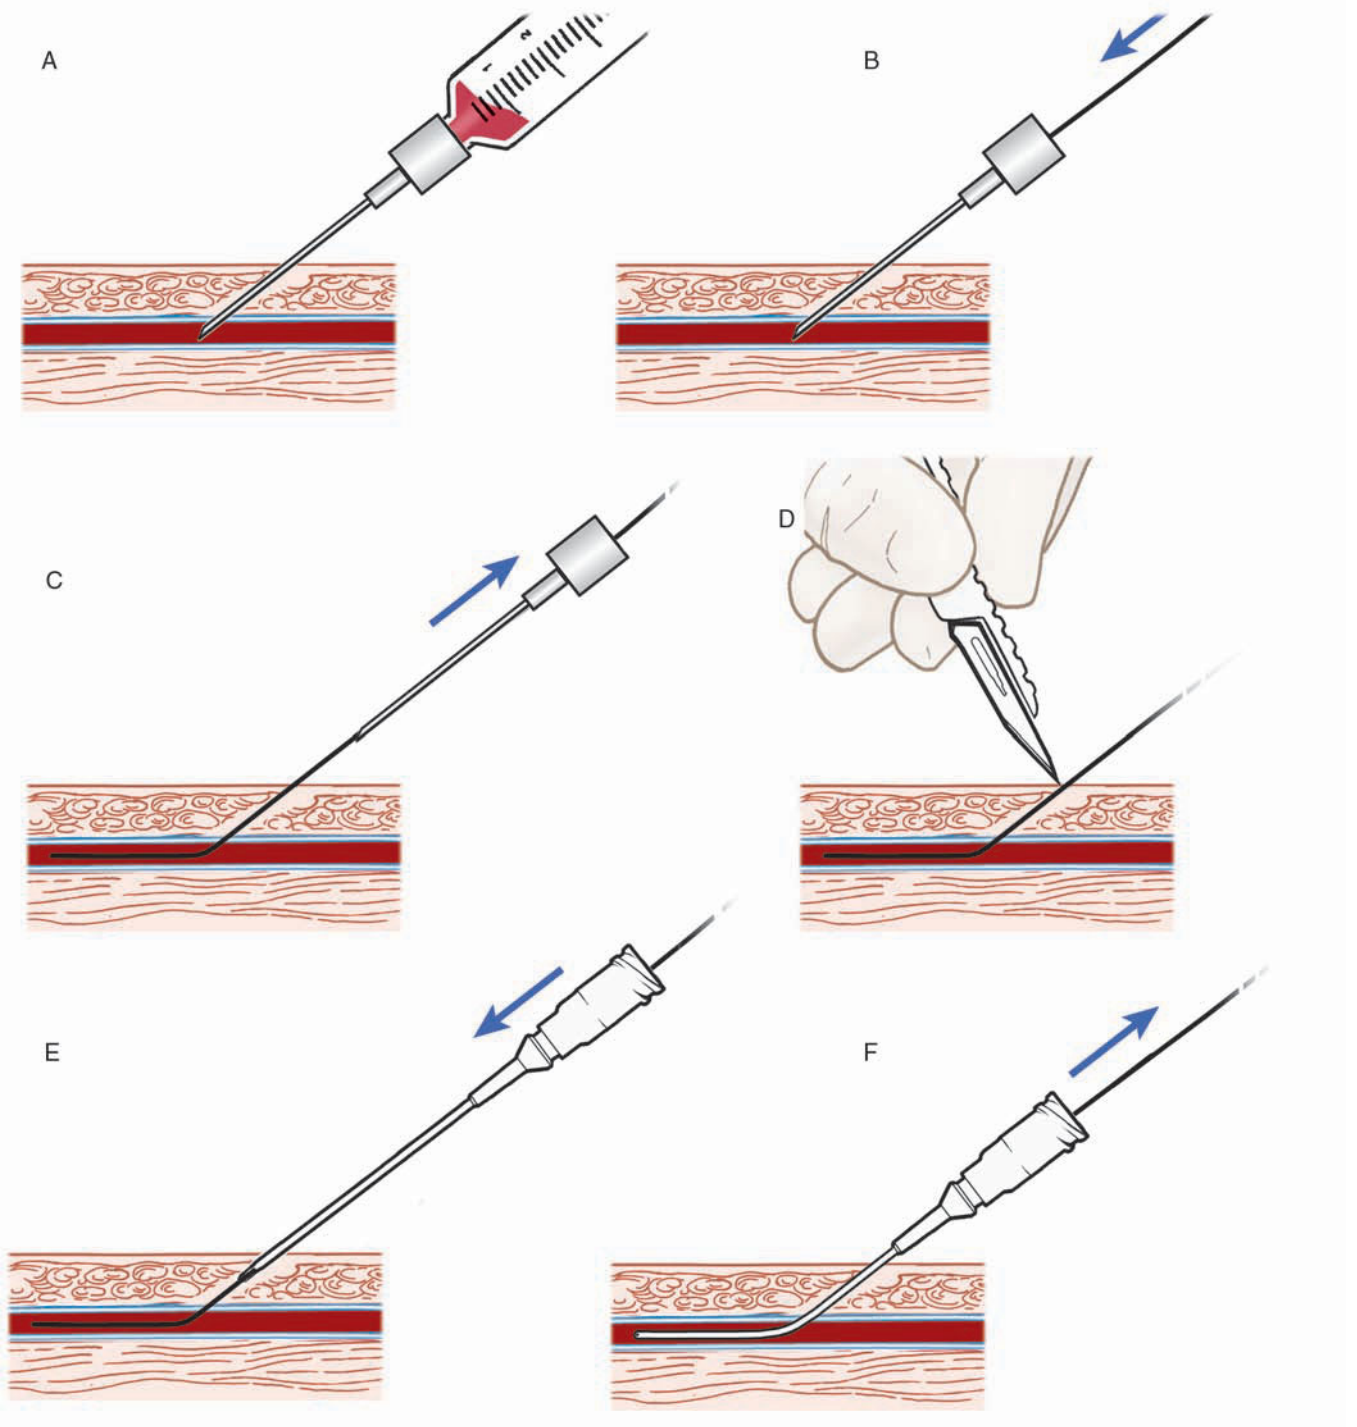

FIGURE 47-12. The Seldinger technique. **A.** The vein is punctured by the needle and blood is aspirated. **B.** The syringe has been removed. The guidewire is inserted through the needle and into the vein. **C.** The needle is withdrawn over the guidewire. **D.** The skin puncture site is enlarged to permit catheter passage. **E.** The catheter is advanced over the guidewire and into the vein. **F.** The guidewire is withdrawn through the catheter.

is against the skin (**Figure 47-12E**). A twisting motion of the catheter may aid in its advancement through the subcutaneous tissues and into the vein. Securely hold the hub of the catheter. Remove the guidewire through the catheter (**Figure 47-12F**).

Aspirate blood from the catheter with a syringe to confirm intravenous placement. Flush the catheter with sterile saline or begin an infusion. Secure the catheter to the skin with sutures and tape. While this technique seems complicated at first glance, it is easy to learn and can be performed in a few minutes by an experienced Emergency Physician.

COMPLICATIONS

Complications specific to each technique and site are discussed more fully in the following chapters. Venous catheters should be assessed immediately after their placement and also be reassessed frequently. The assessment must include the skin puncture site, catheter function, the extremity distal to the catheter, and the patient's overall condition. Some of the common problems are noted in **Table 47-2**. Other specific complications of peripheral and central venous access are discussed in the following chapters.

TABLE 47-2 Complications of Venous Catheterization

	Observation	Complications	Errors in technique	Response
Skin puncture site	Immediate swelling	Hematoma	Laceration or through-and-through puncture	Remove catheter, apply pressure
Skin puncture site	Delayed swelling	Extravasation or hematoma	Catheter dislodged or damaged, vein lacerated	Remove catheter, apply pressure
Skin puncture site	Erythema or discharge	Infection	Catheter in place too long, catheter or skin contaminated	Remove catheter, give parenteral antibiotics
Catheter	Cannot infuse	Thrombosis or kinking	Catheter not flushed enough, catheter not secured properly	Flush catheter, check position, remove catheter
Catheter	Blood runs up IV tubing	Arterial placement	Arterial puncture not recognized	Remove catheter, apply pressure
Catheter	Cannot aspirate from proximal lumens of multilumen line	Extravascular placement or migration of proximal lumens	Not enough catheter inserted; patient movement; catheter not properly secured	Change catheter over a wire if distal port is intravascular
Systemic	Fever	Line sepsis	Catheter left in place too long or contaminated	Remove catheter once infection is verified
Systemic	Hemodynamic or respiratory compromise	Pneumothorax, pericardial tamponade	Pleura punctured during insertion; catheter tip malpositioned	Chest radiograph, auscultate chest; pericardial or pleural drainage

SUMMARY

Venous access is an essential skill for all providers of care to the acutely ill and injured. As with most procedures, success rates increase and complication rates decrease with experience. Successful venipuncture or cannulation is not the end of the provider's obligation to the patient. Frequent reassessment of the venous access site, the equipment, and the patient is essential to prevent complications.

48 Venipuncture and Peripheral Intravenous Access

Daniel Belmont

INTRODUCTION

Puncture of a peripheral vein is the most common invasive procedure performed in the Emergency Department. While some newer point-of-care testing techniques require only capillary blood, the vast majority of laboratory studies require venous blood. Cannulation of a peripheral vein is performed on a daily basis and is the cornerstone of circulatory resuscitation. It is an essential skill for all emergency personnel, from phlebotomists to nurses to the Emergency Physician. A variety of approaches for obtaining peripheral venous access are described in this chapter.

ANATOMY AND PATHOPHYSIOLOGY

Veins and arteries are composed of a three-layered wall of internal endothelium surrounded by a layer of muscle then a layer of connective tissue (**Figure 48-1**).[1] The muscular layer of a vein is much thinner and weaker than that of an artery. While veins can dilate and constrict somewhat on their own, they do so mostly in response to the pressure within them. Veins with high internal pressures become engorged and are easier to access. The use of venous tourniquets, dependent positioning, "pumping" via muscle contraction, and the local application of heat or nitroglycerin ointment all contribute to venous engorgement.[2] These maneuvers can be used to aid in the identification of a peripheral vein.

The connective tissue surrounding veins can be a help or a hindrance during attempts at gaining peripheral venous access. Deficient connective tissue permits the vein to "roll" from side to side and evade the needle. Tough connective tissue can impede the entry of a flexible catheter through the soft tissues and into the vein. This tissue also serves to stabilize the vein and prevent its collapse.

Venous valves are an important aspect of peripheral venous anatomy (**Figure 48-2**).[1] Venous valves encourage unidirectional flow of blood back to the heart. Because of gravitational forces, they prevent blood from pooling in the dependent portions of the extremities. Valves can impede the passage of a catheter through and into a vein. Forcing a catheter past venous valves may damage them and contribute to later venous insufficiency. Valves are more numerous at the points where tributaries join larger veins and in the lower extremities. Valves are almost totally absent within the large central veins and the veins of the head and neck.

Veins can be subdivided into central veins and peripheral veins. The important central veins with regard to venous access are the internal jugular, subclavian, and femoral veins. Central veins are usually larger than peripheral veins and have fewer tributaries.

Superficial peripheral veins are generally visible beneath the surface of the skin of the extremities and neck. They are often tortuous and continually merge and divide. Peripheral veins are easiest to access at the apex of the "Y" formed when two tributaries merge into a larger vein or where the vein is straight and free of branches (and hence valves) for 2 cm or more proximal to the site of puncture (**Figure 48-3**). These sites tend to be anchored and hence "roll" less than other sites. The superficial veins of the upper extremity are preferred to those of the lower extremity for peripheral venous access. Indwelling catheters in the upper extremity interfere less with patient mobility, and they pose a lower risk of phlebitis.[2] The superficial veins of the extremities are shown in **Figures 48-4 & 48-5**. The veins most commonly used for venipuncture and venous access are the basilic and cephalic veins as well as their branches and tributaries (**Figure 48-4**). The veins of the dorsal foot and the distal saphenous veins are the most commonly used veins in the lower extremity (**Figure 48-5**).

The depth of the vein beneath the epidermis will affect the ease with which it may be accessed. Very superficial veins are often small, fragile, and easily passed "through-and-through" with a

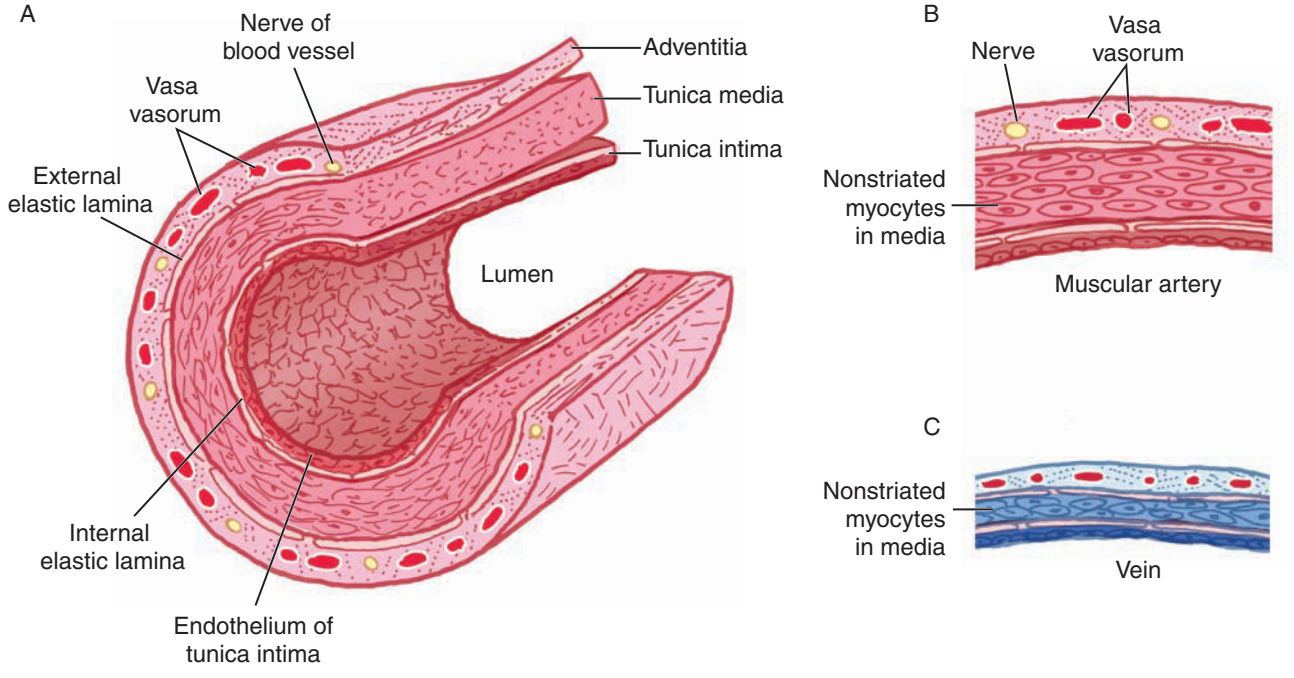

FIGURE 48-1. Comparative anatomy of an artery and a vein. **A.** The generic blood vessel. **B.** A muscular artery. **C.** A vein. Note the vein's thinner wall with fewer myocytes and elastic fibers. This is indicative of the lower pressure within veins compared to arteries.

needle, resulting in a hematoma. The deeper veins are often not visible and must be located by surface landmarks and palpation. The angle of insertion of the needle must be varied depending on the depth of the vein being punctured (**Figure 48-6**). A shallow angle of approximately 30° to 45° should be used for small and superficial veins (**Figure 48-6A**). A more obtuse angle of approximately 60° should be used to access deeper veins (**Figure 48-6B**). This angle allows the vein to be penetrated within a reasonable horizontal distance from the skin puncture site. Very small and very superficial veins should be entered at a very acute angle of approximately 15° to 30° (**Figure 48-6C**).

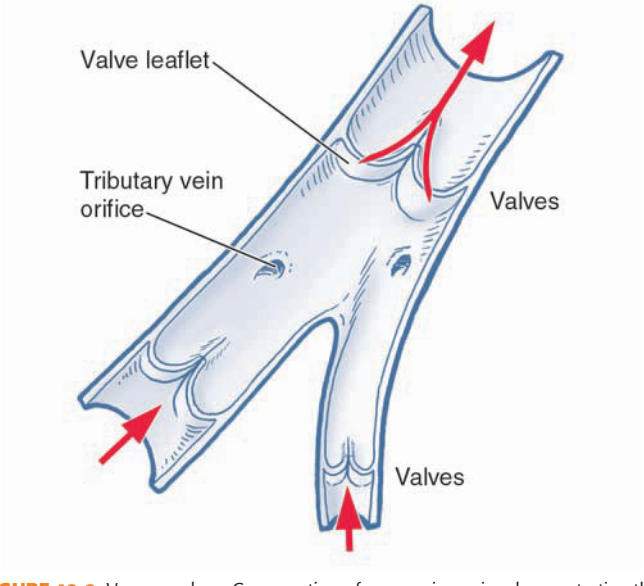

FIGURE 48-2. Venous valves. Cross section of converging veins demonstrating the valve leaflets that permit only forward flow, proximally, toward the right heart. The arrows represent the directional flow of blood.

The upper extremity is preferred to the lower for venous cannulation, and distal placement should be attempted before moving proximally.[3] Avoid veins overlying a joint if possible. Adherence to these simple principles will allow the patient maximum mobility

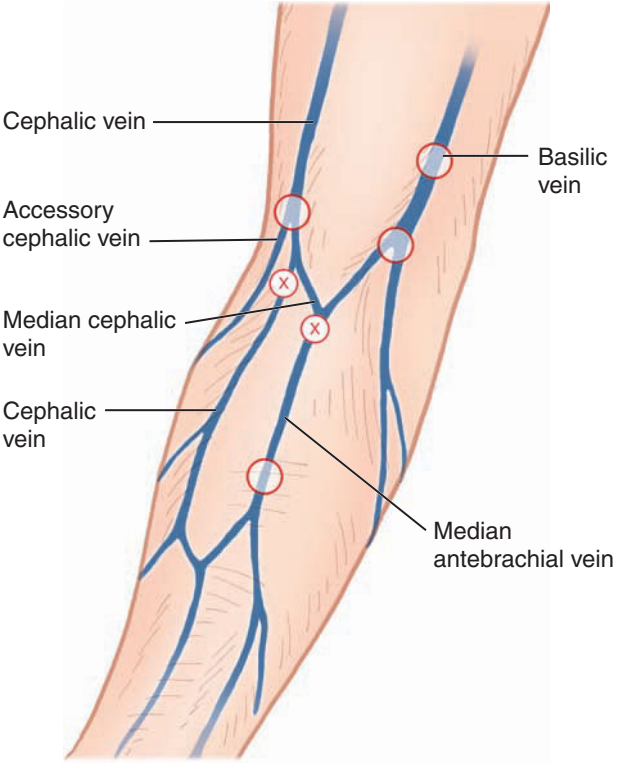

FIGURE 48-3. Preferred vein entry points. Preferred sites (*open circles*) are at the apex of converging veins or in the middle of a long straight vein. Sites just distal to branching or convergence of veins (red ⊗) are best avoided due to the presence of valves and the difficulty in threading a cannula.

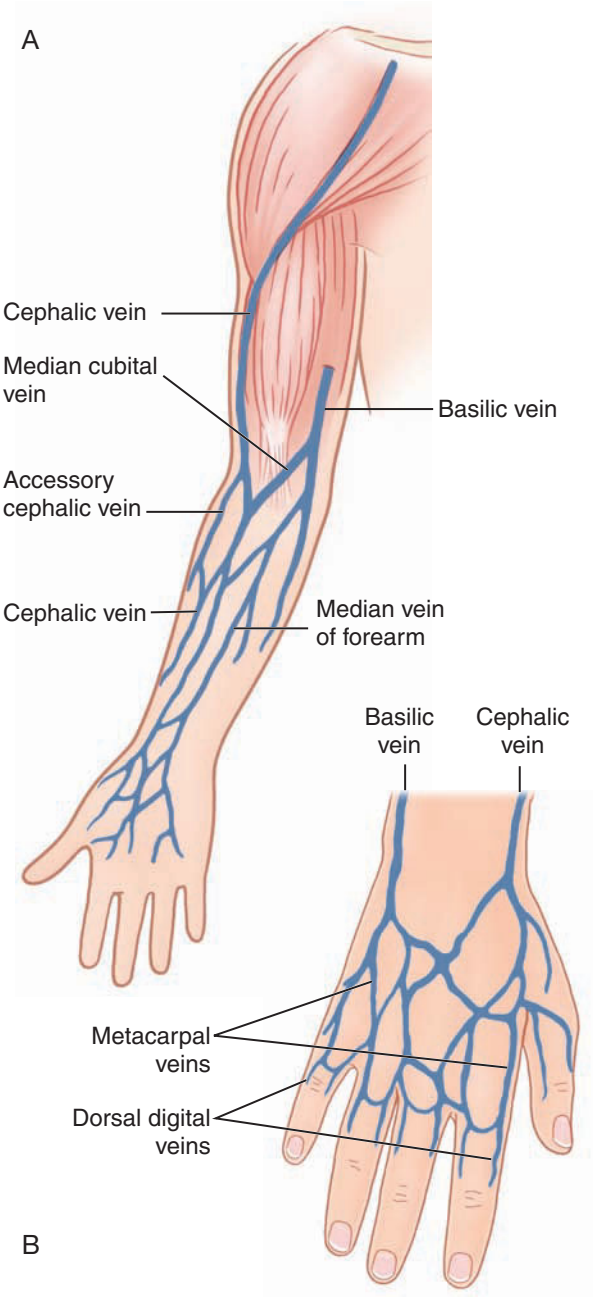

FIGURE 48-4. Superficial veins of the upper extremity. **A.** Volar surface of the upper extremity. **B.** Dorsal surface of the hand and wrist.

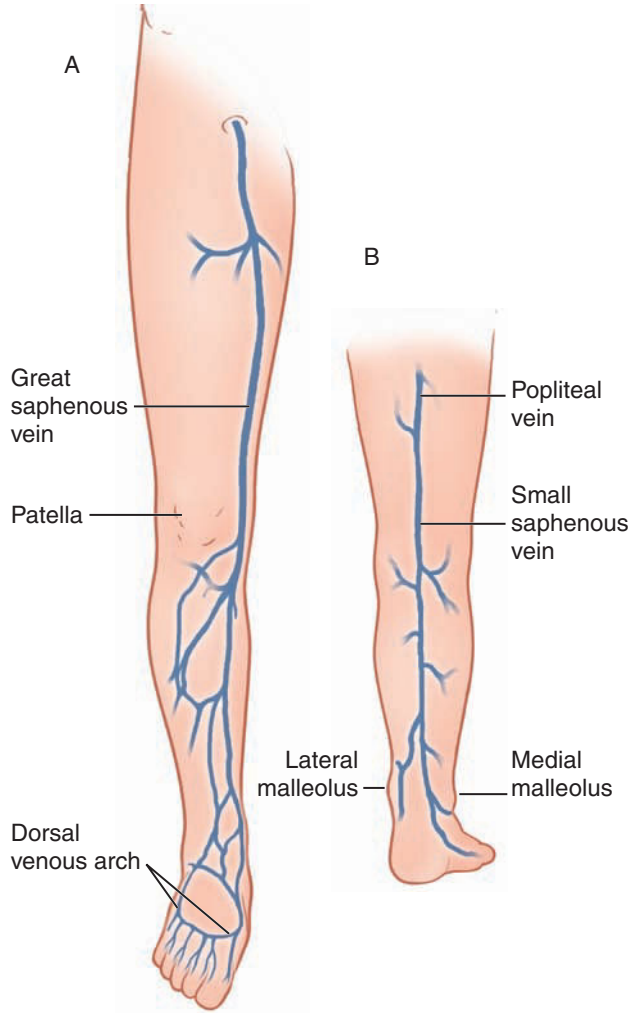

FIGURE 48-5. Superficial veins of the lower extremity. **A.** Anterior surface. **B.** Posterior surface.

and increase the chance of successfully cannulating a vein in the chosen extremity. Any solutions or medications infused distally can extravasate and injure the surrounding tissues once a proximal vein has been punctured unsuccessfully.

It is easiest to insert a venous cannula where two tributaries merge and form a "Y." Choose a straight portion of vein without branches to minimize the chance of hitting valves within the vein. This also makes it easier to thread the catheter (**Figure 48-3**).

The deep brachial veins are variably located alongside the brachial artery, running lateral and/or medial to the artery (**Figure 48-7**).[4,5] The brachial veins are relatively small, deep and not visible, have a close relationship to the brachial artery, and are thus not normally accessed. **It is important to prevent injury to the brachial artery when cannulating or puncturing the brachial veins.** The brachial artery is the sole arterial supply of the forearm, hand, and median nerve. The deep brachial veins may be used when superficial veins have been destroyed by scarring due to intravenous drug abuse, chemotherapy, or prior infusions. The location and cannulation of the brachial veins can be aided through the use of ultrasound.[6]

The neck is an important potential site for peripheral venous access through the external jugular vein (**Figure 48-8**). This vein begins at the level of the mandible and runs obliquely across the sternocleidomastoid muscle. It dives beneath the fascia in the subclavian triangle in the neck to join with the subclavian vein.[5] Some patients have two external jugular veins on one or both sides as an anatomic variant. The external jugular vein has two sets of valves (**Figure 48-8**). One is located where the external jugular vein joins the subclavian vein and the other is located approximately 4 cm above the clavicle. These valves are not fully competent but may prevent the passage of a guidewire or catheter.[5,7]

INDICATIONS

Peripheral venous access is indicated for venous blood sampling. It is also performed for the administration of intravenous medications, fluid solutions, and blood products. Peripheral venous lines may be used for short-term partial nutritional support; full nutritional support requires central venous access.

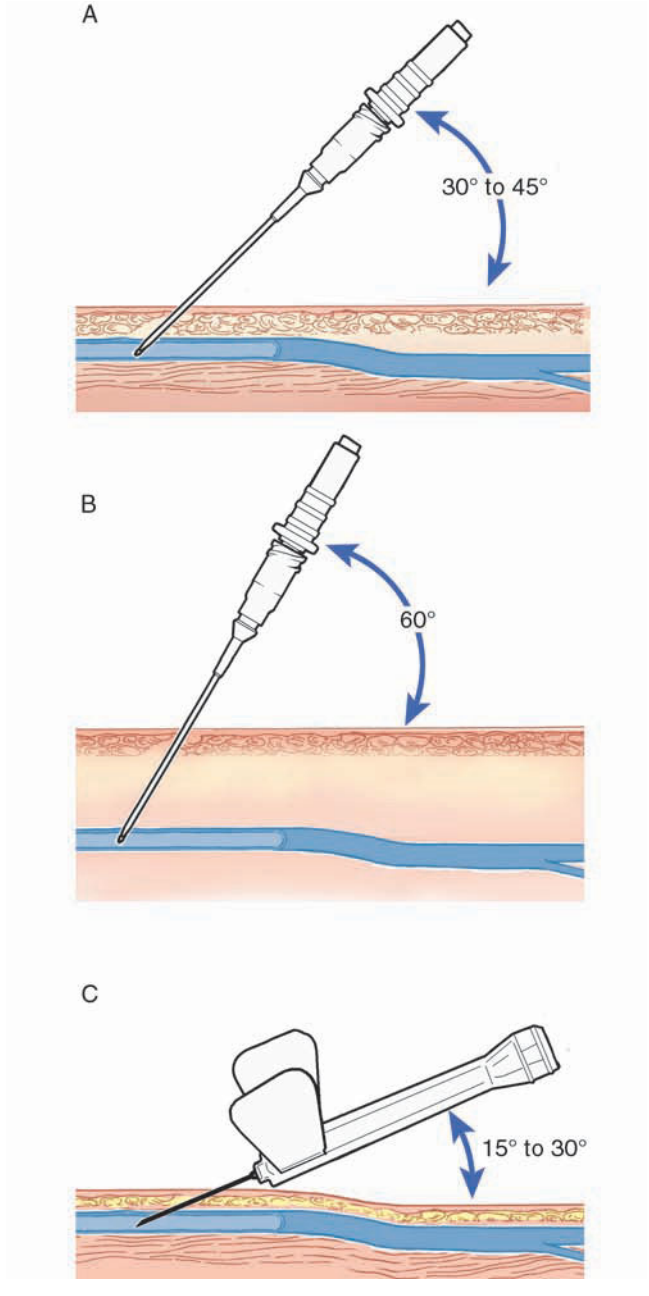

FIGURE 48-6. The angle between the needle and the skin must be varied based upon the depth and diameter of the target vein. **A.** A shallow angle must be used for small and superficial veins. **B.** A steeper angle must be used for deeper veins. **C.** A butterfly-type needle permits the shallowest angle of entry for very small and superficial veins.

CONTRAINDICATIONS

Sclerosing solutions, vasopressors, concentrated solutions of electrolytes or glucose, and chemotherapeutic agents are more safely infused into a central vein. Peripheral venous access in an injured extremity should be avoided, if possible, so as not to interfere with care of the injury and venous drainage of the limb. Avoid using the veins of an upper extremity for peripheral venous access if they may be used for the construction of an arteriovenous fistula for future dialysis. If possible, venipuncture should not be performed through infected or burned skin.

EQUIPMENT

- Alcohol swabs
- Povidone iodine or chlorhexidine solution
- Local anesthetic solution
- 25 gauge needle
- 1 mL syringe
- Gloves
- Immobilization supplies if necessary
- 1 in. tape, waterproof or plastic
- Transparent dressing
- Gauze 4 × 4 squares
- Tourniquet
- Desired venous access device
- Heparin/saline lock or infusion set
- Intravenous fluids
- Vacuum blood collection tubes
- Heparin
- Medicine cup
- Scissors
- Gauze roll or stockinette

PATIENT PREPARATION

Explain the procedure to the patient and/or their representative. Obtain verbal consent for the venipuncture unless it is an emergency. Select a site for the venipuncture. A site in the upper extremity is preferred. While a satisfactory vein is usually evident upon inspection, the placement of a venous tourniquet will aid the process greatly. It is easiest to place the tourniquet a few inches proximal to the elbow when first trying to locate a vein in the upper extremity. This restricts venous return from the entire extremity distal to the tourniquet and allows rapid inspection of the entire limb. Release the tourniquet once the site is chosen.

If difficulty is encountered in finding a vein, the use of dependent positioning, "pumping" via muscle contraction, and the local application of heat or nitroglycerin ointment will all contribute to venous engorgement.[2] These maneuvers can be used to aid in the performance of a venipuncture or peripheral venous access. A device specifically designed to identify veins may also be used. Refer to Chapter 47 for a more complete discussion regarding how to locate a vein.

Clean the puncture site of any dirt and debris. Apply an alcohol swab, povidone iodine solution, or chlorhexidine solution to the area above the identified vein and allow it to dry.[8] If using povidone iodine, wipe it off with an alcohol swab after it dries to lessen the chance of a local skin reaction. Infiltrate a small amount of local anesthetic solution subcutaneously, with a 25 gauge needle, over the puncture site. Take care not to puncture the target vein accidentally. Other methods of anesthesia are reviewed in Chapter 47. Reapply the tourniquet.

TECHNIQUES

PERIPHERAL VENIPUNCTURE

Stabilize the vein with the nondominant hand (**Figure 48-9**). Insert the needle attached to a syringe or vacuum tube adapter, with the bevel upward, into the vein at a 30° to 45° angle (**Figure 48-6A**). Lower angles, at times nearly parallel to the skin, may be needed

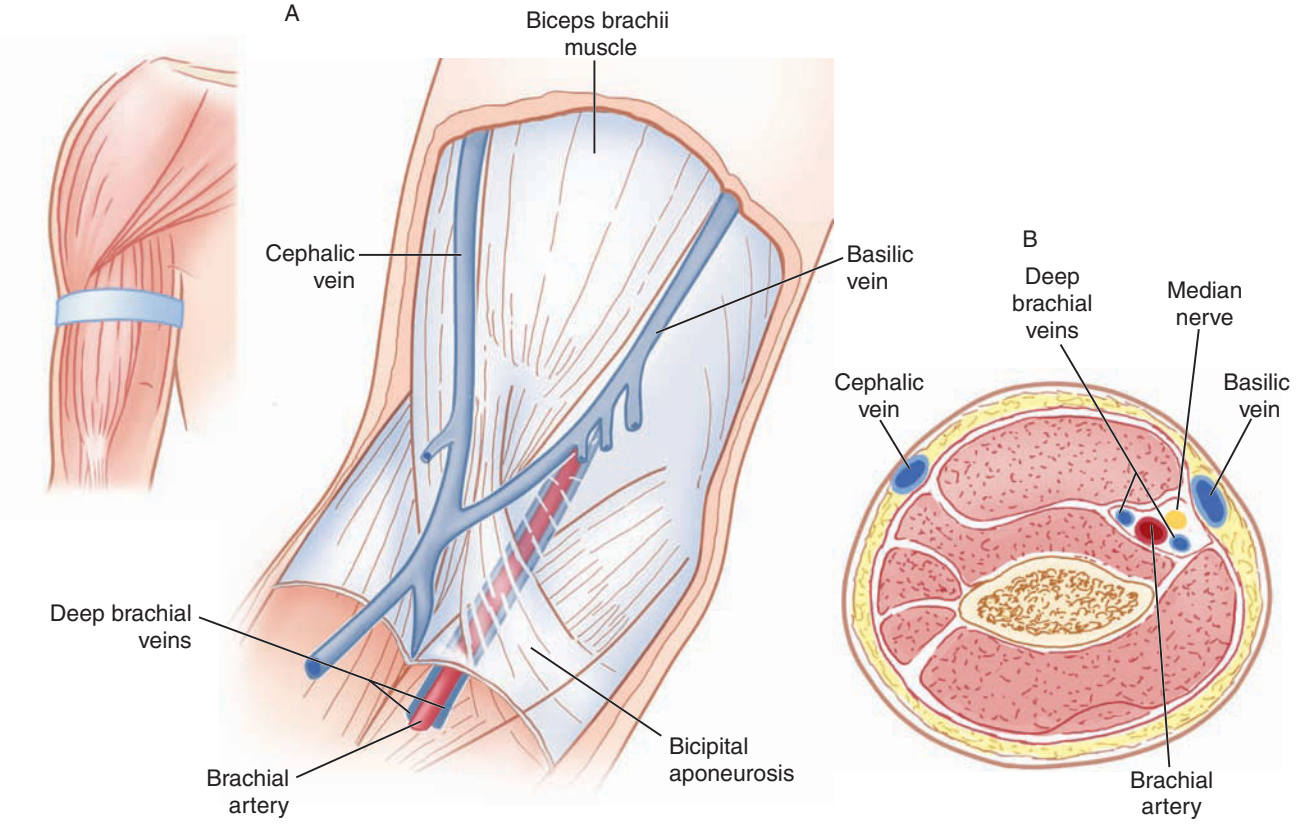

FIGURE 48-7. The deep brachial veins. **A.** The deep brachial veins are located deep to biceps tendon and muscle and adjacent to the brachial artery. **B.** Cross section of the arm 2 cm above the elbow. Note the two deep brachial veins, one on each side of the brachial artery.

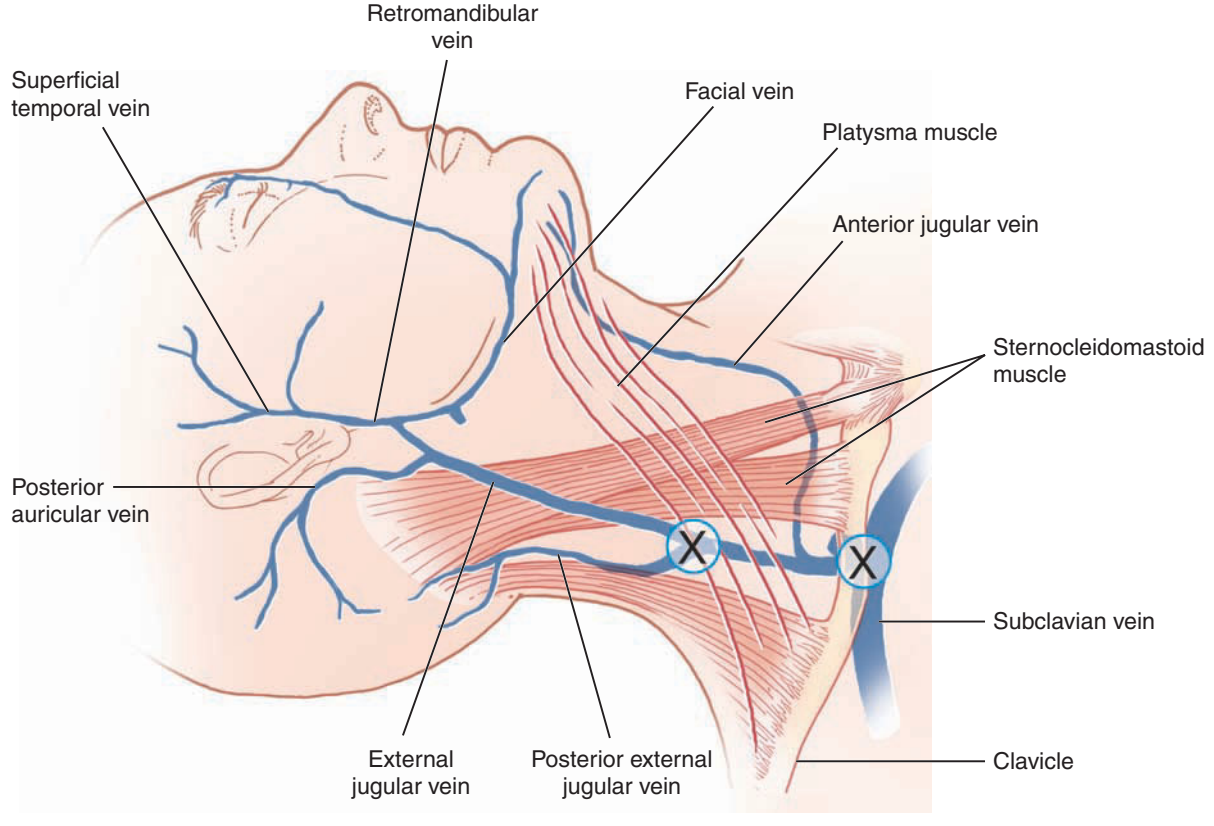

FIGURE 48-8. The external jugular veins. The anterior external jugular vein is usually larger than the posterior and runs deep to the platysma muscle. Note its relationship to the internal jugular vein. Valves (noted by the ⊗) are normally present in the external jugular vein where it enters the subclavian vein and approximately 4 cm superior to the clavicle.

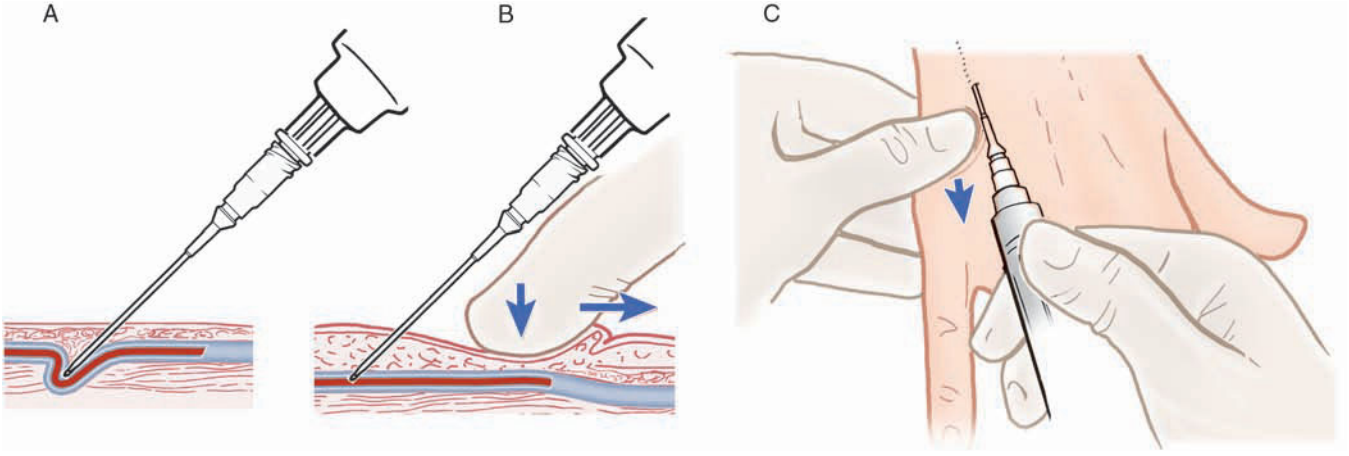

FIGURE 48-9. Stabilization of the vein during venipuncture. **A.** Without stabilization, the vein may kink or roll away from the tip of the hypodermic needle. **B.** Gentle stabilizing pressure with the operator's fingertip allows entry into the vein, as shown in (**C**).

to enter very narrow or superficial veins. This is easiest to achieve with a butterfly-type needle (**Figure 48-6C**). Apply negative pressure to the syringe. A flashback of blood in the hub of the needle indicates that the tip of the needle is within the vein. Pulsatile blood that pushes back the syringe plunger indicates an arterial puncture. Unless venous blood is specifically needed for a test, collect the necessary samples before removing the needle. No additional harm will be done by withdrawing a blood sample from an artery that has already been punctured.

If no blood is obtained, slowly advance the needle until it is deeper than the judged depth of the vein. Apply negative pressure to the syringe and slowly withdraw the needle. Occasionally, the advancing needle can collapse a vein (**Figure 48-10A**). The vein will often have been punctured through-and-through (**Figure 48-10B**), and the specimen will be obtained as the needle is withdrawn (**Figure 48-10C**). If no blood is obtained by the time the needle is withdrawn to just beneath the skin, redirect the needle and make another attempt at puncturing the vein. Before redirecting the needle, it must be withdrawn to just beneath the skin. **Never sweep the point of the needle around without withdrawing it, as the sharp bevel of the needle can lacerate nearby structures.** If swelling develops, indicating a hematoma formation, remove the tourniquet and apply direct pressure for several minutes. Search for another venous access site. Accidental peripheral arterial punctures should have direct pressure applied for at least 5 minutes.

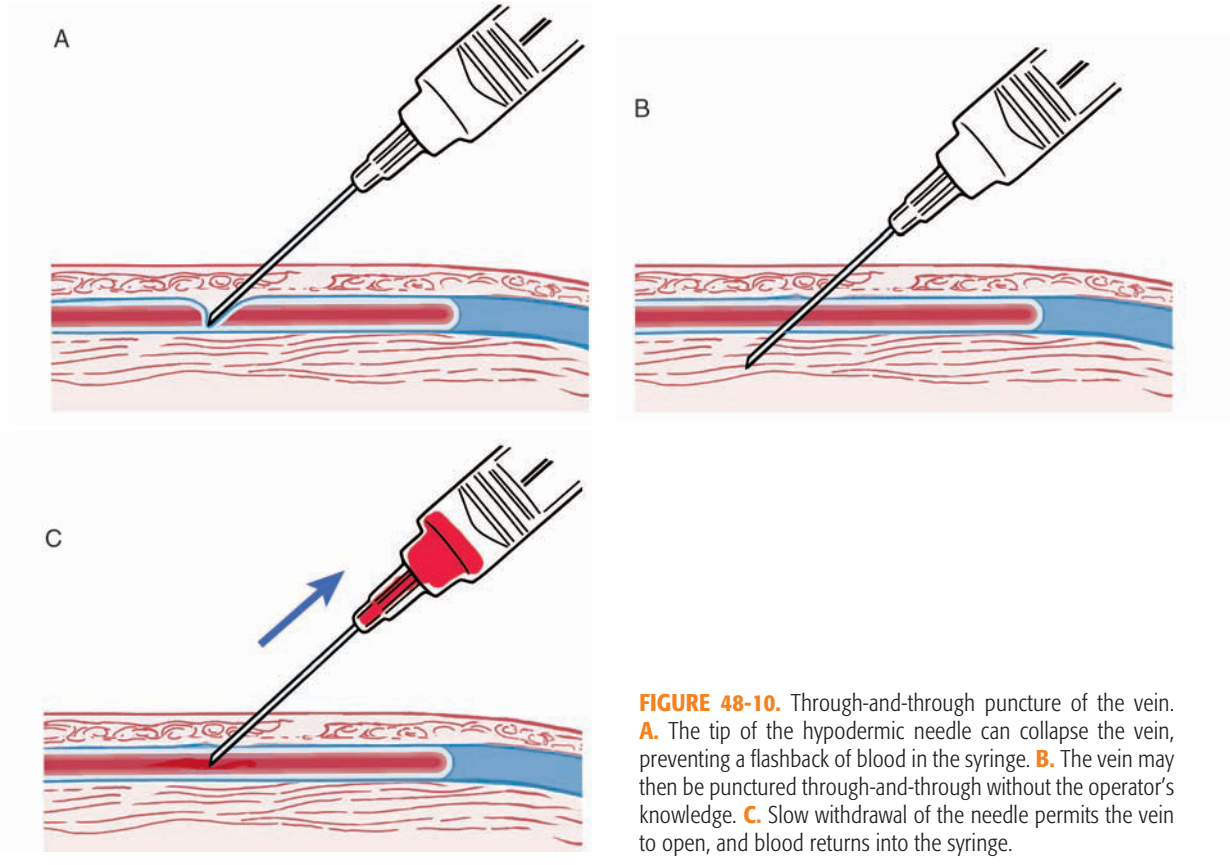

FIGURE 48-10. Through-and-through puncture of the vein. **A.** The tip of the hypodermic needle can collapse the vein, preventing a flashback of blood in the syringe. **B.** The vein may then be punctured through-and-through without the operator's knowledge. **C.** Slow withdrawal of the needle permits the vein to open, and blood returns into the syringe.

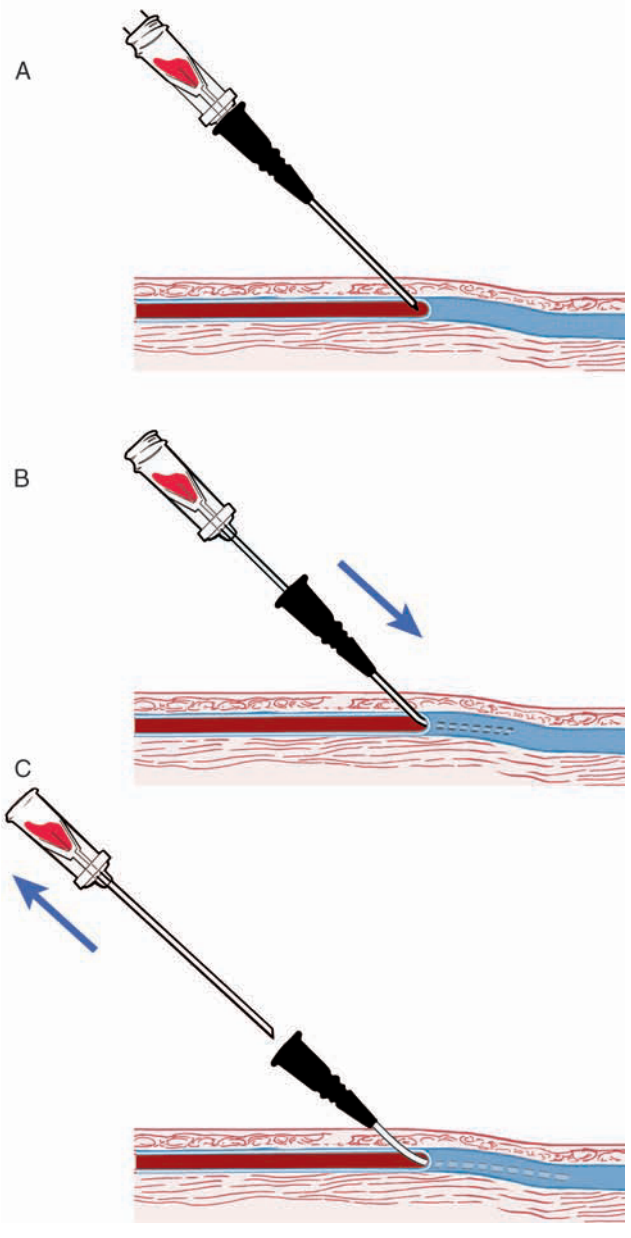

FIGURE 48-11. The catheter-over-the-needle technique. **A.** The vein is punctured and blood returns in the needle hub. **B.** The catheter is advanced over the needle and into the vein. **C.** The needle is removed.

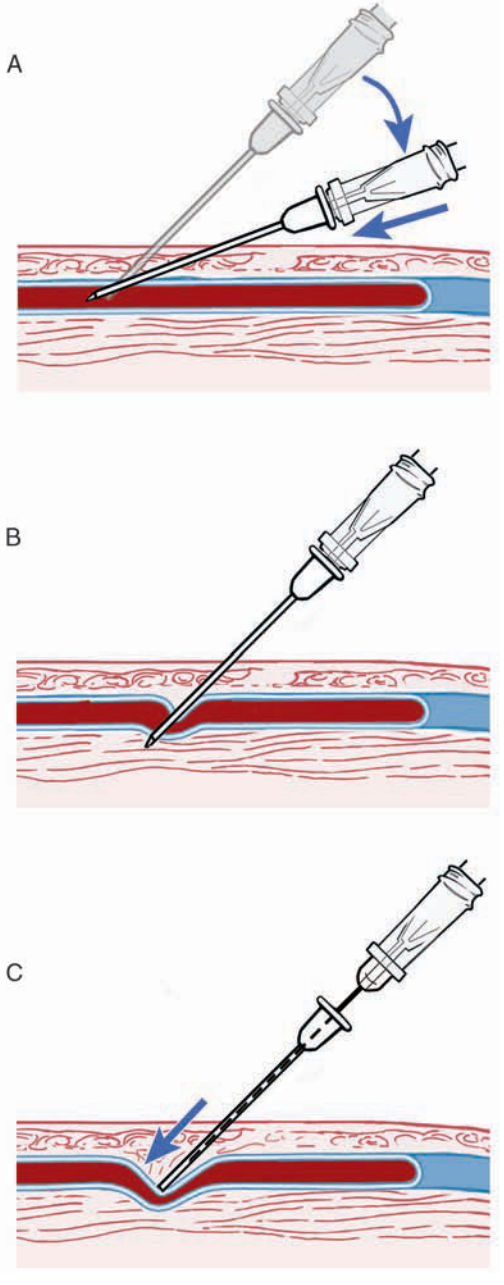

FIGURE 48-12. Advancing the catheter-over-the-needle. **A.** Drop the catheter hub toward the skin, then advance the catheter-over-the-needle 2 to 3 mm into the vein. **B.** If it is advanced at the original angle to the skin, the far wall of the vein may be punctured. **C.** If the catheter is advanced over the needle as soon as the vein is entered, the catheter may push the vein off the end of the needle, resulting in unsuccessful venous cannulation.

PERIPHERAL INTRAVENOUS CANNULATION

Cannulation of a vein begins with a successful venipuncture with the desired device, as described above. This section focuses on the use of the catheter-over-the-needle technique of peripheral venous access, as it is the most commonly used method.

Insert the catheter-over-the-needle through the skin and into the vein (**Figure 48-11A**). A flash of blood in the hub of the needle confirms that the tip of the needle is within the vein. Advance the catheter-over-the-needle an additional 2 to 3 mm to ensure that the catheter is within the vein. An alternative is to drop the hub of the needle nearly parallel to the skin before advancing the catheter-over-the-needle (**Figure 48-12A**). This will prevent the needle from puncturing the far wall of the vein (**Figure 48-12B**) and the catheter from pushing the vein away from the needle (**Figure 48-12C**). Hold the hub of the needle securely. Advance the catheter over the needle until its hub is against the skin (**Figure 48-11B**). Securely hold the hub of the catheter against the skin. Withdraw the needle (**Figure 48-11C**). Apply pressure, with the nondominant index finger, over the skin above the catheter to prevent blood from exiting the catheter (**Figure 48-13A**).

While applying digital pressure over the catheter, apply a device or intravenous tubing to the hub of the catheter. A syringe or vacuum device may be attached to the catheter to draw blood samples (**Figure 48-13B**). Intravenous tubing can be attached to the catheter to begin a fluid infusion (**Figure 48-13C**). A saline or heparin lock may be attached to the catheter to be used later for intravenous access (**Figure 48-13D**).

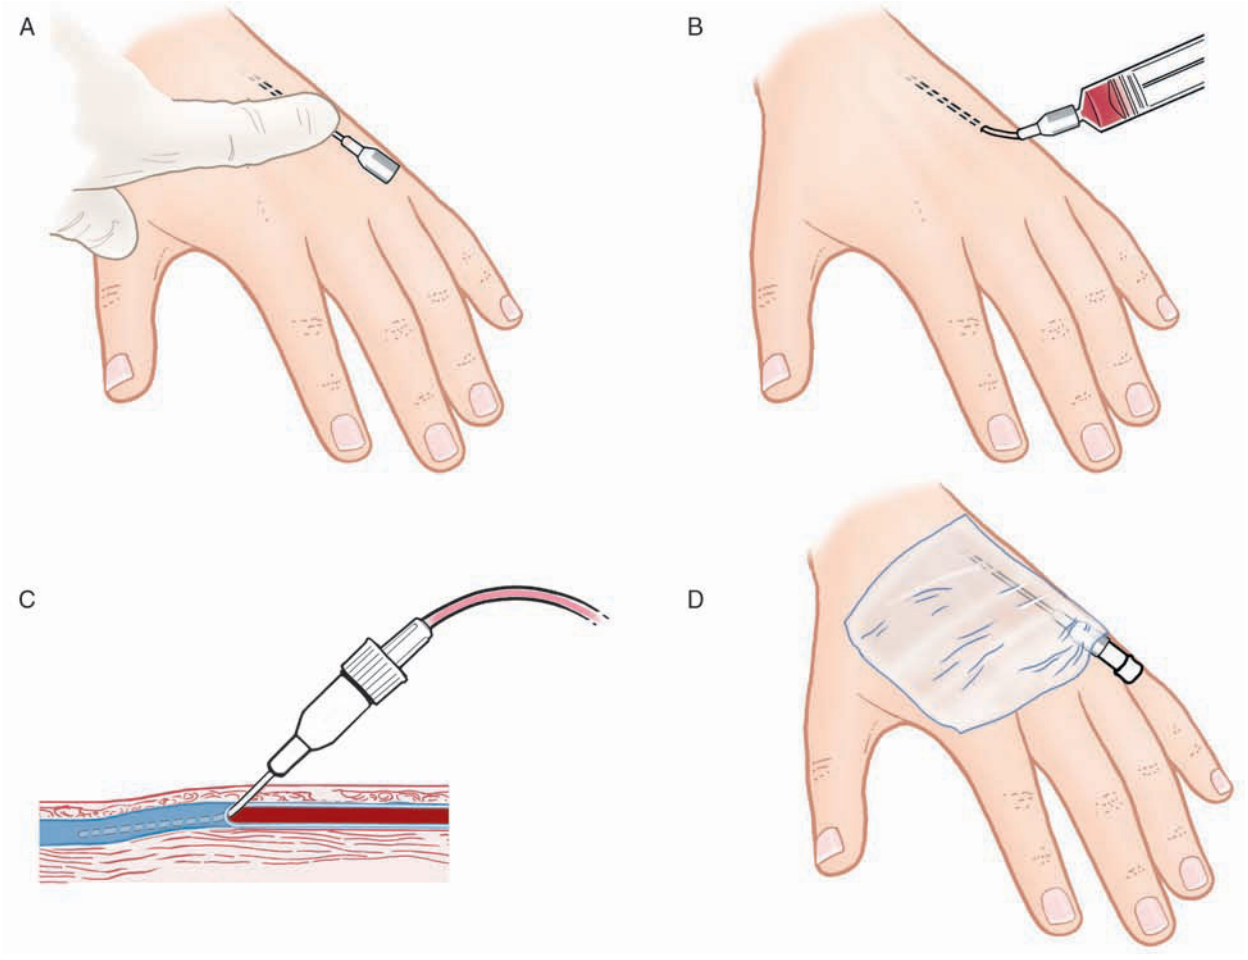

FIGURE 48-13. Peripheral intravenous cannulation. **A.** Apply gentle pressure over the catheter with a gloved finger to prevent hemorrhage from the catheter hub. **B.** Blood samples may be withdrawn from the cannula via a syringe or vacuum tubes. **C.** Intravenous infusion tubing is attached to the catheter. **D.** A saline (heparin) lock is attached to the catheter.

Secure the intravenous catheter to the skin (**Figure 48-14**). There are numerous methods to tape the catheter to the skin; only a few are described here. Place a 2 in. piece of adhesive tape sticky side up under the catheter hub (**Figure 48-14A**). Fold the ends of the adhesive tape over the catheter and onto the skin to form a "chevron" (**Figure 48-14B**). Alternatively, fold the adhesive tape to form a "U" (**Figure 48-14C**). Apply a 2 in. piece of adhesive tape over the catheter hub (**Figure 48-14D**). Place a transparent dressing over the catheter hub and distal intravenous tubing (**Figure 48-14E**). Some prefer to use the transparent dressing without the adhesive tape. The catheter may be sutured to the skin when vascular access is essential and when the catheter may be pulled out by a young child or combative patient. It is very rare that a peripheral intravenous catheter must be sewn into place.

ALTERNATIVE TECHNIQUES

ARTERIAL LINE KIT

The modified Seldinger technique, used with a QuickFlash radial artery catheterization set (Arrow International, Bloomington, IN), is very useful for the catheterization of deep brachial and external jugular veins. The unit is commonly available in Emergency Departments and Intensive Care Units. It consists of a one-piece unit that incorporates a catheter-over-the-needle, a guide-wire in a feed tube, and a lever to advance the guidewire (**Figure 48-15**). The black mark on the feed tube is a reference mark. The tip of the guidewire is positioned at the tip of the needle when the advancement lever is at the reference mark. The unit is also available without the catheter-over-the-needle as the Positive placement Spring-Wire Guide (Arrow International, Bloomington, IN). It can be attached to a standard stock catheter-over-the-needle. A similar device is The WAND (Access Scientific, San Diego, CA).

The integral guidewire and soft, 2 in. long, 20 gauge catheter found in the QuickFlash set can ease the process of catheterization considerably. The depth of the deep brachial vein combined with the overlying skin (which is often scarred from previous venipunctures) makes catheterization with the usual 1¼ in catheter difficult. The external jugular vein is quite mobile, and the overlying tissues are fairly tough. This can make it quite difficult to thread an over-the-needle catheter into the vein without pushing the vein off the end of the needle.

Select a vein to cannulate. Clean and prep the skin overlying the puncture site. Place a tourniquet on the extremity. Open the package and remove the unit. Advance the guidewire through the needle and then retract it. Do not use the catheterization unit if the guidewire does not advance and retract smoothly. Ensure that the guidewire advancement lever is retracted as far as possible so that the guidewire is not within the needle. **The flashback of blood will not be seen if the guidewire is not fully retracted and out of the needle.**

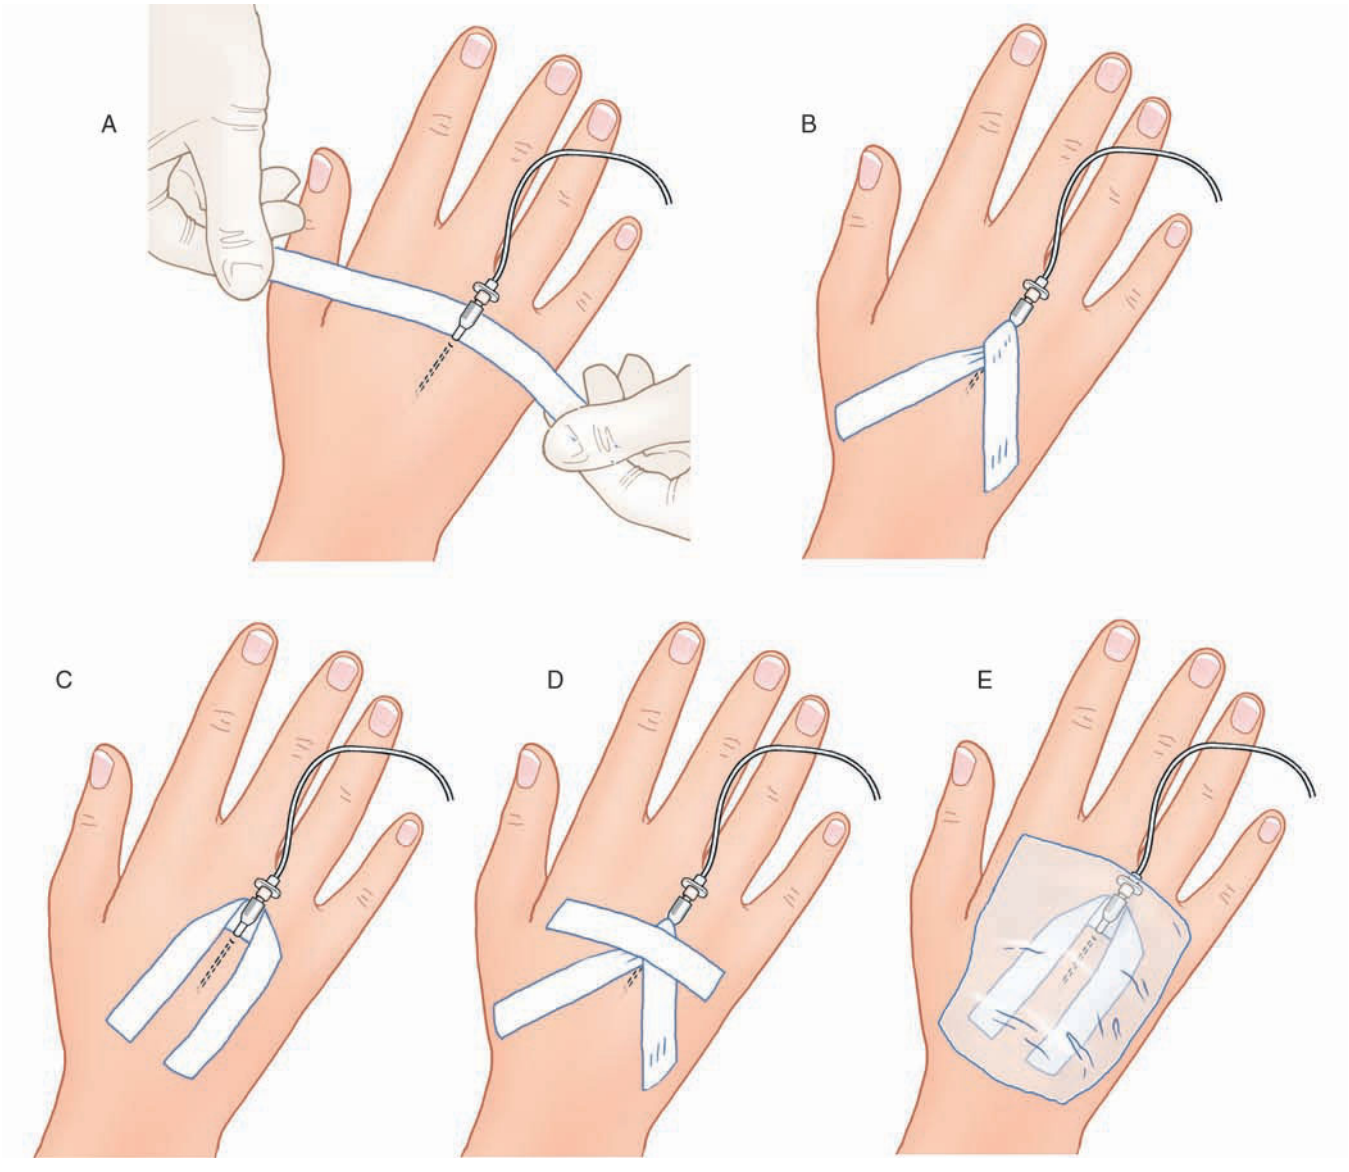

FIGURE 48-14. Securing the intravenous catheter. **A.** Place a narrow strip of adhesive tape sticky side up under the catheter hub. **B.** Fold the tape over the catheter to form a "chevron." **C.** Alternatively, the tape with the sticky side up can be folded to form a "U." **D.** A second piece of tape is applied to better secure the catheter to the skin. **E.** A transparent dressing is applied over the catheter.

Stabilize the vein with the nondominant hand. Insert the catheter-over-the-needle through the skin and into the vein (**Figure 48-16A**). A flash of blood in the hub of the needle indicates that the tip of the needle is within the vein. Hold the needle hub securely. Advance the guidewire, using the advancement lever, into the vein (**Figure 48-16B**). Continue to advance the guidewire as far as possible into the vein. The advancement lever must be distal to the reference mark to ensure that the guidewire is past the tip of the needle. **Stop advancing the guidewire if resistance is encountered. Do not force the guidewire against resistance. Do not retract the guidewire if resistance to advancement is encountered. Doing so may damage the vein or shear off a piece of the guidewire. Withdraw the entire unit and repeat the procedure with a new unit.**

FIGURE 48-15. The Arrow QuickFlash radial artery catheterization set. Note the different positions of the guidewire. The guidewire is within the feed tube (*top*). The tip of the guidewire is at the tip of the needle when the advancement lever is at the reference mark (*middle*). The guidewire is advanced through the catheter-over-the-needle (*bottom*).

Advance the guidewire as far as possible into the vein. Advance the catheter-over-the-needle an additional 1 to 2 mm into the vein. This will ensure that the tip of the catheter is within the vein. Hold the hub of the needle securely. Advance the catheter over the needle and guidewire until its hub is against the skin (**Figure 48-16C**). A twisting motion may help to advance the catheter against resistance. Release the tourniquet. Hold the catheter hub firmly against the skin. Remove the needle and guidewire, through the catheter, as a unit. Attach a syringe, vacuum blood collection system, intravenous line, or saline (heparin) lock onto the catheter hub. Secure the catheter with adhesive tape.

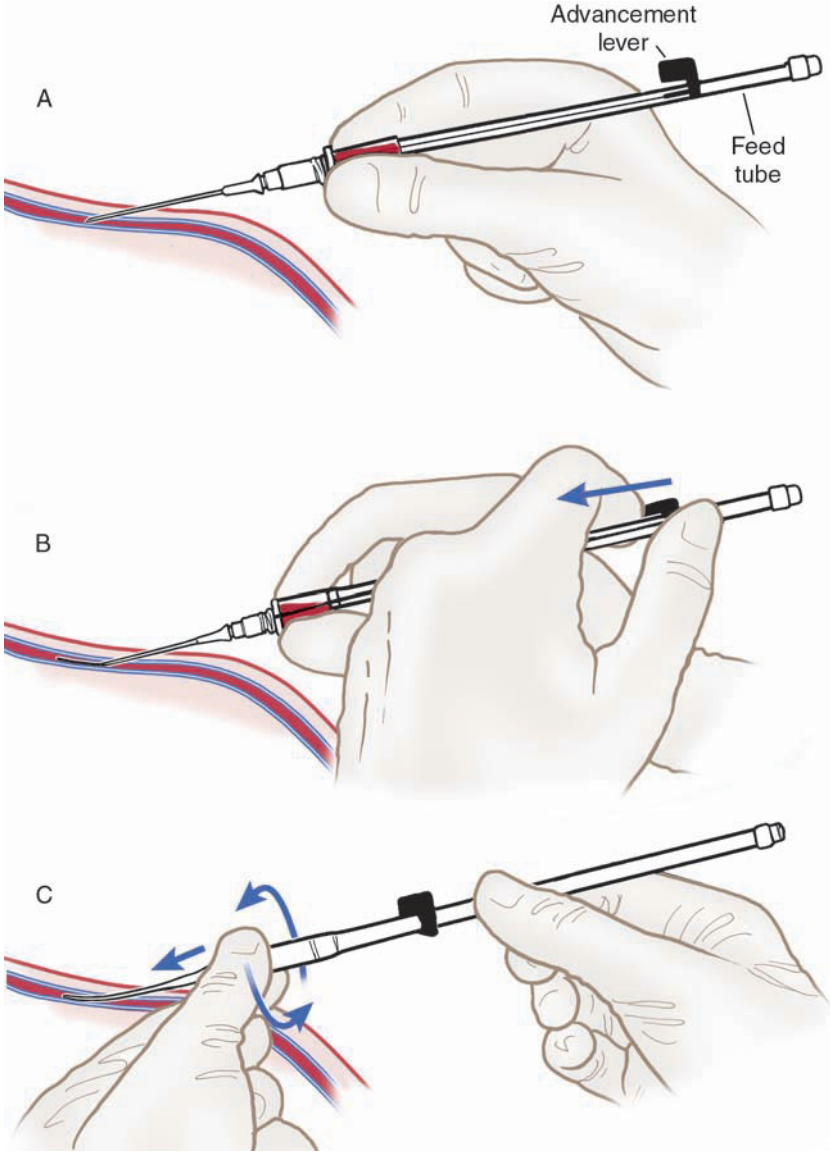

FIGURE 48-16. The Arrow QuickFlash radial artery catheterization set. **A.** The vein is punctured and blood returns into the hub of the needle. **B.** The guidewire is advanced into the vein. **C.** The catheter is advanced over the needle and guidewire with a back-and-forth rotating motion. The needle and guidewire are then removed as a unit.

EXTERNAL JUGULAR VEIN CANNULATION

Place the patient in the Trendelenburg position to distend the external jugular vein. Turn the patient's head to the opposite side. This will gently stretch the vein and prevent it from rolling. Clean and prep the skin of the neck. Place the nondominant thumb or index finger above the midportion of the clavicle to obstruct outflow and distend the external jugular vein. Align the catheter-over-the-needle parallel to the vein with the bevel of the needle upward and the tip of the needle pointing toward the clavicle. Enter the vein midway between the angle of the mandible and the midclavicle. Insert the catheter-over-the-needle during inspiration, when the valves of the external jugular vein are open. **Be sure to cover the open hub of the needle and/or catheter with a finger at all times to prevent an air embolism.** If the vein rolls, attempt to insert the catheter-over-the-needle obliquely into the vein. Another option is to cannulate the vein in the area where a tributary joins it. These areas are often anchored in the subcutaneous tissue. The remainder of the technique is similar to that described previously.

DEEP BRACHIAL VEIN CANNULATION

Extend the patient's arm. By palpation, identify the brachial artery pulse in the antecubital fossa. Clean and prep the skin of the antecubital fossa. Place a tourniquet on the upper arm. Reidentify the brachial artery pulse. Place a 2 to 3 in. long catheter-over-the-needle onto a 5 mL syringe and insert it just medial or lateral to the brachial artery pulse and at a 30° to 45° angle to the skin with the tip of the needle pointing cephalad. Advance the catheter-over-the-needle while applying negative pressure to the syringe. A flash of blood in the syringe indicates that the vein has been entered. If a flash is not seen, slowly withdraw the catheter-over-the-needle. It may have gone "through-and-through". A flash will be seen as the catheter-over-the-needle is withdrawn and the tip of the needle reenters the vein. The remainder of the technique is similar to that described previously. The use of ultrasonography can significantly improve the success rate of deep brachial vein cannulation. Complications include brachial artery puncture, hematoma formation, loss of vascular access, and transient paresthesias.[20,21]

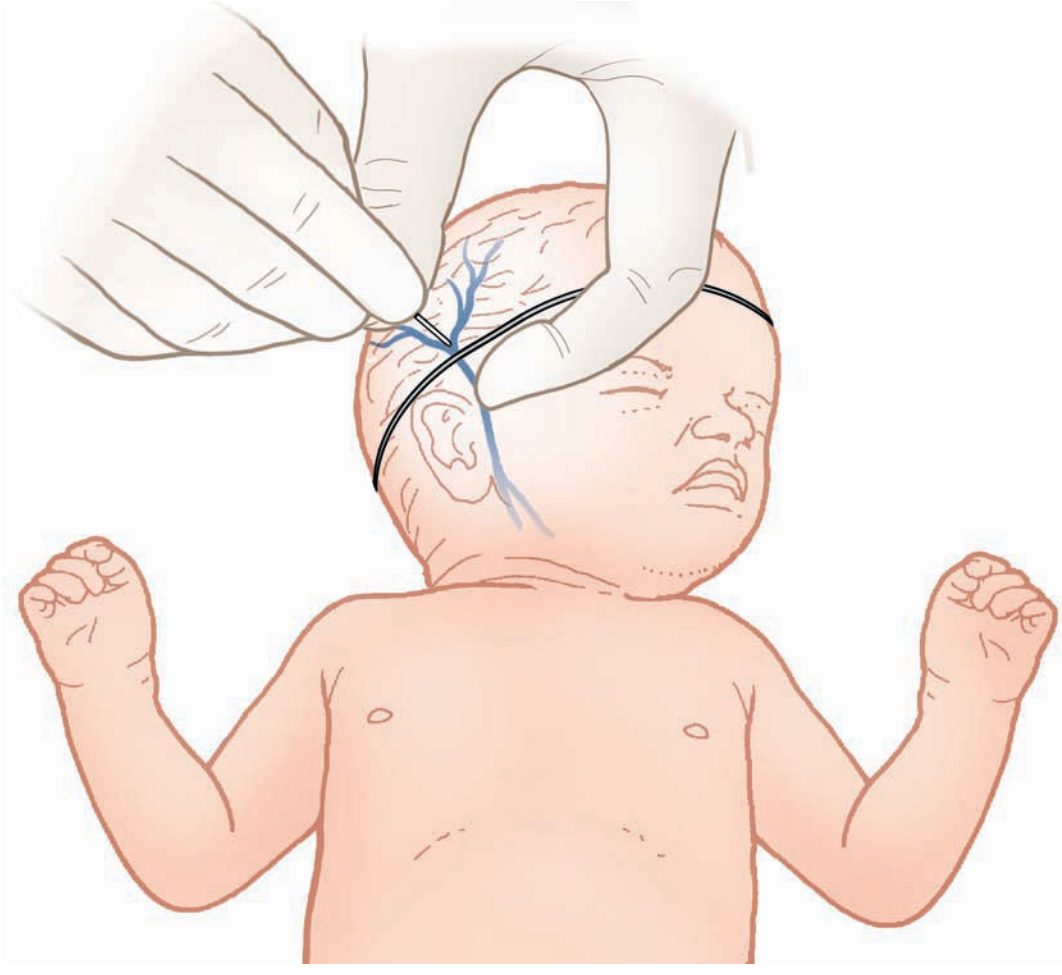

FIGURE 48-17. Scalp vein cannulation in the neonate. A rubber band makes a convenient tourniquet.

ULTRASOUND-GUIDED PERIPHERAL VEIN CANNULATION

A deep peripheral vein, often the brachial or basilic vein, may be cannulated under direct visualization using ultrasonography.[9] Ultrasound may also be used to identify a superficial vein when one is not palpable or visible. Place a tourniquet on the upper arm. Identify the vein by placing the ultrasound probe perpendicular to the vein. Identify the vein as a thin-walled, nonpulsatile, vascular structure. Move the probe along the vein to identify its most superficial and easiest accessed point. A catheter-over-the-needle can then be inserted in the vein under direct visualization.[10,11]

The easiest way to determine the depth of the vein is to note its depth on the ultrasound screen. Move the ultrasound probe distally this same distance while still maintaining visualization of the vein. Insert the catheter-over-the-needle at a 45° angle and advance it until the tip of the needle is seen on the ultrasound screen. Puncture the vein wall using a quick and short jabbing motion. Take care to not puncture through the posterior wall of the vein. Once the tip of the needle is seen within the vein, advance the catheter over the needle and into the vein. Refer to Chapter 50 for the complete details of ultrasound-guided vascular access.

PEDIATRIC CONSIDERATIONS

Venipuncture and peripheral venous access can be quite a challenge in the infant, neonate, and small child. Proper restraint of the extremity with a board or an assistant will greatly aid the process. Aside from the techniques discussed above, there are a few techniques that can facilitate pediatric vascular access.[12,13] The scalp veins can be used for venous access in newborns, infants, and children up to 1 year of age. They are most easily cannulated with a small (i.e., 23 or 25 gauge) butterfly needle or catheter. A rubber band can be placed about the baby's head as a tourniquet (**Figure 48-17**). Other veins commonly used include those of the antecubital fossa, dorsal hand, dorsal foot, external jugular vein, and the saphenous vein at the knee or groin. For small and superficial veins, it can be helpful to place a small bend at the hub of the catheter-over-the-needle assembly (**Figure 48-18**). This allows for the use of a less acute angle and easier entry into the vein without puncturing the far wall.

The best guide to the gauge or diameter of catheter to use is to compare the catheter to the vein. The catheter should be at least slightly smaller than the vein. In practice, the smallest readily available catheters are 24 gauge. A 22 gauge catheter will allow a much higher flow rate if it can be inserted successfully.

Keeping a peripheral intravenous line from being pulled out by an active child is quite a challenge. Each institution has its own "recipe" for securing pediatric IVs. The catheter is taped to the skin in the usual manner. Several strips of tape can be placed to secure the tubing to the skin and act as "strain reliefs" to prevent traction applied to the tubing from being transmitted to the catheter. Half of a medicine cup can be used as a shield for the catheter itself (**Figure 48-19A**). Apply tape over the cut edges of the cup to prevent the sharp edges from cutting the child's

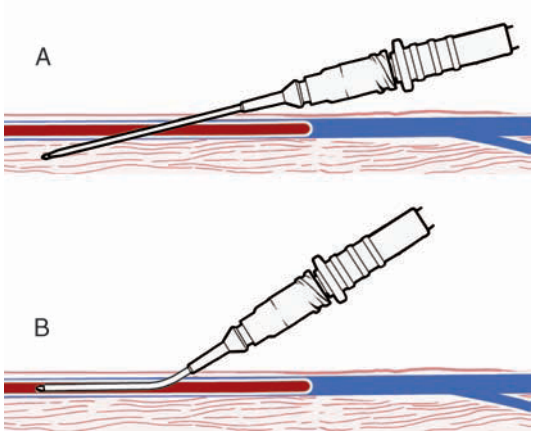

FIGURE 48-18. Cannulation of a small superficial vein with a catheter-over-the-needle. **A.** The "shoulder" of the catheter hub prevents the needle from being placed nearly parallel to the skin. **B.** A slight bend at the base of the needle permits the needle to run nearly parallel to the skin surface, enabling the subcutaneous vein to be cannulated. Always make sure that the catheter can be advanced over the needle before puncturing the patient's skin.

delicate skin. The clear medicine cup acts as a window, so that the catheterization site can easily be inspected without removing all the dressings. The whole assembly, or just the taped intravenous line, can then be covered with a gauze roll or stockinette (**Figure 48-19B**). A cup with one-quarter or one-third cut away may be used to protect a scalp vein access site (**Figure 48-19C**). A splint applied to the extremity will increase the duration of intravenous line patency.[14]

ASSESSMENT

Refer to **Table 47-2**, in the preceding chapter, for some general principles of intravenous line assessment. The line should flush easily. Any infusions should flow by gravity alone. Progressive swelling at the catheterization site indicates the formation of a hematoma or extravasation of infused fluids. Peripheral infusions of vasopressors and caustic solutions require the skin puncture site to be assessed frequently and carefully, since extravasation may lead to extensive local soft tissue necrosis. Pain at the intravenous access site must be taken seriously and should prompt a search for the cause. Pinched skin, extravasation, or thrombosis must be looked for and ruled out.

AFTERCARE

Most authorities recommend changing peripheral infusion sites at least every 3 days, although this is probably overly cautious.[15,16] It may be impractical if the patient has poor superficial veins. Any cannula with signs of venous thrombosis, skin erythema, or puncture site discharge must be removed at once. Heparin or saline locks that have not been accessed should be flushed regularly, usually every 8 hours. Saline works as well as heparin solutions for most applications.[17] Approximately 1 to 2 mL of sterile saline to flush is adequate for peripheral venous catheters. Heparin flushed cannulations have an increase in duration of patency.[12]

Dressings should be inspected and changed if they have become moist or contaminated. Routine dressing changes are probably unnecessary.[17] The transparent dressings are widely used despite some studies suggesting that transparent occlusive dressings are associated with higher rates of infection than plain gauze dressings.[18] Transparent dressings have the advantages of allowing easy inspection of the catheter site and holding the catheter securely in place. Individual institutions often have their own nursing guidelines and infection control statistics to support their choice of dressing.

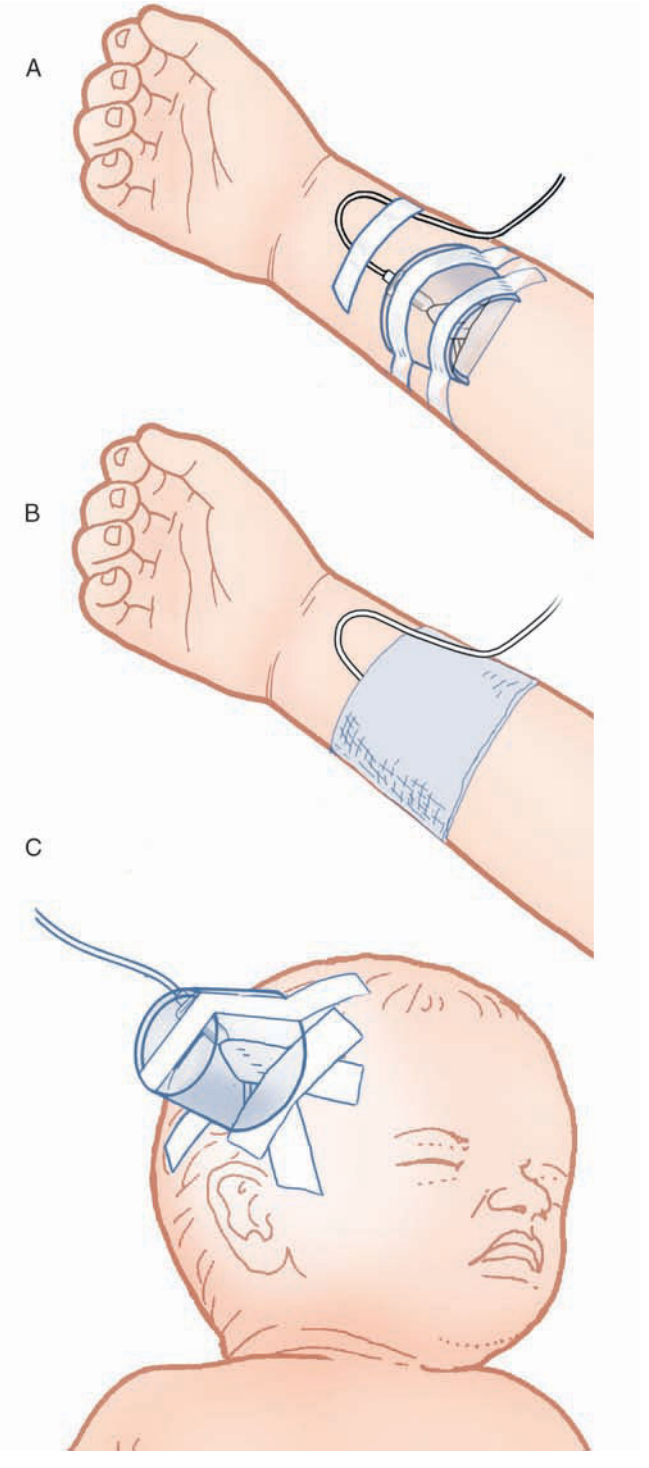

FIGURE 48-19. Securing pediatric intravenous lines. **A.** Use a clear plastic medicine cup, cut in half lengthwise, to protect the skin puncture site. **B.** A stockinette or gauze roll can be used to further protect the site from manipulation. **C.** Protecting a scalp vein cannula with tape and a clear plastic medicine cup.

REMOVAL OF INTRAVENOUS CATHETERS

Turn off any intravenous infusions and clamp the tubing. Place the infusion site in a dependent position below the right atrium to prevent a venous air embolism. Remove any tape and dressings from the infusion site. Apply direct pressure to the skin puncture site with a gauze pad. Briskly remove the catheter or needle. Hold firm direct pressure for several minutes. Apply a bandage. Instruct the patient to check for signs of thrombophlebitis, cellulitis, and an infection for the next several days.

COMPLICATIONS

PERIPHERAL VENIPUNCTURE

The main complications of venipuncture are pain and hematoma formation. Pain during venipuncture can be minimized by using small gauge needles, clearly identifying a vein before attempts at venipuncture, and minimizing the number of attempts at venipuncture. Hematomas and bleeding can be prevented by removing the tourniquet before removing the needle and applying direct pressure after the needle is removed. Hematomas are self-limited and easily treated with nonsteroidal anti-inflammatory drugs, cool compresses for analgesia, and warm compresses to hasten hematoma resorption. Other complications include nerve injury, usually reversible paresthesias. Arterial puncture is common with deep brachial lines and may rarely be catastrophic if it causes thrombosis of the brachial artery, the sole arterial supply of the forearm and hand.[18] Infection from simple venipuncture is uncommon.

PERIPHERAL INTRAVENOUS CANNULATION

In addition to the complications described for venipuncture, indwelling venous catheters pose additional risks. Some of these are summarized in **Table 47-2** of the preceding chapter. The steel needle cannula of the butterfly needle can move easily, causing lacerations of the vein and neighboring structures. The risk of infection is greater the longer a catheter is left in place. Intravenous catheters increase the risk of superficial venous thrombosis and thrombophlebitis. This may be prevented by limiting catheter manipulation during tubing changes and by using extension tubing at the catheter hub. Complications are more common when the intravenous catheter is placed in the hand or forearm when compared to other sites.[19] This may be the result of the higher frequency of catheters placed in these two sites in this small study. It is possible to injure a number of structures in the neck during external jugular vein cannulation. This includes the carotid artery, internal jugular vein, and trachea. It is also possible to cause a pneumothorax. None of these complications should occur as long as deep penetration with the needle is avoided.

Extravasation of vasopressors or caustic solutions can cause local skin necrosis. Extravasation of large volumes into a muscle compartment can lead to a compartment syndrome, although this is rare with superficial peripheral venous lines. Extravasation and tissue injury may be prevented by using a small gauge catheter in a large vein, diluting medications before administration, and observing intravenous access sites frequently.

Infections can often be prevented by using aseptic technique and sterile dressings, and changing peripheral catheters every 48 to 72 hours. The complications of peripheral nerve palsies, pressure necrosis, and compromised peripheral circulation are rare but do occasionally occur. They can be prevented with frequent neurovascular checks to any restrained extremity, by padding all pressure points, and by avoiding the placement of circumferential tape on an extremity.

SUMMARY

Venipuncture and peripheral venous access is an essential skill for nearly all medical practitioners, from paramedics to physicians. The only way to become proficient at these techniques is to master them during training and to practice them regularly. Equally important is the frequent reassessment of venous cannulas so that complications can be detected and treated early, before they become major problems for the patient and the Emergency Physician.

49 Central Venous Access

Arun Nagdev and Craig Sisson

INTRODUCTION

Percutaneous cannulation of the central veins is an essential technique for both long-term and emergent medical care. Access to the major veins of the torso allows rapid high-volume fluid resuscitation, administration of concentrated ionic and nutritional solutions, and hemodynamic measurements.

Obtaining venous access is an essential skill for the Emergency Physician. Indications for peripheral venous access are broad, ranging from simple fluid and medication administration to delivery of intravenous (IV) contrast for imaging studies. Central venous access is less often compulsory, but still remains an indispensable procedure in the practice of Emergency Medicine. Central venous access allows for multiple critical actions to be performed from the administration of blood products and vasoactive medications to transvenous cardiac pacing. Central venous access is often undertaken in cases where peripheral IV access cannot be obtained.

Even the most experienced provider can have difficulty securing rapid and functional access to the venous system in specific situations such as severe dehydration, cardiac arrest, large body habitus, and injection drug users with sclerosed veins. The classical "blind" technique, based on anatomical and vascular landmarks, has been the most commonly taught method. The growing integration of bedside ultrasound (US) into the practice of Emergency Medicine has slowly changed the way Emergency Physicians are choosing to perform central venous access. US visualization of the patients' vascular anatomy allows the specific advantage of determining the ideal location to access the central venous circulation. A thrombosed femoral vein can be identified, allowing the Emergency Physician to preemptively choose another site. The visualization of the overlap of the right internal jugular vein and the carotid artery may prevent inadvertent arterial puncture and the resultant sequelae in the anticoagulated patient. US guidance for central venous access has altered the clinical algorithm of obtaining vascular access, making the procedure easier for the Emergency Physician and safer for the patient.

Evidence supporting US guidance for central vascular access is fairly robust.[1–5] Convincing data from the Critical Care and Emergency Medicine literature indicate an increased success rate and a decrease in the complication rates. Recently, the Agency for Healthcare Research and National Institute for Clinical Excellence both recommended US guidance for central venous access. The availability of small, low cost, and portable US machines has made US guidance for central venous access a requisite skill for all Emergency Physicians. A brief description of US-guided central venous access is discussed in the following sections as appropriate. Refer to Chapter 50 for the complete details.

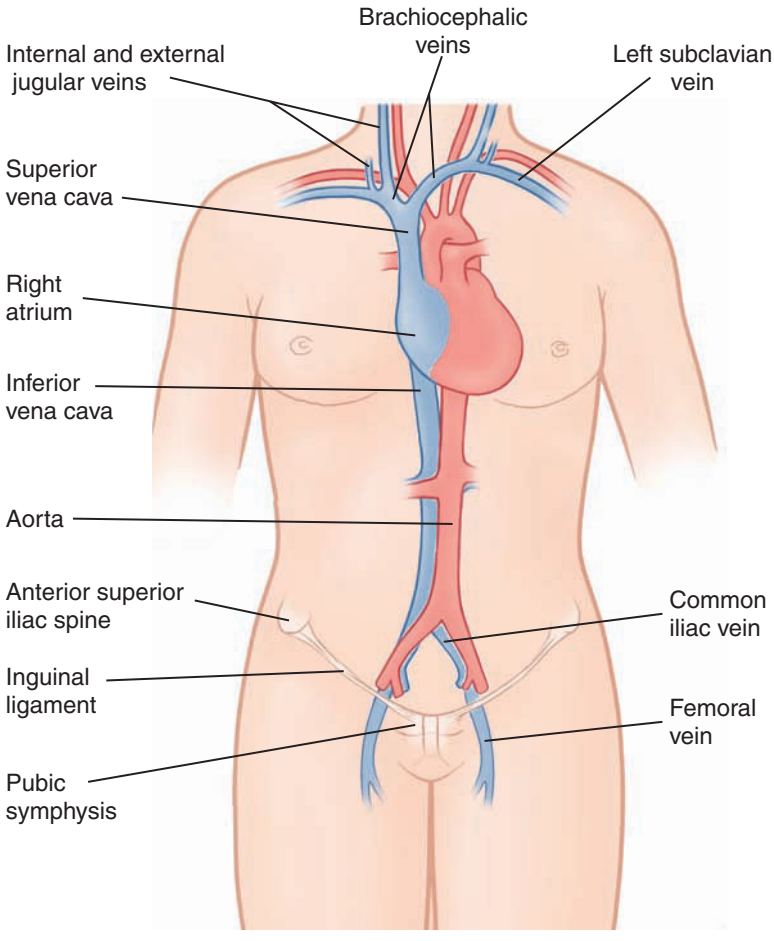

FIGURE 49-1. The anatomy of the central venous system.

ANATOMY AND PATHOPHYSIOLOGY

The tip of the central venous catheter must lie in the superior or inferior vena cava and never in the right atrium. The thin wall of the right atrium may easily be perforated by the catheter tip, resulting in hemorrhage and cardiac tamponade. The central venous anatomy is shown in **Figure 49-1**. The superior vena cava is accessed through the internal jugular veins, the subclavian veins, and less commonly via the external jugular veins. The inferior vena cava is accessed through the femoral veins. These access routes are discussed in greater detail in the corresponding sections below. The advantages and disadvantages of each route for central venous access are summarized in **Table 49-1**.

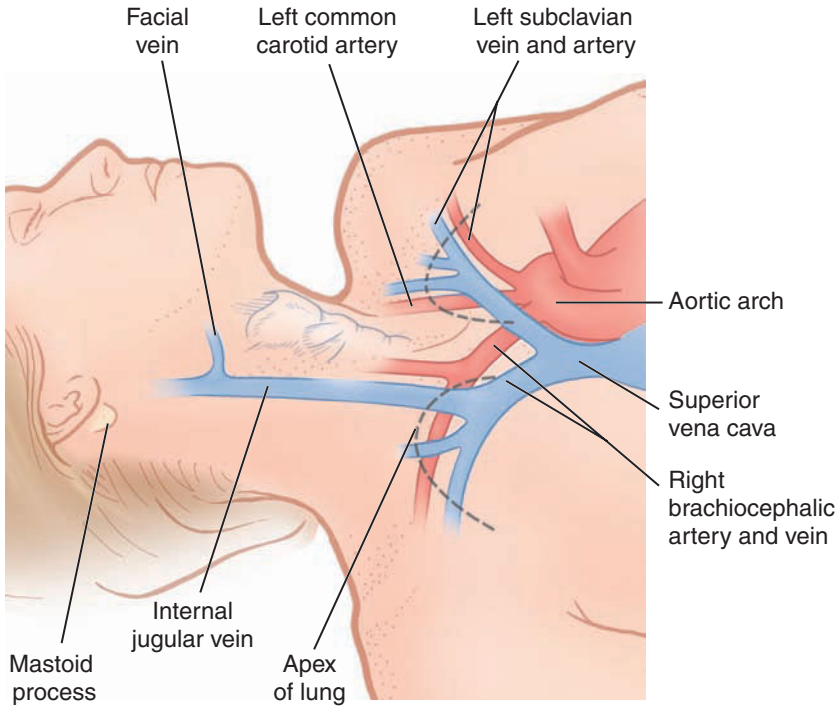
INTERNAL JUGULAR VEIN

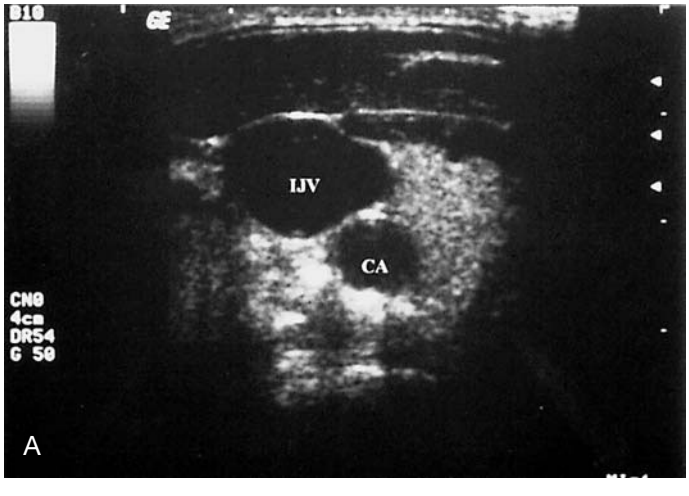
The internal jugular vein is not directly visible from the surface of the skin. A thorough knowledge of its anatomic relationships is essential for successful cannulation. The internal jugular vein is a direct continuation of the sigmoid sinus and exits the skull through the jugular foramen, just anteromedial to the mastoid process.[6] It joins the subclavian vein deep and just lateral to the head of the clavicle (**Figure 49-2**).[6] The internal jugular vein drains blood back to the heart from the brain, face, and neck. There is a proximal and distal dilatation of the vein known as the superior and inferior bulbs of the internal jugular vein. The inferior bulb contains a bicuspid valve to prevent retrograde flow. The surface projection of the internal jugular vein runs from the earlobe to the medial clavicle, between the sternal and clavicular heads of the sternocleidomastoid muscle. The internal jugular vein increases in diameter as it descends. It is joined by tributary veins in the upper neck, making it easier to cannulate below the level of the cricoid cartilage.

The internal jugular vein is collapsible (**Figure 49-3**). Its overall diameter is dependent on the patients' intravascular volume status as well as their position. It has a very small diameter in low-flow

TABLE 49-1 Characteristics of the Different Routes for Central Venous Cannulation

	Internal jugular vein	External jugular vein	Subclavian vein	Femoral vein
Risk of infection	Low	Low	Low	High
Patient mobility	Fair	Poor	Good	Bedridden
Trendelenburg required?	Yes	Yes	Yes	No, best for CHF or dyspnea
Need to stop CPR?	Probably	Probably	Yes	No, may continue CPR
Suitable for long-term use?	Yes, but not if ambulatory	No	Yes–best choice	No, remove within 2–3 days
Risk of venous thrombosis	Low	Low	Low	High





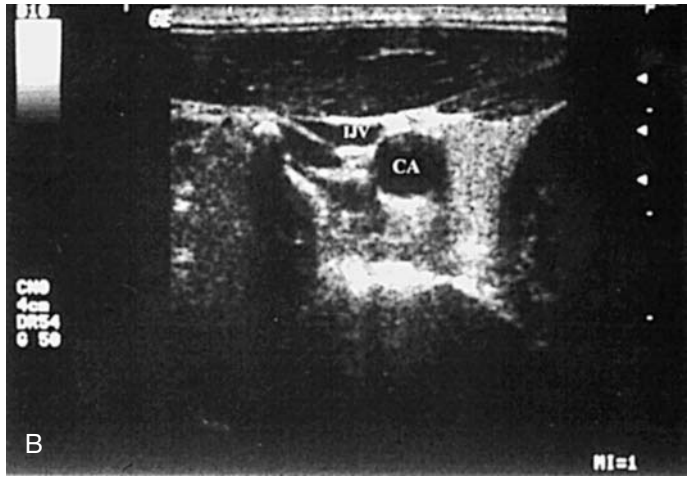


FIGURE 49-2. Anatomy and surface relationships of the internal jugular vein.

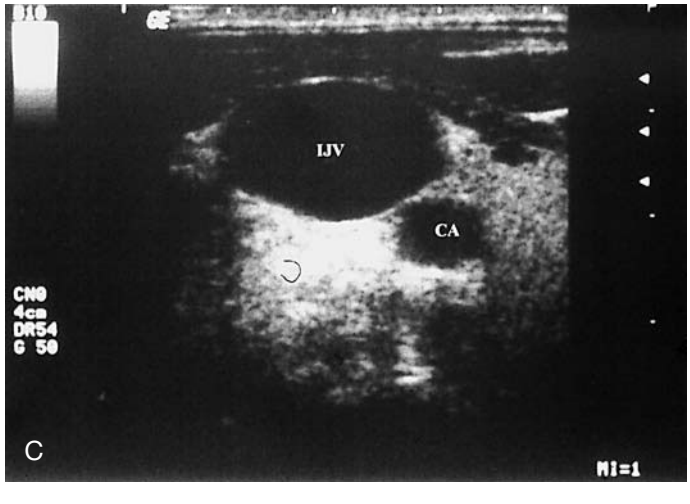

FIGURE 49-3. Transverse US images of the left internal jugular vein (IJV) and carotid artery (CA). **A.** The patient is supine. **B.** With gentle external pressure applied, the low-pressure internal jugular vein collapses easily while the carotid is still patent. **C.** The Valsalva maneuver or placement of the patient in the Trendelenburg position dilates the internal jugular vein.

states, as during cardiopulmonary resuscitation (CPR) and when the patient is upright. The vein is easily compressible and will collapse with gentle external pressure from a palpating finger or a large-diameter needle indenting the skin (**Figure 49-3B**). Local masses such as tumors, a goiter, and a hematoma can also easily collapse the internal jugular vein. Fortunately, the vein is also very distensible. Placing the patient in the Trendelenburg position or having the patient perform the Valsalva maneuver will distend the vein, making it easier to locate and cannulate (**Figure 49-3C**).

Along its course, the internal jugular vein lies in close proximity to the carotid artery, vagus nerve, phrenic nerve, brachial plexus, cervical sympathetic plexus, thyroid gland, and the pleural cupula of the lung. Inferiorly, the left internal jugular vein also lies in close proximity to the thoracic duct. The location of these structures places them at risk for injury during central venous cannulation of the internal jugular vein.

The position of the internal jugular vein in relation to the common carotid artery within the carotid sheath can vary considerably between individuals. The simple assumption that the internal jugular vein is always lateral to the carotid artery has not born out in ultrasonographic studies. Overlap with the carotid artery can vary from 0% to 100% depending on individual anatomic variation, patient positioning, and where along its course the internal jugular vein is imaged.[7–12] It can even lie medial to the carotid artery in some patients, making blind needle puncture nearly impossible and extremely dangerous.[7,8,12]

This variability in location is mirrored by the size variability of the internal jugular vein. Between individuals, the actual and apparent size of the internal jugular vein can vary widely for anatomic and physiologic reasons. Mey et al. showed that an internal jugular vein size of less than 0.7 cm may be an independent risk factor for unsuccessful venous cannulation.[13] The internal jugular vein can vary in size and location when comparing the right to the left and the proximal vein to the distal vein.[7,10] Each of these individual factors form a strong argument for ultrasonographic assistance during internal jugular vein central line placement.

The common carotid artery travels alongside the internal jugular vein and is an important anatomic landmark for locating the internal jugular vein. The carotid artery runs deep and slightly anterior to the internal jugular vein. The left internal jugular vein usually overlaps the carotid artery in the lower neck (**Figure 49-3A**). The right internal jugular vein and the right carotid artery are usually separated slightly.

The right internal jugular vein is generally preferred to the left internal jugular vein as the site of central venous cannulation. The right internal jugular vein provides a nearly direct route to the superior vena cava. The dome of the right lung is somewhat lower than that of the left lung and thus decreases the chance of an iatrogenic pneumothorax. The thoracic duct is relatively large and lies high in the left chest. These favor the right internal jugular approach to central venous cannulation to minimize complications.

There are three main "blind" or landmark approaches to the internal jugular vein as defined by their relationship to the sternocleidomastoid muscle. These are the anterior, central, and posterior approaches (**Figures 49-4** to **49-6**). The central approach is most commonly used. These three approaches are summarized in **Table 49-2** and described below.

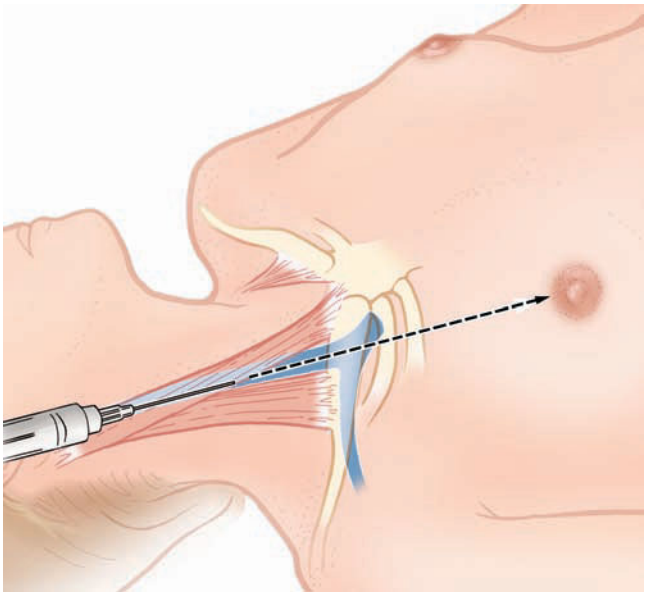

FIGURE 49-4. Central approach to the right internal jugular vein.

SUBCLAVIAN VEIN

The subclavian vein begins as the continuation of the axillary vein at the lateral edge of the first rib (**Figure 49-7**). The subclavian vein courses anterior to the anterior scalene muscle, which separates it from the subclavian artery. The subclavian vein descends to join the internal jugular vein and form the brachiocephalic trunk, which empties into the superior vena cava. Because the subclavian vein lies directly underneath the clavicle, US visualization of the vein is not usually possible.

The subclavian veins are 1 to 2 cm in diameter in an adult. Fibrous connective tissue joins the subclavian vein to the clavicle and first rib, preventing collapse of the vessel even in the event of a low-flow state. Anatomically associated structures include the thoracic duct, which joins the left subclavian vein at its junction with the left internal jugular vein. The right subclavian vein is preferred to the left for central venous access for this reason. The domes of the pleura lie posterior and inferior to the subclavian veins and medial to the

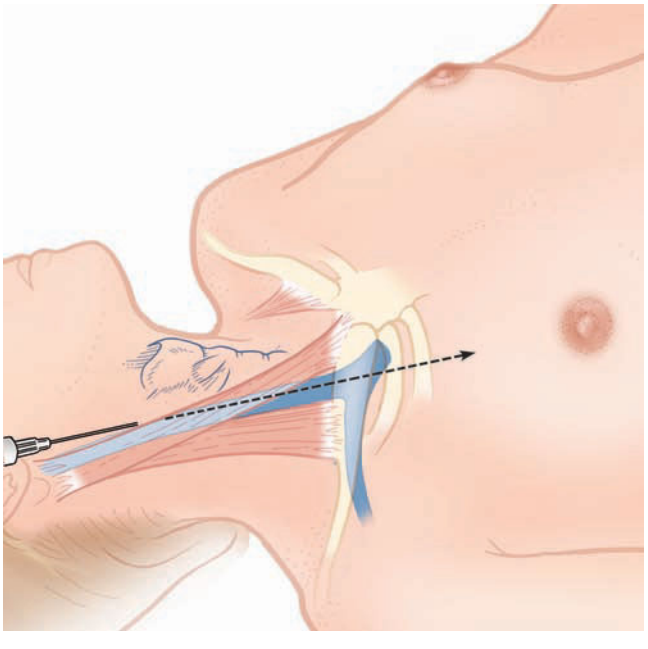

FIGURE 49-5. Anterior approach to the right internal jugular vein.

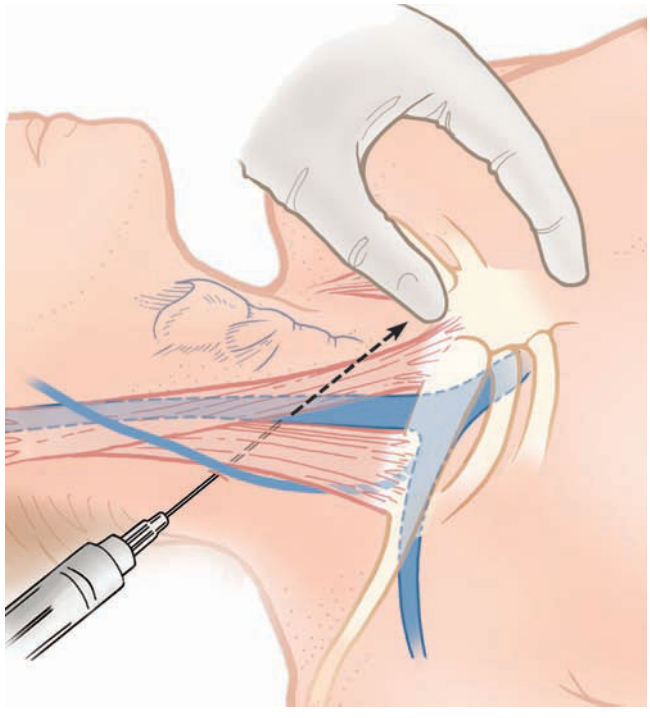

FIGURE 49-6. Posterior approach to the right internal jugular vein.

anterior scalene muscles. The subclavian arteries lie immediately posterior to the veins (**Figure 49-7**).

Subcutaneous fatty tissue, chest morphology, the close proximity of the pleura, and the close proximity of the subclavian artery make the subclavian vein the least favored site for central venous access in children. This is especially true in infants. An experienced Emergency Physician must perform the procedure if this route must be used in a neonate, an infant, or a small child.

AXILLARY VEIN

The axillary vein is defined as the continuation of the brachial vein from the medial border of the teres major to the lateral border of the first rib. The axillary vein continues under the clavicle as the subclavian vein, which then joins the internal jugular vein to form the brachiocephalic vein (**Figure 49-2**). Cadaver-based and radiologic studies have demonstrated a great variation in the anatomic relationship between the axillary vein and artery.[14,15] This makes the blind or landmark technique difficult for even the most experienced Emergency Physician.[14,15] An US study of the axillary vein in volunteers demonstrated a decreased overlap between the axillary vein and artery, and a farther distance from the pleura, as it was followed laterally.[16]

FEMORAL VEIN

Anatomically, the femoral vein is a continuation of the iliac vein after it crosses the inguinal ligament (**Figure 49-8**). The femoral vein lies within the femoral sheath and just medial to the femoral artery in the groin. This relationship can be remembered by the mnemonic "toward the NAVEL." This describes, from lateral to medial, the contents of the femoral sheath (femoral Nerve, femoral Artery, femoral Vein, Empty space, and Lymphatics). The femoral artery lies at the midpoint of the line connecting the symphysis pubis and the anterior superior iliac spine.[17,18] The femoral vein lies approximately 1 cm medial to the femoral artery pulse in an adult and approximately 0.5 cm medial in infants and young children.[19,20]

Recent anatomical US surveys on adult and pediatric populations have demonstrated variation in the classical anatomical teaching. Hughes et al. demonstrated an increased overlap between the femoral vein and artery as they moved distally to the inguinal ligament.[21] Warkentine et al. evaluated the amount of venous and arterial overlap in euvolemic children 1 cm distal to the inguinal ligament.[22] They noted that in 12% of cases, the femoral vein had either partial or complete overlap with the femoral artery. Both these studies noted the great variability of the vascular anatomy and recommended US visualization before femoral venous cannulation attempts.

Classically, the puncture site for femoral vein cannulation lies medial to the femoral artery and inferior to the inguinal ligament (**Figure 49-8**).[17,18,23] Femoral venous cannulation should be performed 1 to 2 cm inferior to the inguinal ligament (a commonly difficult landmark in the obese patient), in order to prevent inadvertent intraabdominal external iliac vein puncture. The femoral vein becomes the external iliac vein superior to the inguinal ligament (**Figure 49-8**). **Blood can flow freely into the retroperitoneal space, forming a potentially large and externally invisible hematoma if the posterior wall of the femoral vein is punctured by a through-and-through needle track above the inguinal ligament. It is imperative to puncture the femoral vein inferior to the inguinal ligament!**

Despite the believed higher rates of line infection and thrombosis associated with femoral venous cannulation, this access remains a popular route due to its relative ease of placement.[24] A recent large, randomized, multicenter study put into question the classically held notion that the femoral venous cannulations have higher rates of infection.[25] The study did not demonstrate a higher rate of infection between catheter tips (a well-accepted surrogate marker) removed from the femoral vein and the internal jugular vein. The rate of catheter-related bloodstream infection between femoral vein cannulation and internal jugular vein cannulation were similar (2.3% vs. 1.5%, respectively).

CENTRAL VENOUS ACCESS IN THE OBESE PATIENT

Central venous access is more complicated in the obese patient.[26] Surface landmarks may be obscured by adipose tissue and skin folds. The clavicle, carotid artery pulses, the thyroid cartilage, and

TABLE 49-2 Approaches to the Internal Jugular Vein

	Central	Anterior	Posterior
Insertion landmark	Superior apex of the triangle formed by the two heads of the sternocleidomastoid muscle and the clavicle	Medial edge of the sternocleidomastoid muscle at the level of thyroid cartilage	Lateral edge of sternocleidomastoid muscle, 1/3 of the way from the clavicle to the mastoid process
Angle with skin	30° (child), 45°–60° (adult)	30° (child), 45° (adult)	30°–45°, dive under the border of the sternocleidomastoid muscle
Aim toward	Ipsilateral nipple	Ipsilateral nipple	Sternal notch
Internal jugular vein depth in an adult	Within 3 cm	Within 3 cm	Within 5 cm

The anatomy of the subclavian vein. **A.** The right subclavian vein. **B.** Magnified view of the right subclavian vein demonstrating adjacent structures that may be injured during attempted cannulation. **C.** Sagittal section through the midclavicle. Note that the first rib protects the subclavian artery during an infraclavicular approach to the subclavian vein. **D.** Sagittal section through the medial third of the clavicle. Note the proximity of the subclavian artery and pleural dome to the subclavian vein.

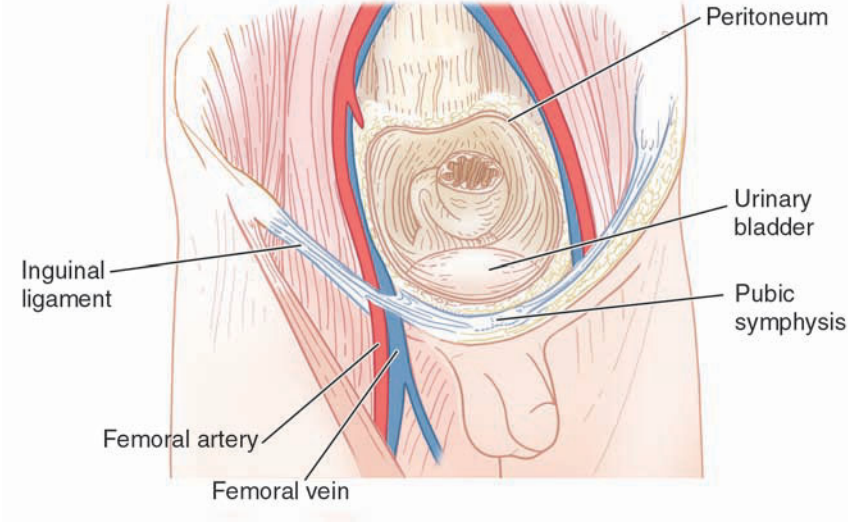

FIGURE 49-8. Anatomy of the femoral vein.

the trachea can be difficult to palpate. This makes internal jugular and subclavian venous access problematic. The anterior superior iliac spine, femoral artery pulse, and the pubic symphysis can be difficult to palpate. This makes femoral venous access problematic. Femoral venous access is often performed lower than normal due to an overhanging pannus. Placing the obese patient in the Trendelenburg position may not be possible. They may acutely decompensate in this position due to their poor pulmonary reserves, decreased lung and tidal volumes, increased intraabdominal pressure against the diaphragm, and difficult airway anatomy. All these factors may increase the rate of complications in the obese patient.

INDICATIONS

The internal jugular route is acceptable for central venous access in most cases. It allows ready access to the superior vena cava for long-term central venous access, caustic infusions, and monitoring of central venous pressure. Pulmonary artery catheters and transvenous pacing wires can be introduced through the right internal jugular vein. The internal jugular vein is accessible without terminating CPR efforts, although chest compressions and the lack of carotid pulsations make accessing it difficult. The risk of an iatrogenic pneumothorax is probably less with internal jugular vein cannulation as opposed to the subclavian vein, although patient mobility is less and discomfort is greater. In the coagulopathic patient, the internal jugular vein puncture site is compressible, but a hematoma formation may lead to airway compromise. Oguzkurt et al. showed that patients historically labeled as having "difficult access" had very low complication rates using US-guided central venous access of the internal jugular vein.[27] In this study, 27.7% (61/220) of the total procedures performed were on patients with disorders of hemostasis.

The subclavian vein is the preferred route for long-term central venous access. This site allows for ambulation (unlike a femoral line) and neck movement without discomfort (unlike an internal jugular line). The catheter is concealable under clothing, making outpatient use more acceptable.

The axillary vein is not a commonly used venous access site. It is more commonly used in children for long-term access. The use of US guidance has allowed the axillary vein to be used as an alternate access site. Due to the depth of the vessel and its close proximity to the brachial plexus, the axillary vein should only be cannulated in thin patients and as an alternative site when other sites are not available, have failed, or are contraindicated.

The femoral vein is often the preferred route for emergent central venous cannulation. The indications are the same as for any other site with a few exceptions. The femoral vein is not a suitable route for ambulatory patients beyond the initial resuscitation and stabilization period, as patients with femoral central venous lines must be confined to bed. Femoral venous access is easily obtained in patients with respiratory distress and pulmonary edema, since they do not need to be placed in the Trendelenburg position. Femoral venous access is relatively easy during CPR and does not require the cessation of chest compressions. The femoral vein is easily compressible. This makes it preferable to the subclavian vein in coagulopathic patients or those undergoing thrombolysis, although peripheral access would be preferred in these cases.[6] There is no risk of injury to the airway, pleura, or carotid arteries in very young or combative patients. Femoral central venous lines are generally preferred for initial central venous access in the very young or combative patient if deep sedation or neuromuscular paralysis is contraindicated or otherwise unnecessary.

CONTRAINDICATIONS

The usual contraindications to any invasive procedure apply to central venous access. Cellulitis or overlying infection at the puncture site is a contraindication to central venous access. A mass or hematoma causing external compression and/or obliteration of the vessel lumen, an intraluminal thrombosis, or a small size vein when visualized by US are also contraindications. An alternative should be sought if the patient is combative, agitated, or uncooperative. These patients require sedation and/or paralysis prior to insertion of the central venous line. Distorted anatomic landmarks due to fractures, deformities, obesity, previous catheterization at the site, surgery, or trauma are relative contraindications. There is a small but real risk of serious morbidity and even death due to the procedure. **Do not place a central venous line unless a peripheral IV line or an intraosseous line is inadequate or unobtainable and unless personnel capable of managing the procedural complications are immediately available.**

INTERNAL JUGULAR VEIN CANNULATION

Anatomic distortion of the neck, such as from subcutaneous emphysema or a hematoma, may make placement of an internal jugular line difficult and hazardous. Known severe carotid artery stenosis or atherosclerosis on the desired side of cannulation is a relative contraindication to internal jugular vein cannulation. Accidental carotid artery puncture during line placement may result in plaque rupture and a subsequent stroke. The vein may be collapsed and difficult to access in the hypovolemic patient. Other contraindications to cannulating the internal jugular vein include cervical spine fractures (actual or suspected) or penetrating neck injuries. Do not cannulate the ipsilateral internal jugular vein if the patient has an implanted pacemaker or a defibrillator. Central venous access can result in needle injury to the leads, lead displacement, and thromboembolism.

The subclavian or femoral route may be preferable in some circumstances. The subclavian route is probably a better choice for long-term lines in ambulatory patients, as for hemodialysis. The limited neck mobility due to an internal jugular line is very uncomfortable. Ongoing or impending thrombolytic administration is a relative contraindication to internal jugular puncture. A femoral central venous line is preferable in this case. Successful internal jugular cannulation requires the patient to be placed supine and preferably in 15° to 30° of Trendelenburg tilt. This may be impossible in a patient with severe pulmonary compromise. The femoral route is preferred in this case. Internal jugular vein cannulation is difficult in children under 1 year of age due to poor landmarks and a very short neck. Internal jugular cannulation is contraindicated in any child who cannot be adequately immobilized or paralyzed after insertion of the central venous line. Internal jugular cannulation will be more difficult if the patient's neck cannot be turned. However, the more rotation applied to the neck the greater the vascular overlap between the internal jugular vein and carotid artery. This will increase the risk of arterial puncture. Head rotation should be minimized if a blind technique is used. US guidance can minimize head rotation and free the Emergency Physician from the historical anatomic approaches. This allows for any needle approach to be used depending on the location of the internal jugular vein in relation to the carotid artery.

A left bundle branch block is a relative contraindication to central venous cannulation. The guidewire can induce complete heart block when it enters the right ventricle.[28] Extreme caution should be taken if an internal jugular or subclavian central

line is necessary. **Avoid inserting the guidewire into the heart.** Continuous cardiac monitoring should be used and transcutaneous and transvenous cardiac pacing equipment should be readily available.

SUBCLAVIAN VEIN CANNULATION

The subclavian vein is incompressible and should be accessed with care in any patient who is coagulopathic. Current or imminent systemic thrombolysis is an absolute contraindication to placing a subclavian vein catheter.[6] Subclavian vein cannulation should be performed on the contralateral side if the patient is relying on a single lung. Chest wall deformities, distorted anatomy, and suspected vascular injury to the chest or ipsilateral upper extremity are also contraindications. This route should also be avoided if the patient has had prior surgery or trauma to the clavicle, the first two ribs, or the subclavian vessels. Do not cannulate the ipsilateral subclavian vein if the patient has an implanted pacemaker or defibrillator. Central venous access can result in needle injury to the leads, lead displacement, and thromboembolism.

AXILLARY VEIN CANNULATION

US-guided axillary vein cannulation can be difficult for the Emergency Physician inexperienced in accessing this vein. Use the axillary vein as an access point only when other central veins are not accessible or contraindicated, and the Emergency Physician is comfortable with the procedure of US-guided vascular access. The depth of the axillary vein, commonly >3 cm, makes access difficult in patients who are not thin. The close proximity of the brachial plexus can result in significant injury if the needle penetrates it. The length of the catheter may be too short to reach the superior vena cava if placed in the left axillary vein.

FEMORAL VEIN CANNULATION

Contraindications to femoral line placement include infection, venous thrombosis, or significant trauma to the ipsilateral lower extremity or groin area. Abdominal trauma may result in an interruption of the inferior vena cava, allowing any infused fluid or blood to flow into the abdomen rather than into the central circulation. During CPR, blood return below the diaphragm is reduced and a femoral catheter must end near the level of the diaphragm for medications to be most effective.

Catheterization via the internal jugular vein or subclavian vein is usually easier if the purpose of central venous access is pulmonary artery catheterization or transvenous cardiac pacing. These procedures often require fluoroscopy when they are performed through the femoral vein. Central venous pressures measured through a femoral vein catheter may be inaccurate unless the patient is perfectly supine.

EQUIPMENT

- Sterile gloves and gown
- Face mask and cap
- Povidone iodine or chlorhexidine solution
- Sterile drapes or towels
- Local anesthetic solution
- 25 gauge needle
- 5 mL syringes
- "Finder" needle, usually 22 gauge for an adult
- 5 mL syringe with a nonlocking hub
- Thin-walled introducer needle or catheter-over-the-needle
- Guidewire
- Gauze 4 × 4 squares
- Central venous line
- Dilator
- #11 scalpel blade
- Nylon or silk suture, 3-0 or 4-0
- Sterile saline
- Needle driver
- Tape and catheter site dressing material
- Catheter clamp, if supplied with the kit

A variety of standard kits are commercially available (**Figure 49-9**). They contain all required equipment except local anesthetic solution and sterile gloves. The appropriate catheter should be chosen based on the patient's needs. The optimal catheter lengths for patients of different ages are summarized in **Table 49-3**.

Catheters with between one and four lumens are available. Multiple-lumen catheters are available in a variety of sizes and allow simultaneous venous pressure measurement, administration of numerous medications, and venous sampling without disconnecting the infusion apparatus. Disadvantages of multiple-lumen catheters over single-lumen catheters include smaller lumen sizes for a given catheter's outside diameter, greater cost, and the need to maintain unused lumens to prevent them becoming thrombosed. There is probably no increased risk of infection in using triple-lumen versus single-lumen catheters.[29–31] Some comparisons between these devices are summarized in **Table 49-4**.

Percutaneous sheaths are intended primarily for the introduction of intravascular devices, such as pulmonary artery catheters and transvenous pacing wires. They are most often used in the Emergency Department as a large-bore line for the rapid resuscitation of hypotensive and hypovolemic patients. Sheaths are available in many sizes and configurations. Many models have an adjustable hemostasis valve that may be removed and a side port that allows infusion while the main lumen is being used for monitoring.

The equipment required for subclavian vein cannulation is the same as that for internal jugular vein cannulation. Subclavian vein catheters must be slightly longer or inserted farther than internal jugular vein catheters. Left-sided catheters must be a few centimeters longer or inserted farther than right-sided catheters. The longer needle should be used for subclavian vein cannulation if the kit used has two different lengths of introducer needles.

PATIENT PREPARATION

Explain the procedure, its risks, and its benefits to the patient and/or their representative. Obtain an informed consent for the procedure unless it is being performed emergently. Place the patient in the Trendelenburg position if catheterization of the internal jugular vein is being attempted. Position the patient in at least 15° of Trendelenburg to prevent an air embolism. Slightly rotate the patient's head toward the side opposite that to be cannulated. A large degree of head rotation has been show to increase the overlap between the internal jugular vein and carotid artery, theoretically increasing the risk of carotid artery puncture.[32]

The subclavian vein is fixed to the surrounding tissues and will neither collapse nor distend. Therefore, the Valsalva maneuver or the extreme Trendelenburg position is not necessary. Head rotation is neither necessary nor helpful. Slightly abduct the patient's arm on the side to be cannulated. Avoid placing rolled towels between

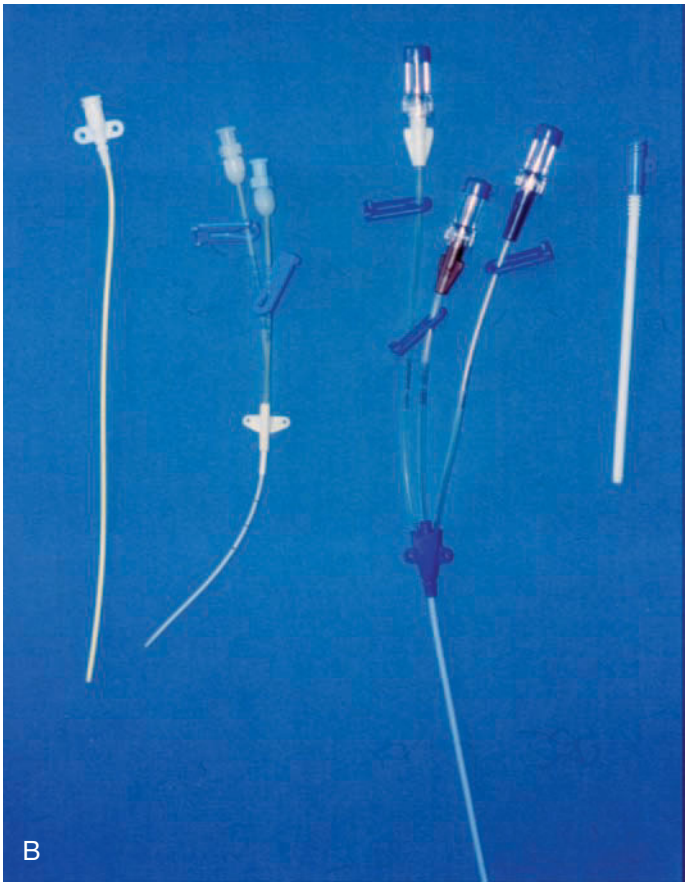

FIGURE 49-9. Equipment needed for central venous catheterization. **A.** A commercially available central venous line kit. **B.** Examples of different catheter types available. From left to right: single-lumen, double-lumen, triple-lumen, and introducer sheath (Cordis).

TABLE 49-3 Catheter Sizes, Types, and Characteristics

Catheter size (French)	Number of lumens	Patient size	Venous access site	Minimum catheter length (cm)*
2	1	Infant	Femoral, internal jugular, external jugular, or subclavian	5
3	1	<5 kg	Femoral, internal jugular, external jugular, or subclavian	5
4	1, 2	5–10 kg	Femoral	5
		10–15 kg	Femoral, internal jugular, external jugular, or subclavian	8–12
5	1, 2, 3	>15 kg	Femoral, internal jugular, external jugular, or subclavian	12–25
7	1 (sheath), 2, 3	>40 kg	Femoral, internal jugular, external jugular, or subclavian	15–25
8 and larger	1 (sheath), 2, 3, 4	Adult	Femoral, internal jugular, or subclavian	15–25

*The longer end of the catheter length range is for use in the subclavian veins, with the longest catheters needed for the left subclavian vein.

TABLE 49-4 Comparisons Between Central Venous Catheter Types

	Single-lumen	Multiple-lumen	Sheath (Cordis)
Minimum outer diameter	Smallest	Intermediate	Largest
Infusion rate	Moderate	Lowest (resuscitation catheters with larger lumen available)	Fastest (for central lumen; side port is slower)
Simultaneous infusions, or infusion while monitoring	No	Yes	Yes, if central lumen and side port both used
Length	Varies, fairly long	Long	Short
Allows device insertion (pulmonary artery lines and transvenous pacemakers)	No	No	Yes

the shoulder blades as this can decrease the distance between the clavicle and first rib, compress the subclavian vein, and make the procedure more difficult.[33]

Place the patient supine or in slight reverse Trendelenburg if femoral vein catheterization is being attempted. The reverse Trendelenburg position will increase the cross-sectional area of the femoral vein.[34] The Trendelenburg position is contraindicated due to the risk of venous air embolism. Slight external rotation and abduction of the extremity may increase the amount of femoral vein accessible for cannulation.[35] It is easier for a right-handed Emergency Physician to perform the procedure standing on the patient's right side, regardless of which femoral vein is being accessed. The opposite is true for those that are left-handed.

Identify the anatomic landmarks for the procedure after positioning the patient. Clean any dirt and debris from the area of the puncture site. Apply povidone iodine or chlorhexidine solution and allow it to dry.[36] **It is recommended to prepare the entire neck and clavicular area if the internal jugular or subclavian routes are attempted so that, if access to one site is unsuccessful, another site may be accessed without re-prepping and draping. Due to the risk of inducing a pneumothorax, attempts at contralateral internal jugular or subclavian vein cannulation after an unsuccessful attempt must be delayed until a chest radiograph is checked to prevent bilateral pneumothoraces.**

Infiltrate the subcutaneous tissues at the needle puncture site with a generous volume of local anesthetic solution, including any areas that will be used for suturing the catheter in place. This allows the local anesthetic to diffuse throughout the area and take effect before the main procedure begins. Any distortion of anatomic landmarks caused by anesthetic infiltration decreases as the anesthetic is absorbed into the subcutaneous tissues.

Apply electrocardiographic monitoring, pulse oximetry, and noninvasive blood pressure monitoring to the patient and administer supplemental oxygen. Electrocardiographic monitoring during insertion of a central line is recommended due to the risk of ventricular dysrhythmias should the guidewire or catheter enter the right ventricle. It is preferable to have a designated person—physician or nurse—whose only job is to watch the monitoring equipment. The patient's face and chest will be draped for the internal jugular or subclavian vein cannulation procedure. The Emergency Physician will be focused on the procedure and unaware of any sudden patient deterioration, ventilator disconnect, or other irregularities. Resuscitation equipment should be immediately available. A postinsertion chest radiograph to verify line placement and the lack of a pneumothorax must be immediately available.

Prepare for the procedure. Apply sterile gloves, a sterile gown, and a face mask. Some Emergency Physicians prefer to double-glove. If one glove becomes contaminated, it can be discarded and the procedure continued without interruption. Open the desired venous access kit using aseptic technique on a bedside table. Perform a quick inventory and identify all necessary equipment before beginning the procedure. Set up a sterile field next to the patient and within easy reach. Place the equipment that must be immediately at hand on the sterile field. This includes a sterile drape, syringe, large-bore hollow needle, guidewire, and gauze squares. Any other equipment, including the catheter itself, may be temporarily left in the kit. **Never use the patient as a table.** If they move, everything can fall onto the floor. A needlestick injury can occur from the falling needles or if the instinct to grab the falling equipment occurs.

INTERNAL JUGULAR VEIN CATHETERIZATION TECHNIQUES

CENTRAL APPROACH TO THE INTERNAL JUGULAR VEIN

While an internal jugular vein cannula can be inserted using the over-the-needle and through-the-needle techniques, the Seldinger technique is often preferred.[37,38] See Chapter 47 and **Table 49-5** for a more complete discussion. The Seldinger technique uses a flexible guidewire, inserted through a special thin-walled hollow needle, to guide a catheter of any desired length through the skin and into the central circulation. This technique is described below and summarized in **Table 49-6**.

Clean, prep, and drape the area as described previously. Place the patient in the Trendelenburg position with their head down 15° to 30°. Slightly rotate the patient's head away from the side that will be cannulated. Excessive rotation will distort the anatomic landmarks and may bring the internal jugular vein closer to the carotid artery.

Several cardinal rules for the insertion of the catheter should be observed. Always occlude the open hub of a needle or catheter in a central vein to prevent an air embolism. Never let go of the guidewire, so as to prevent its embolization into the central venous circulation. Never apply excessive force to the guidewire on insertion or removal. Doing so may injure the vessel, break the guidewire, and/or embolize the guidewire.

Attach the thin-walled introducer needle to a 5 mL syringe containing 1 mL of sterile saline or local anesthetic solution. The specially designed introducer needle included with the catheter should be used, as it has a relatively thin wall and a larger internal diameter relative to its external diameter. It has a shorter bevel than a conventional hypodermic needle. It also has a tapered hub to guide the guidewire into the needle proper.

If there is doubt about the exact location of the vein, it may first be located with a small "finder" needle. Insert a 25 or 27 gauge needle attached to a 5 mL syringe through the skin puncture site previously chosen. Advance the needle at a 30° to 60° angle to the skin while applying negative pressure to the syringe. A flash of blood signifies that the tip of the needle is within the vein. Note the depth and location of the vein. Remove the finder needle. Alternatively, the finder needle may be left in place for reference.

Insert the introducer needle at a 30° to 60° angle at the apex of the triangle formed by the sternal and clavicular heads of the sternocleidomastoid muscle and the clavicle (**Figure 49-4**). This point is just lateral to the carotid artery pulse. Direct the introducer needle

TABLE 49-5 Comparison of Central Venous Catheterization Methods

	Seldinger	Catheter-over-the-needle	Catheter-through-the-needle
Insertion needle	Small	Large	Largest
Speed	Slowest	Fastest	Fast
Number of steps	4+	1	2
Risk of catheter shear	None	Low	Highest
Catheters and lumens available	Single- or multiple-lumen, sheath/introducer	Single-lumen only	Single-lumen only
Rate of infusion	Highest (with sheath)	Moderate	Low to moderate

TABLE 49-6 Summary of the Seldinger Method of Central Venous Cannulation*

Step	Action	Tips and caveats
1	Prep and drape the skin puncture site.	For internal jugular vein, prepping down to the clavicle and up to the jaw will enable an attempt at the ipsilateral subclavian vein (or vice versa).
2	Anesthetize the puncture site if not already done.	Anesthetize the suture sites also.
3	Uncap the distal lumen.	Additional lumens may be flushed at this point or after insertion, as desired.
4	Locate the vein using the finder needle and aspirating syringe.	Internal jugular vein should be reached within 3 cm. Stop advancing after 4–5 cm if the vein is not located.
5	Remove the finder needle, noting the direction and depth of the internal jugular vein. Or withdraw the needle slightly so it is outside the internal jugular vein and leave it in place as a guide	A few drops or a line of blood may be left on the skin as the finder is withdrawn to show the proper direction.
6	Insert introducer needle on a syringe along the "finder's" path until venous blood is aspirated. Alternatively, an introducer catheter and needle assembly can be used to cannulate the internal jugular vein; the needle is then withdrawn.	Syringe must have a nonlocking hub. A little saline in the syringe allows any occluding skin plug to be ejected. The vein is often located on withdrawal of the needle, since the friction of the large needle in the tissues can compress the internal jugular vein.
7	Disconnect the syringe from the needle, immediately occluding the open needle hub to prevent air embolism.	Do not move the needle at all! Keep the hand holding the needle in contact with the patient's skin to prevent movement.
8	Insert the guidewire through the introducer needle and into the vein.	Do not move the needle! Do not force the guidewire—it should pass easily!
9	Advance the guidewire into the vein to the desired depth or until ventricular ectopy is seen on the ECG monitor.	The guidewire must be securely in the vein, not just in the subcutaneous tissue.
10	Withdraw the introducer needle a few millimeters and use the scalpel to enlarge the puncture site slightly.	Keeping the needle in place eliminates any possibility of cutting the guidewire.
11	Remove the introducer needle.	Never let go of the guidewire!
12	Thread the dilator over the guidewire until it can be grasped outside the hub, then insert and withdraw the dilator.	Always keep a firm grip on the guidewire!
13	Thread the catheter tip over the guidewire and withdraw the guidewire from the skin until it can be grasped at the infusion hub.	Never let go of the guidewire.
14	Insert the catheter to the desired depth; most catheters are marked in centimeters, with larger markings every 5 and 10 cm. Introducer sheaths should be inserted completely.	The tip of the catheter should be in the superior vena cava, at the level of the manubriosternal angle.
15	Holding the catheter in place, remove the guidewire. Occlude the open hub with a gloved finger to prevent air embolism.	Do not apply excessive force to the guidewire. If it is trapped, withdraw the catheter a few centimeters and try again. Do not break the wire!
16	Attach a syringe to the catheter hub and aspirate blood, taking samples as desired; then flush the lumen with saline and begin the desired venous infusion.	Other lumens may be aspirated, flushed, and clamped.
17	Verify intravenous placement before suturing the catheter in place	If the patient's blood travels up the intravenous tubing, the catheter is in the carotid artery!
18	Remove the patient from the Trendelenburg position.	
19	Suture the catheter to the skin with sutures and tape.	Take care not to puncture the catheter or to occlude it with a tight suture
20	Apply a dressing to the catheter site.	
21	Verify catheter tip position by chest X-ray.	Catheter tip must be in the superior vena cava, not in the right atrium. Tip should be above the azygos vein and the carina, with the tip parallel to the vessel wall.

*The central approach to the internal jugular vein is used as an example, although the same technique is used for other approaches and central veins.

toward the ipsilateral nipple. Shallower angles make it necessary to traverse a greater amount of subcutaneous tissues and structures before entering the vessel. Steeper angles make insertion of the catheter over the guidewire difficult, as the guidewire tends to kink. Shallower angles are generally necessary in children whose vessels are smaller. Inject a small amount of the fluid in the syringe to remove any skin plug that may block blood return once the vein has been penetrated.

Apply negative pressure to the syringe by withdrawing the plunger. Advance the introducer needle into the vein (**Figure 49-10A**). If the vein is not located within 3 to 5 cm of the skin—this distance will vary depending on the patient's size and the target vessel's location—stop advancing the introducer needle. Withdraw the needle slowly while continuing to aspirate. Often, the vessel will have been completely traversed and no blood will return due to collapse of the vein by the pressure of the skin being forced inward as the introducer needle passes through it. Under normal physiologic conditions, veins have very low pressures within them and are easily collapsed by external pressure. If no blood is aspirated while withdrawing the needle, withdraw the introducer needle to the subcutaneous plane and redirect it slightly medially. Avoid putting continuous pressure on the carotid artery pulse, as even gentle pressure may collapse the internal jugular vein (**Figure 49-3B**).

Stabilize and hold the introducer needle perfectly still with the nondominant hand once blood returns in the syringe. The carotid artery has been entered if the blood is bright red and/or forces

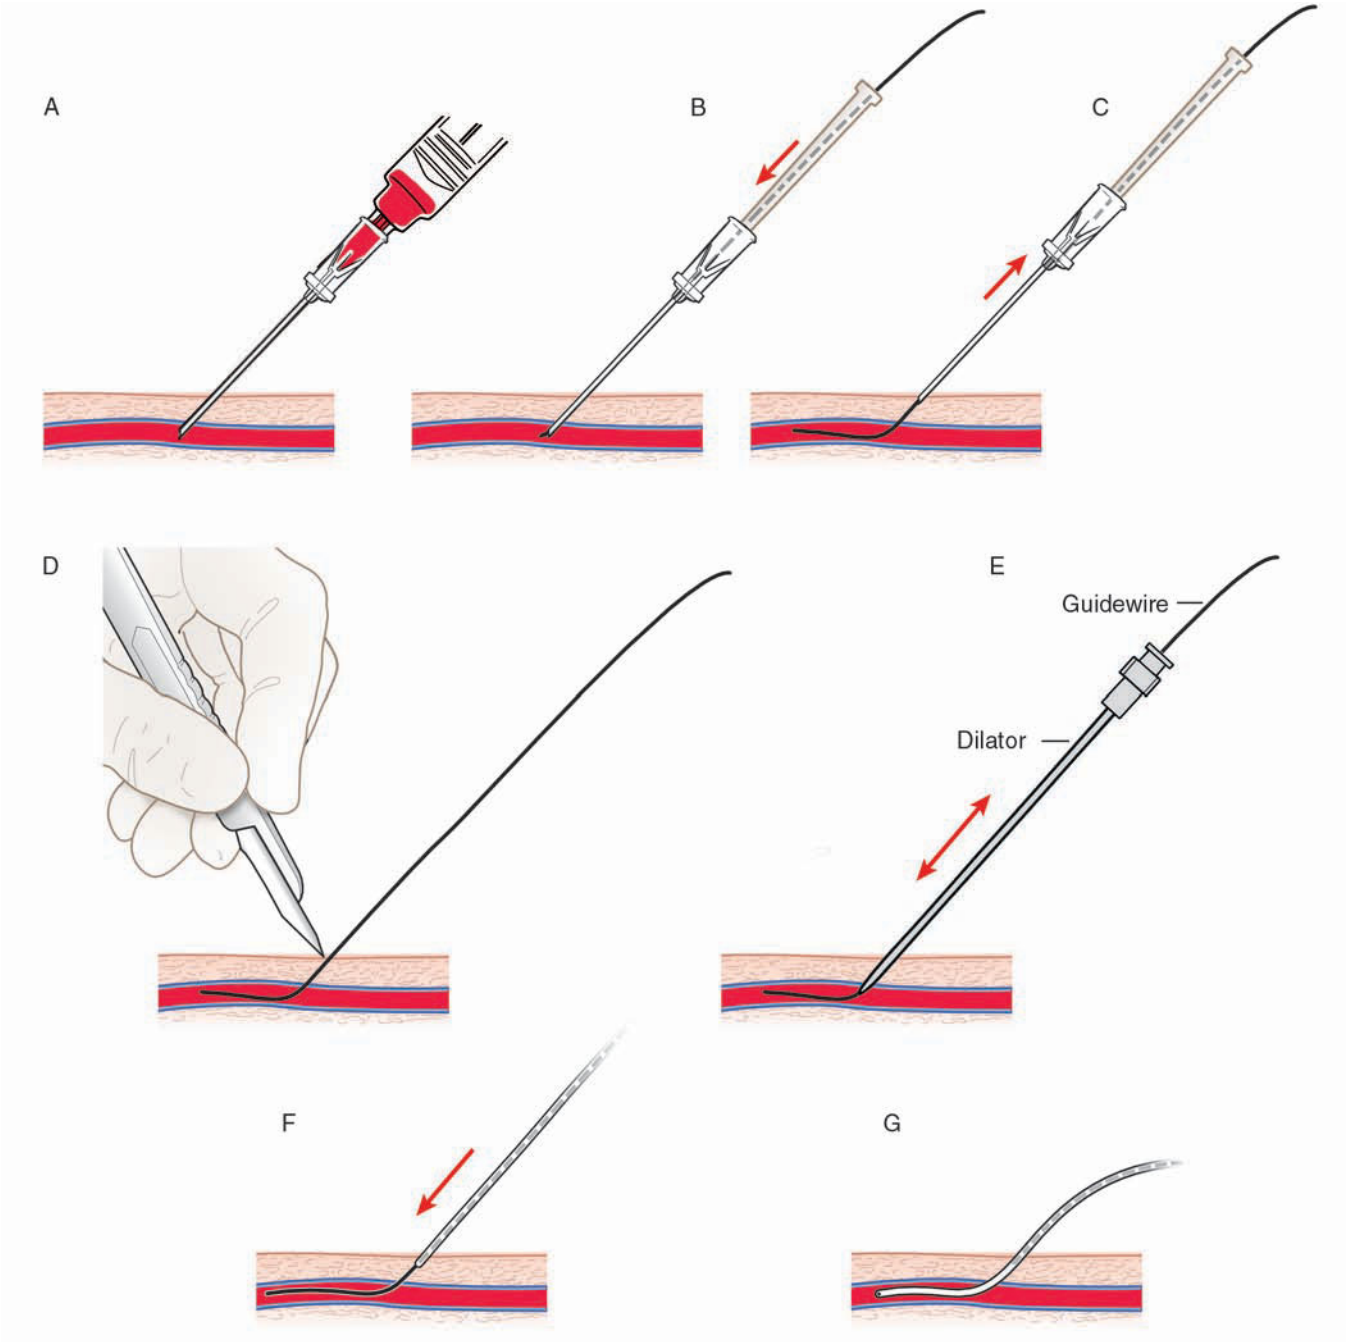

FIGURE 49-10. The Seldinger technique. **A.** The vein is punctured by the introducer needle and blood is aspirated. **B.** The syringe has been removed. The guidewire is inserted through the introducer needle and into the vein. **C.** The introducer needle and guidewire sleeve are withdrawn over the guidewire. **D.** The skin puncture site is enlarged. **E.** The dilator is advanced over the guidewire until the hub is against the skin; then it is removed. **F.** The catheter is advanced over the guidewire and into the vein. **G.** The guidewire is withdrawn through the catheter.

the plunger of the syringe back. Remove the syringe. Blood should flow slowly and freely from the hub of the needle. The introducer needle is in the carotid or subclavian artery if blood squirts out the introducer needle hub. If blood dribbles out or does not flow from the hub and the patient has spontaneous circulation, reattach the syringe and reposition the introducer needle until free flow is obtained. Occlude the open hub of the introducer needle with the thumb of the nondominant hand while keeping the small finger of the hand in contact with the patient's skin. The Emergency Physicians proprioceptive reflexes will prevent movement of the introducer needle by maintaining contact with the patient's skin. Even a millimeter of movement may result in failure of the needle tip to stay within the lumen of the vein.

Prepare the guidewire (**Figure 49-11**). Grasp the guidewire and its sleeve with the dominant hand. The tip of the guidewire has a "J" shape when the sleeve is retracted (**Figure 49-11A**). Slide the sleeve forward to straighten out the "J" of the guidewire (**Figure 49-11B**). Insert the wire sleeve into the hub of the introducer needle (**Figures 49-10B & 49-11C**). Advance the guidewire through the sleeve and into the introducer needle. **Never let go of the guidewire! One end of the wire must always be held to prevent loss of the wire and embolization into the central circulation.**

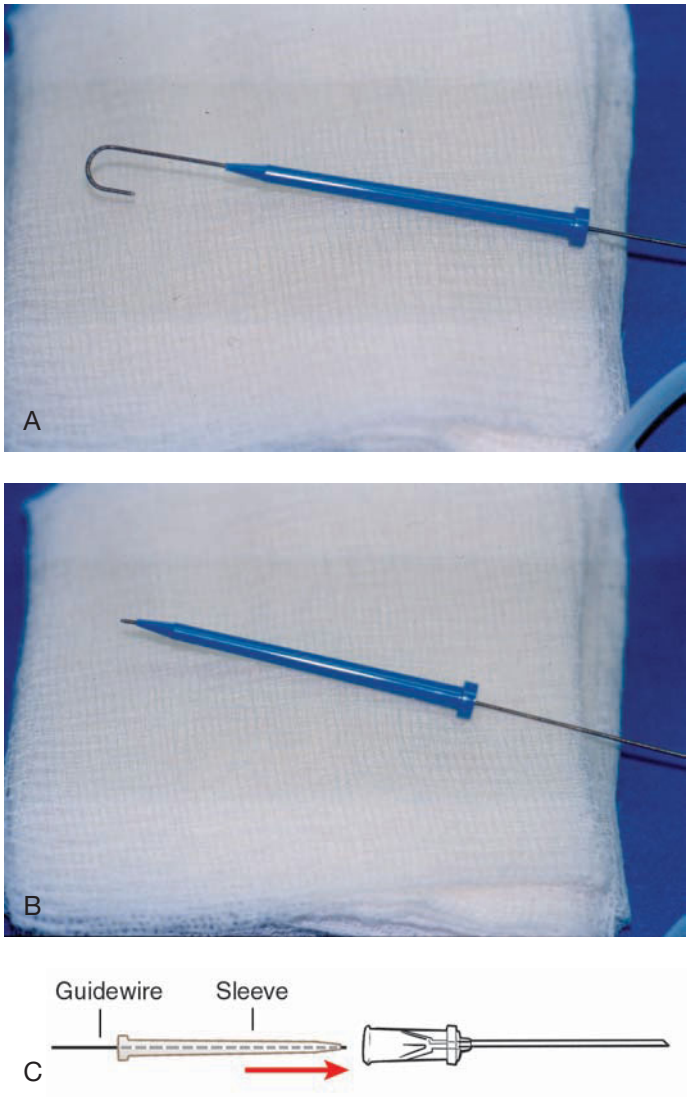

FIGURE 49-11. Guidewire preparation. **A.** The plastic sleeve is retracted, showing the "J" tip. **B.** The plastic sleeve is advanced to cover the guidewire tip, allowing the wire to be threaded into the introducer needle. **C.** The sleeve is inserted into the hub of the introducer needle.

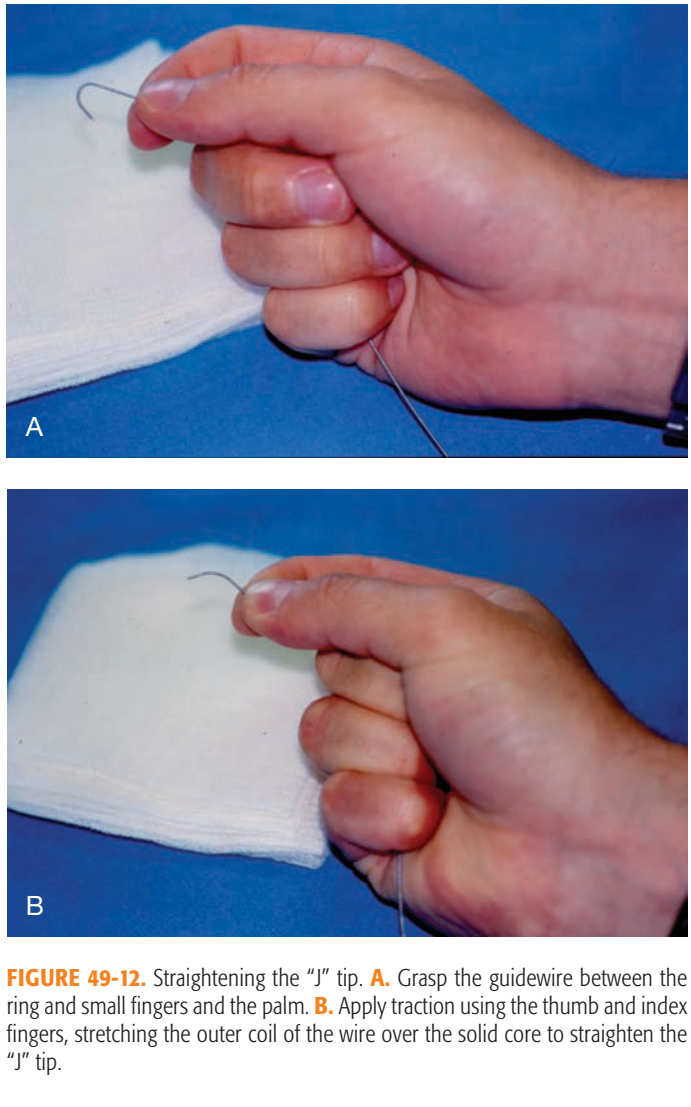

FIGURE 49-12. Straightening the "J" tip. **A.** Grasp the guidewire between the ring and small fingers and the palm. **B.** Apply traction using the thumb and index fingers, stretching the outer coil of the wire over the solid core to straighten the "J" tip.

Do not simply reverse the guidewire if the sleeve used to straighten the curved end of the guidewire is lost. The straight end of the guidewire can puncture the wall of the vein. Grasp the guidewire between the fourth and fifth fingers and the palm of the dominant hand (**Figure 49-12A**). Apply gentle traction on the curved guidewire tip with the thumb and the second and third fingers in order to straighten the guidewire (**Figure 49-12B**). The guidewire can then be inserted into the introducer needle hub without the use of the sleeve.

Advance the guidewire through the introducer needle and into the vein (**Figure 49-10B**). The guidewire should advance easily into the vein. **Never force the guidewire.** Guidewire resistance may indicate that the introducer needle is not within the vein, is against the wall of a vessel, or is caught as the vessel bends. Slightly withdraw the guidewire, rotate it slightly, and readvance it. **The use of force will kink the guidewire and may cause it to damage the vein and adjoining tissues.** Advance the guidewire 5 to 10 cm into the vessel or until ectopic beats are seen on the cardiac monitor. Withdraw the introducer needle and guidewire sheath while securely holding the guidewire (**Figure 49-10C**). Grasp the guidewire with the nondominant hand as soon as the guidewire is visible between the tip of the introducer needle and the skin. Finish removing the needle over the guidewire.

Make a small incision in the skin adjacent to the guidewire using a #11 scalpel blade (**Figure 49-10D**). Place the dilator over the straight end of the guidewire (**Figure 49-10E**). Advance the dilator over the guidewire, through the skin, and into the vein. A slight twisting motion of the dilator as it is advanced may aid in its insertion. Continue to advance the dilator until its hub is against the skin. **Do not release hold of the guidewire at any time.** Remove the dilator over the guidewire.

Place the catheter tip over the guidewire. Advance the catheter over the guidewire and into the vein to the desired depth (**Figure 49-10F**). **Do not release hold of the guidewire.** Gently rolling or twisting the catheter between the thumb and the forefinger may aid in its advancement. Hold the catheter securely in place and remove the guidewire (**Figure 49-10G**). Occlude the open catheter lumen with a sterile-gloved finger to prevent an air embolization and excessive blood loss.

Attach a syringe to the catheter hub and aspirate blood to confirm that the catheter is within the vein. Withdraw any necessary blood samples from the catheter. Attach infusion tubing or a heparin lock to the port and flush the catheter to prevent a blood clot from obstructing the lumen. If a multilumen catheter is inserted, flush any other lumens after first withdrawing any air (**Figure 49-13**).

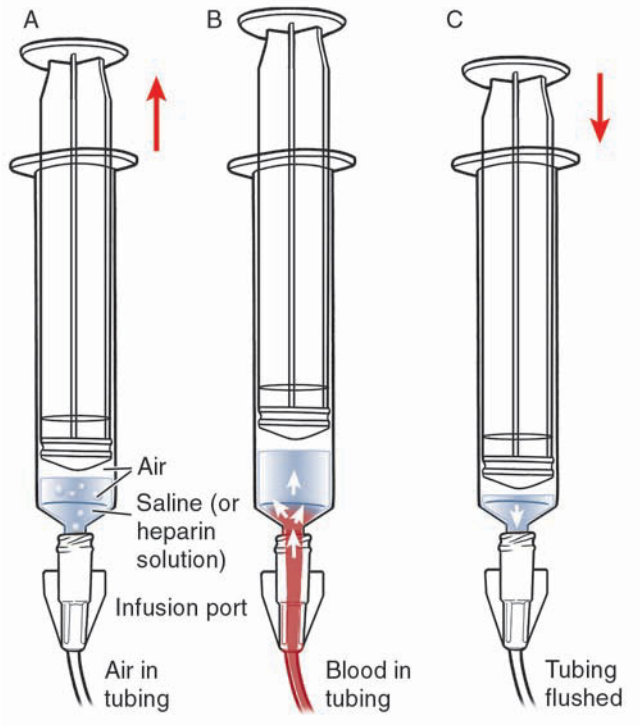

FIGURE 49-13. Aspiration and flushing of catheters. **A.** Any air in the lumen of the tubing is aspirated into the syringe of flush solution. The syringe must be held upright, as shown. **B.** Stop aspirating once all the air is removed from the catheter and blood begins to enter the syringe. **C.** Flush solution is injected until the lumen is filled and contains no blood. This usually requires 2 to 4 mL of flush solution.

Securely attach the catheter to the skin with nylon or silk sutures. Cover the skin puncture site with a sterile dressing.

ANTERIOR APPROACH TO THE INTERNAL JUGULAR VEIN

The skin puncture site is at the anterior border of the sternal head of the sternocleidomastoid muscle, just lateral to the carotid artery and at the level of the cricoid cartilage (**Figure 49-5**). Enter the skin at a 45° to 60° angle. Direct the introducer needle toward the ipsilateral nipple. The internal jugular vein in an adult should be encountered within 3 to 5 cm. If the vein is not encountered by 5 cm, withdraw the tip of the introducer needle to the subcutaneous space and redirect it slightly medially. The remainder of the procedure is as described for the central approach above and in **Table 49-6**.

POSTERIOR APPROACH TO THE INTERNAL JUGULAR VEIN

Enter the skin at the posterior edge of the sternocleidomastoid muscle, one-third of the way from the clavicle to the mastoid process (**Figure 49-6**). Alternatively, the point where the external jugular vein crosses the lateral border of the sternocleidomastoid muscle can be used. Direct the introducer needle under the sternocleidomastoid muscle at a 30° to 45° angle to the skin and toward the sternal notch. Place the index finger of the nondominant hand in the sternal notch to provide a landmark with the patient draped. In an adult, the internal jugular vein should be encountered within 5 cm. This approach is not recommended in children. The remainder of the procedure is as described for the central approach above and in **Table 49-6**.

TABLE 49-7 Comparison of Subclavian Vein Cannulation Routes

	Infraclavicular approach	Supraclavicular approach
Entry site	Just inferior to the clavicle at the midclavicular line	1 cm lateral to the clavicular head of the sternocleidomastoid muscle, 1 cm posterior to the clavicle
Needle orientation	Keep as close to the coronal plane as possible	Tip aimed 10° anterior to the coronal plane
Needle bevel and "J" wire directed	Medially and caudally	Medially
Aim toward	Just posterior to the sternal notch	Contralateral nipple, needle bisects angle formed by the clavicle and the clavicular head of the sternocleidomastoid muscle
Distance from skin to subclavian vein	3–4 cm	2–3 cm

SUBCLAVIAN VEIN CATHETERIZATION TECHNIQUES

The technique is identical to that described above for internal jugular vein cannulation except for the puncture site. Two techniques, infraclavicular and supraclavicular, are described below and summarized in **Table 49-7**.

INFRACLAVICULAR APPROACH TO THE SUBCLAVIAN VEIN

The infraclavicular approach to the subclavian vein is most often used. It is commonly thought to be easier to perform and less likely to result in a pneumothorax than the supraclavicular approach, although data for this belief are lacking.[39] Some Emergency Physicians prefer not to use a finder needle for infraclavicular subclavian vein cannulation as there is no danger of penetrating the carotid artery. This also makes as few needle passes near the pleura as possible in order to decrease the risk of an iatrogenic pneumothorax. Estimate the distance from the skin puncture site to the superior vena cava (i.e., the manubriosternal junction).

Several different skin entry sites are described in the literature. Some feel that the preferred entry site is 1 cm caudal to the junction of the medial and middle thirds of the clavicle. The subclavian vein lies just posterior to the clavicle at this site (**Figure 49-14**). The first rib lies between the pleural dome and the subclavian vein. Direct the introducer needle just superior and posterior to the suprasternal notch while staying as close to the frontal (coronal) plane as possible. The needle and syringe should be parallel to the bed (**Figure 49-14A**). Placing the nondominant index finger in the sternal notch will help to guide placement (**Figure 49-14A**).

Some Emergency Physicians prefer to enter the skin inferior to the clavicle at the deltopectoral groove, or the point just lateral to the midclavicular line along the inferior surface of the clavicle. This is the point where the skin may be maximally depressed. Direct the introducer needle parallel to the bed and toward the sternal notch. This entry site may make it easier to keep the introducer needle in the coronal plane. The distance before entering the subclavian vein is longer than in the preceding approach and the protection offered by the first rib is lost.

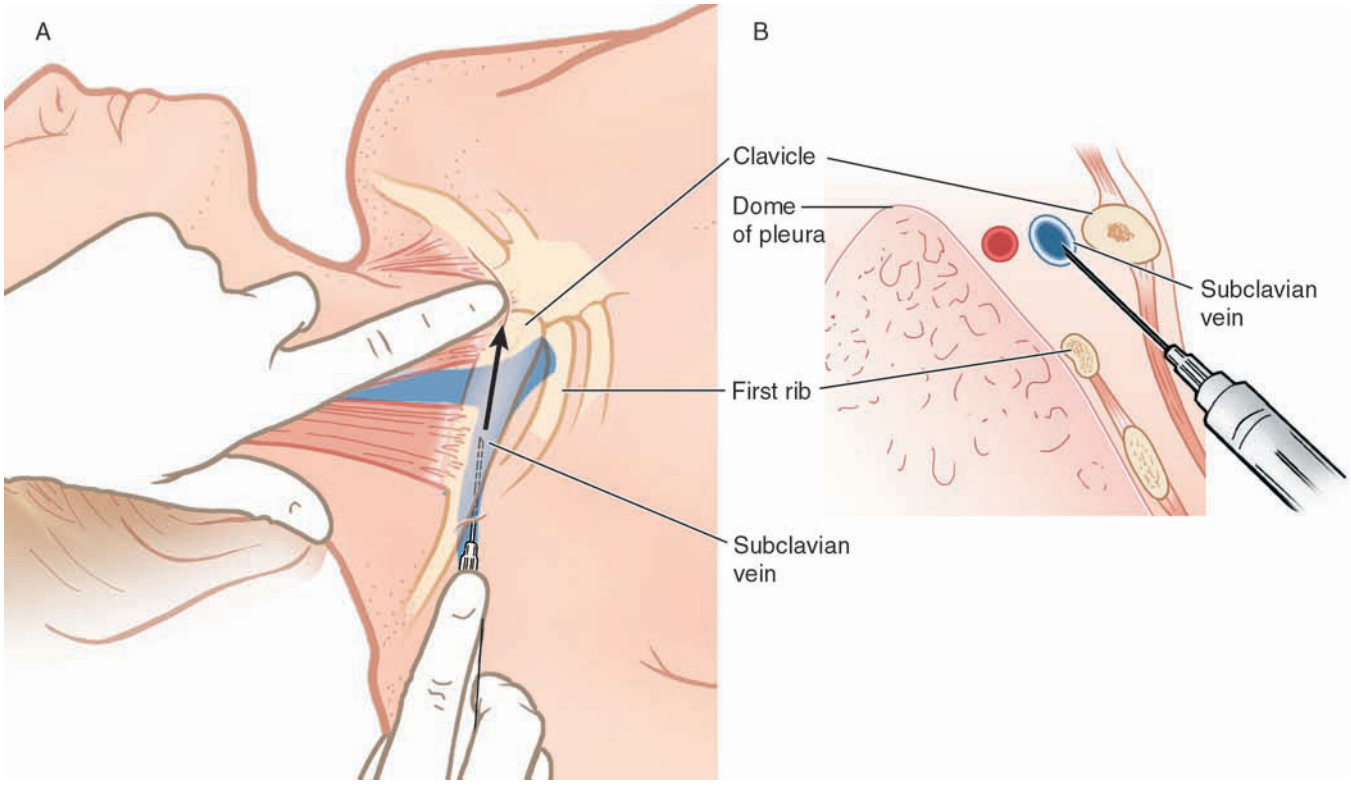

FIGURE 49-14. Infraclavicular approach to subclavian vein cannulation. **A.** Frontal (oblique) view of the procedure. **B.** Sagittal section through the medial third of the clavicle. Note the proximity of the pleura and subclavian artery.

One additional landmark can be used to identify the skin puncture site. Palpate the bony tubercle, or protrusion, on the inferior surface of the clavicle and approximately one-third to one-half the length of the clavicle from the sternoclavicular joint. The advantage of this site is that it is a definitive landmark and avoids approximating distances, as described for the other sites above. Insert the introducer needle parallel to the bed and aimed just posterior to the sternal notch.

The bevel of the introducer needle should be oriented caudally, as should the "J" in the guidewire (**Figure 49-15**). This position will allow the guidewire to enter the innominate vein and superior vena cava rather than being directed upward into the internal jugular vein or across to the contralateral subclavian vein (**Figure 49-15**). Once venous blood is aspirated, the Seldinger technique for catheter insertion is otherwise the same as previously described for internal jugular vein cannulation. Aspiration of bright red blood under pressure indicates subclavian artery puncture, which will be incompressible. Remove the introducer needle and observe the patient for signs of significant hemorrhage over the next several hours. Aspiration of air indicates penetration of the pleura. Observation with serial chest radiographs for at least the next 6 to 24 hours is essential to evaluate the size of the potential resulting pneumothorax.

SUPRACLAVICULAR APPROACH TO THE SUBCLAVIAN VEIN

While most Emergency Physicians are more comfortable with the infraclavicular approach to the subclavian vein, the supraclavicular approach offers some distinct advantages. The supraclavicular subclavian vein is closer to the skin. The route from a right-sided skin puncture site to the superior vena cava is more direct. It allows easier access to the superior vena cava while avoiding the hazards of a left-sided puncture (i.e., the thoracic duct). The skin entry site is

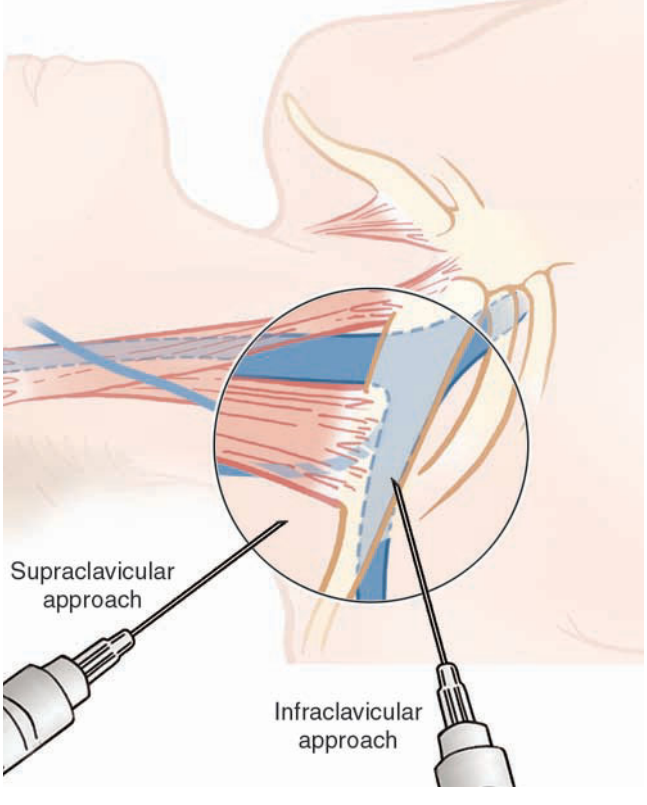

FIGURE 49-15. Introducer needle bevel orientation for subclavian vein cannulation. Varying the orientation of the introducer needle bevel for infraclavicular and supraclavicular techniques helps guide the "J" shaped guidewire into the superior vena cava.

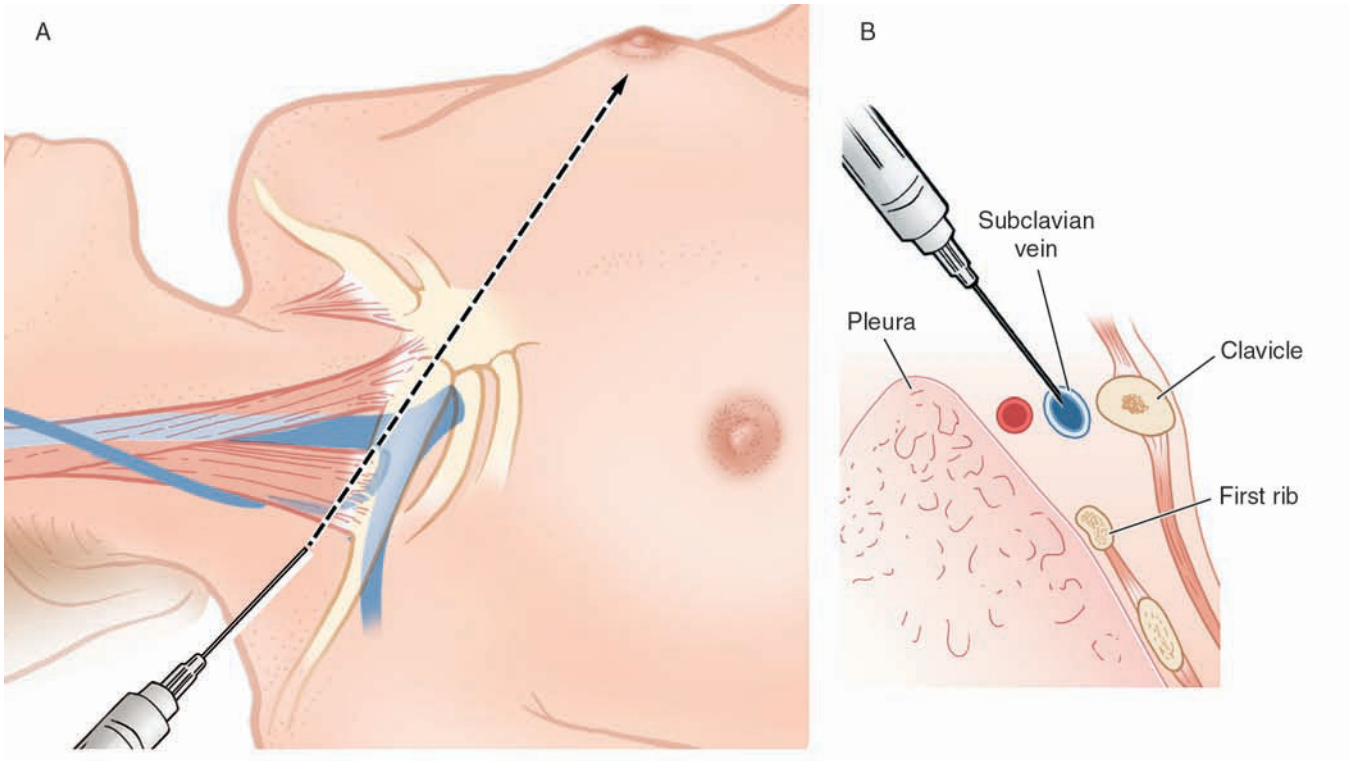

FIGURE 49-16. Supraclavicular approach to subclavian vein cannulation. **A.** From the insertion point 1 cm superior to the clavicle and 1 cm lateral to the border of the sternocleidomastoid muscle, direct the introducer needle tip at a 45° angle to the transverse and sagittal planes and slightly anterior toward the contralateral nipple. **B.** Sagittal section through the medial third of the clavicle. Note that the introducer needle track must be directed anteriorly to avoid the subclavian artery and the dome of the pleura.

more accessible during CPR and requires less interruption of external chest compressions.[40] With experience, the complication rate for the supraclavicular approach is probably lower than that for the infraclavicular approach.[39,41]

Estimate the distance from the skin puncture site to the superior vena cava to guide the catheter insertion depth. The skin is entered at a point 1 cm lateral to the lateral border of the clavicular head of the sternocleidomastoid muscle and 1 cm superior to the clavicle (**Figure 49-16**).[42] The introducer needle should bisect the angle formed by the clavicle and the lateral border of the sternocleidomastoid muscle (**Figure 49-16A**). Direct the introducer needle toward the contralateral nipple or a point just superior and posterior to the sternal notch. Orient the introducer needle bevel medially (**Figure 49-15**). The subclavian vein should be entered within 2 to 3 cm in an adult. The length of catheter inserted will be 2 to 4 cm less than that for the infraclavicular approach.

Alternative skin entry sites and approaches have been described. Enter the skin 1 cm medially and 1 cm superiorly to the midpoint of the clavicle with the introducer needle directed toward the ipsilateral sternoclavicular joint.[43] The skin can be entered just posterior to the clavicle, at the junction of the medial and middle third of the clavicle, with the introducer needle directed toward the ipsilateral sternoclavicular joint and parallel to the coronal plane.[44] This last approach is probably the simplest, although the study cited was performed on cadavers rather than live patients.

AXILLARY VEIN CATHETERIZATION TECHNIQUE

The axillary vein must be accessed using US guidance and not blindly using landmarks. Place the patient supine with their arm abducted in a comfortable position. A recent US study demonstrated no benefit of arm abduction in increasing axillary vein size or decreasing arteriovenous overlap.[16] Locate the axillary vein using a high frequency, 5 to 10 MHz, US probe. Place the US probe, with the marker pointing cephalad, just below the clavicle at approximately its middle third. Identify the axillary artery, axillary vein, and the pleura to obtain proper orientation. Manual compression and color flow Doppler can be used to differentiate between the vein and the artery. Follow the axillary vein laterally on the chest until overlap with the artery is minimized and the pleura is out of the view of the probe. Rotate the US probe into a parallel orientation in respect to the axillary vein with the probe marker toward you to obtain a long axis view of the axillary vein. Gently pivot the US probe in a cephalad and caudal direction to clearly differentiate the axillary vein from the axillary artery. Slight movements of the probe will alter the US image between the vein and artery. It is recommend to stabilize the US probe by resting your distal forearm and wrist against the anterior chest. Note the depth of the vein to ensure that the central venous catheter needle will be able to puncture the vessel. The remaining details of the technique are as described in Chapter 50 (US-Guided Vascular Access).

FEMORAL VEIN CATHETERIZATION TECHNIQUE

This technique is often performed blind using landmarks. It can also be performed under US guidance. The use of an ECG monitor is still recommended even though the short guidewire may not reach the heart. Particular care must be taken if the patient has a preexisting left bundle branch block, as complete heart block may result if the guidewire or catheter enters the right ventricle.[28] Premeasuring from the insertion site to the xiphoid process will give the maximum depth of catheter insertion.

The introducer needle should enter the skin 2 to 4 cm inferior to the midpoint of the inguinal ligament and 1 cm medial to the

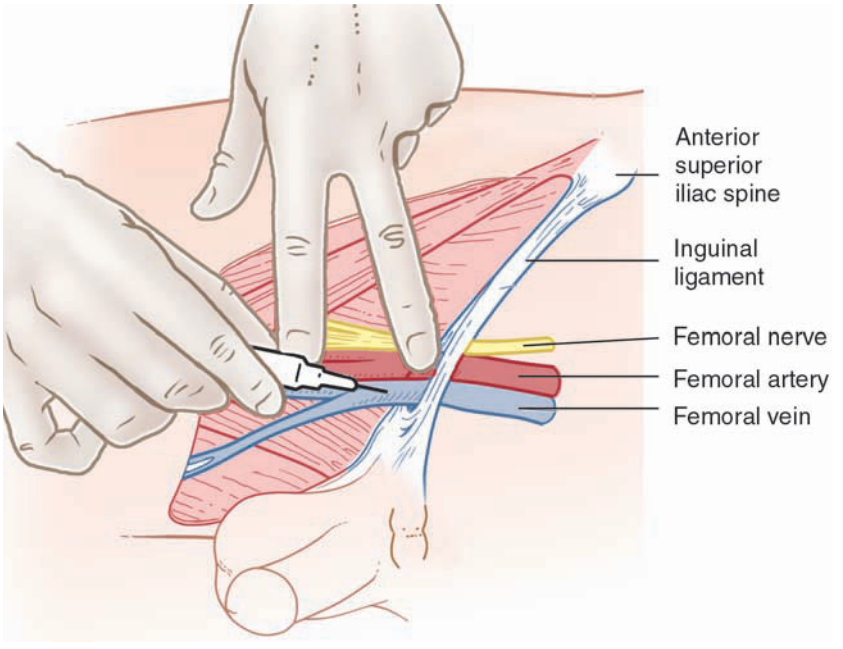

FIGURE 49-17. Femoral vein cannulation. The skin puncture site is 1 cm medial to the femoral artery pulse and 2 to 4 cm inferior to the inguinal ligament. Direct the introducer needle posteriorly at a 45° to 60° angle while aspirating.

femoral artery pulse (**Figure 49-17**). In an infant or young child, the introducer needle should enter the skin 1 to 2 cm inferior to the inguinal ligament and 0.5 cm medial to the femoral artery pulse. The cannulation technique is as described previously for the internal jugular vein.

Two site-specific considerations deserve mention. The use of a finder needle is unnecessary, since there are no vital structures in the area other than the femoral artery that is compressible if it is punctured. The introducer needle is directed at a 45° to 60° angle to the skin and parallel to the long axis of the thigh. Shallower angles may be necessary in very small and thin patients. **Use caution to avoid puncturing the posterior wall of the vein above the inguinal ligament, since this can result in a retroperitoneal hemorrhage.**

ALTERNATIVE TECHNIQUES

USE OF THE SELDINGER-HUB INTRODUCER CATHETER

Some central venous access kits include a catheter-over-the-needle with a tapered hub that can be used in place of the thin-walled introducer needle. This technique has the advantage of allowing the introducer catheter to remain in place while venous placement is verified. It provides less likelihood of the vein being lost as the aspiration syringe is removed and the guidewire advanced. A guidewire advanced through the introducer catheter cannot become sheared off, as when it is inserted through the needle.

The vein is entered with the catheter-over-the-needle assembly attached to an aspirating syringe, as described previously. Once the flashback of blood is obtained, advance the catheter-over-the-needle 2 mm further into the vein. This will ensure that the tip of the introducer catheter is within the vein. Hold the hub of the needle securely. Advance the catheter into the vein until its hub is against the skin. Withdraw the needle. If necessary, the introducer catheter may be attached to a pressure transducer and the venous waveform verified to confirm venous rather than arterial placement. Blood gas measurements may also be performed. Advance the guidewire through the introducer catheter and into the vein. The remainder of the procedure is as previously described.

MULTIPLE-LUMEN CATHETERS

Prior to skin puncture, remove the cap from the distal port's injection hub. It is usually marked "distal." The other lumens may be flushed with saline or heparin solution and recapped or left capped and flushed later (**Figure 49-13**). Heparin concentrations no higher than 100 U/mL should be used to avoid temporarily anticoagulating the patient.[45]

The introducer needle and guidewire are inserted as described previously. Place the multiple-lumen catheter tip over the guidewire. Advance the catheter until the guidewire emerges from the distal port hub (**Figure 49-18**). Insert the catheter to the desired depth. Remove the guidewire. Flush the distal lumen and connect it to the desired infusion. If not done previously, aspirate and flush the other lumens with the desired solution (**Figure 49-13**).

PERCUTANEOUS INTRODUCER SHEATH (CORDIS)

The insertion technique differs slightly from those described above (**Figure 49-19**). Locate the vein, insert the needle followed by the guidewire, and remove the needle leaving the guidewire in place as described previously. Insert the plastic dilator into the lumen of the sheath. The entire assembly must be advanced over the guidewire as a unit rather than utilizing separate dilation and insertion steps (**Figure 49-19C**). A correspondingly larger skin nick must be made with the scalpel, since the sheath is usually of larger diameter than a catheter. Advance the dilator–sheath unit over the guidewire (**Figure 49-19C**) and into the vein (**Figure 49-19D**). A twisting motion may aid in its advancement. Continue to advance the unit until the hub of the sheath is against the skin (**Figure 49-19E**). Remove the guidewire and dilator as a unit (**Figure 49-19E**). The remainder of the procedure is as described previously.

US-GUIDED CENTRAL VENOUS ACCESS

The use of bedside US to guide central venous access is becoming more common. The availability of US, its low cost, portable units, and training during residency are making its use standard procedure for central venous line placement. Please refer to Chapter 50 for the complete details of US-guided vascular access.

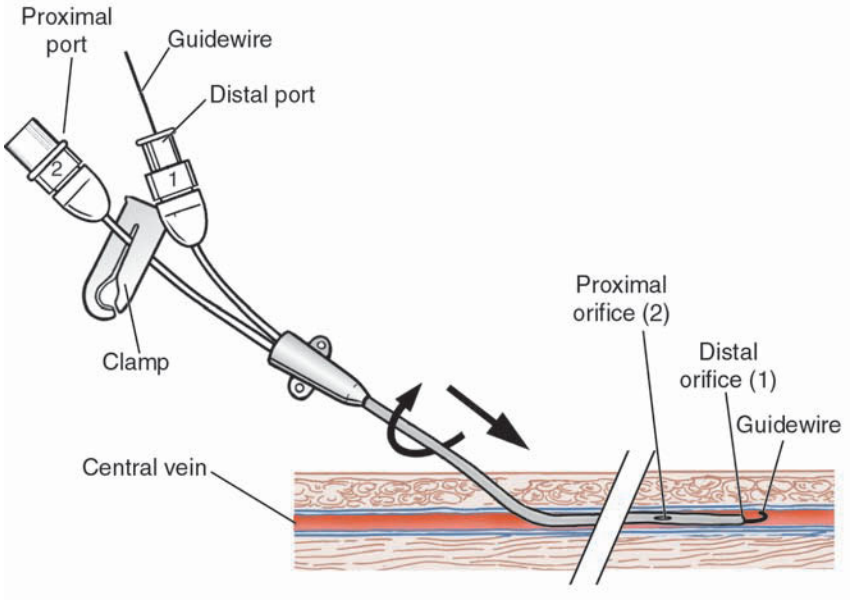

FIGURE 49-18. Inserting a multiple-lumen catheter. The guidewire exits through the uncapped distal port. The proximal port(s) must be clamped or capped to prevent air embolism.

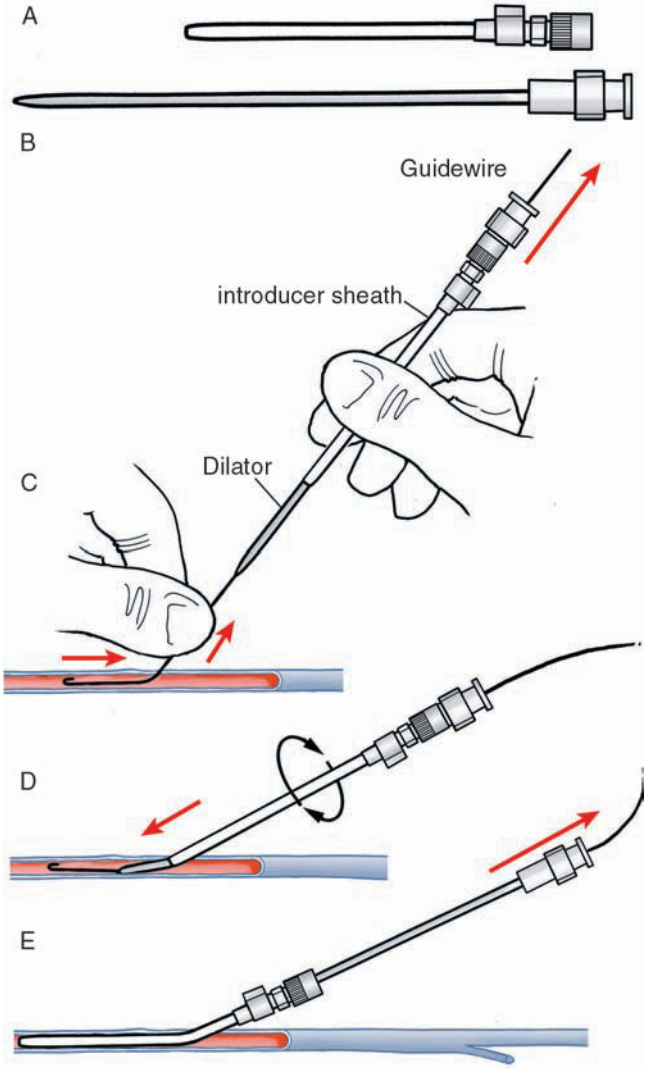

FIGURE 49-19. Inserting an introducer sheath. **A.** The sheath. **B.** The dilator. **C.** The dilator is inserted into the sheath and the unit is threaded over the guidewire. **D.** Advance the unit over the guidewire and into the vein using a twisting motion (*arrow*). **E.** The dilator and guidewire are removed as a unit, leaving the sheath in place.

PEDIATRIC CONSIDERATIONS

The anterior or central approach to the internal jugular vein is preferred for children. Appropriate catheter sizes and lengths are shown in **Table 49-3**. The child must be sedated and immobilized prior to attempts at cannulation of the internal jugular or subclavian vein. The femoral vein is the vein of choice if central venous access is needed in a combative child who cannot be completely restrained. The patient need not be in the Trendelenburg position, the consequences of a misdirected needle are less severe, and the procedure is less threatening as the face is not draped. A shallower angle of skin entry than in an adult is necessary to access the femoral vein. Enter the skin 1 to 2 cm inferior to the inguinal ligament and 0.5 mm medial to the femoral artery. Subclavian vein access in the small child can be difficult due to the anatomic relationships of the vessels as previously described. Despite this, the subclavian vein, in addition to the femoral vein, can be safely and effectively accessed in children less than 1 year of age.[46]

ASSESSMENT

Examine the patient. Examine the lung fields carefully to exclude a significant iatrogenic pneumothorax. Recheck the patient's vital signs frequently after the procedure. Obtain a portable anteroposterior chest radiograph to verify line tip placement in the superior vena cava and rule out an iatrogenic pneumothorax. Check the catheter site for hematoma formation or hemorrhage along the dilated catheter track. Control any hemorrhage with direct pressure.

US, if immediately available, can be used postinsertion to determine the presence or absence of an iatrogenic pneumothorax. Detection of an anterior pneumothorax in a supine patient has been shown to more sensitive using US than standard plain radiographs.[47,48] **The use of US does not negate the need to determine catheter location by plain radiographs.** US may be a useful tool when postline chest radiographs are delayed or the patient suddenly decompensates during or immediately after central line placement.

Check the function of the catheter by aspiration and infusion through all ports, as discussed above. A proximal lumen may be extravascular if it fails to aspirate blood easily. A catheter may be exchanged over a guidewire as long as the distal tip of the catheter is definitely intravascular. Do not attempt to advance the catheter once the guidewire has been removed.

Check the position of the catheter tip on the chest radiograph. The catheter must not be in the heart due to the risk that erosion through the thin right atrial wall will result in a pericardial hemorrhage and tamponade.[49,50] Landmarks for an internal jugular or subclavian vein catheter tip include the following: above the level of the carina, above the azygos vein, and at/above the manubriosternal junction. The tip of the catheter should be parallel to the vein to prevent erosion through the wall of the vein. If the catheter crosses over to the opposite subclavian vein and the patient cannot tolerate an attempt at repositioning, it may be used for intravenous infusion. Lines placed from the subclavian vein into the jugular system must be replaced. Catheters in or below the right atrium must be pulled back immediately to prevent any arrhythmias and perforation of the myocardium.

It is important to ensure that the catheter is within a vein and not an artery. This can be accomplished by US as described in Chapter 50. An arterial line monitoring setup can be attached to the catheter to measure intravascular pressures. This is time consuming, expensive, and takes some time to prepare. A device was recently approved by the FDA to assist in this evaluation. The Compass Vascular Access pressure measurement device (Mirador Biomedical, Seattle, WA) is a disposable, single patient use, digital manometer that attaches between the syringe and introducer needle. It provides a digital pressure measurement through the needle when it is within the blood vessel. It also provides pressure measurements while the guidewire is being inserted through the needle.

Most femoral vein catheters can be fully inserted. Premeasurement is recommended to make sure that the catheter tip will not reach the right atrium. If there is any doubt about the catheter position, postinsertion abdominal and chest radiographs should be obtained. The tip of the catheter must be at or below the xiphoid process of the sternum. Reassess the distal neurovascular status of the lower extremity after line placement.

AFTERCARE

The catheter must be sutured in place to prevent malpositioning of the line. Tie a surgeon's knot at the skin, then secure the suture to the hole(s) provided in the catheter wings. The straight needle contained within most central venous access kits can be difficult to use and it poses a needlestick risk. One option is to use nylon suture on a curved needle and a laceration repair kit. This requires additional equipment and at an additional cost. Another option is to use a needle cap or syringe contained within the kit to protect against the advancing straight needle puncturing your finger.[51,52] Use the cap to apply counter pressure against the skin as the straight needle tip exits the skin. A catheter clamp is often provided in the kit for longer catheters. It too should be sutured in place. The clamp holds the catheter in place by friction. It is not a guarantee that the catheter will not move. The catheter depth should be checked daily by inspection and by frequent chest radiographs. Movement of the patient's head and neck may move the tip of the internal jugular vein catheter by as much as 4 cm.[53]

Introducer sheaths have large lumens and present a significant risk of causing an air embolism. Cap the main lumen if it is not being used for an infusion. Any built-in diaphragm is not a reliable means of preventing an air embolism.[54] Do not use the dilator as an occluder or infusion port, as the stiff plastic can easily erode through the wall of the vein. An occlusive dressing can be used if no occluder is available.

The skin puncture site should be checked regularly for signs of infection. Cellulitis or purulent drainage requires a new central venous line at another site. Remember to restrain any patient who is uncooperative so as to prevent inadvertent removal of the central line.

While the short-term infection rate of femoral lines compares favorably with that in other central lines, some precautions are necessary to prevent soilage of the site.[20,55] Consider the judicious use of bladder catheterization in patients who are incontinent of urine and of rectal tubes in patients with loose stools. Patients with percutaneous femoral vein catheters must be confined to bed to prevent catheter dislodgment and hemorrhage around the catheter. Frequent assessment for venous thrombosis in the lower extremity is essential. It is recommended that femoral lines be discontinued when an alternative venous access site is available or within 3 days, whichever is sooner.[56]

REMOVAL OF THE CENTRAL VENOUS CATHETER

It has been, and sometimes still is, routine policy in some institutions to change all central venous lines placed in the Emergency Department when the patient arrives in the Intensive Care Unit. It was believed that these lines placed in the Emergency Department were "dirty" and at a higher risk of infection. This practice results in an additional procedure, the additional time and cost of the procedure, the associated discomfort or pain of the procedure, and the potential for complications. A recent study demonstrated that the infection rate of central venous lines placed in the Emergency Department using aseptic technique was no different than those placed in the Intensive Care Unit.[57]

When removing a central venous catheter from the internal jugular or subclavian vein, place the patient in the Trendelenburg position. To remove a femoral vein catheter, place the patient supine. Remove the dressing overlying the skin puncture site. Cut the suture securing the catheter to the skin. Ask the patient to exhale and hold their breath. Briskly remove the catheter and cover the puncture site with a gauze dressing. The track from the skin surface to the vein can be a source of a fatal venous air embolism.[58] If the catheter had a large diameter or remained in place for more than 2 to 3 days, apply an occlusive dressing to the site for the first 1 to 2 days after the catheter has been removed. The skin puncture site should be observed for signs of infection twice a day for 48 hours.

COMPLICATIONS

Mechanical complications can occur. The needle and/or guidewire may puncture the lateral or posterior wall of the vein.[59–62] This can result in a hematoma formation, arterial puncture, arterial cannulation, and an arteriovenous fistula. The use of US guidance does not prevent these complications.[59–61] The guidewire or catheter can break, fragment, or become knotted intravascularly. The guidewire can become a venous embolus if it completely enters the vein.

INTERNAL JUGULAR VEIN CATHETERIZATION

Internal jugular venous access has a myriad of potential complications.[49,63–66] Infection can be either at the local site or in a systemic line due to bacteremia and sepsis. A pneumothorax can occur during line placement. A hemothorax may be life-threatening, especially if a venopleural fistula is created. A chylothorax occurs if the thoracic duct is lacerated. Occasionally, carotid artery puncture can result. It may be complicated by a stroke if the blood supply to the brain is interrupted or if a plaque embolizes. Airway compromise can occur due to the formation of a hematoma and compression of the airway. An air embolism can occur if the catheter lumens are left open to the air during insertion or if connections loosen and separate at a later time. Right ventricular irritation from the catheter tip can cause cardiac dysrhythmias. Puncture of the right atrial wall can lead to pericardial tamponade and death. The guidewire can

become entrapped, necessitating surgical or interventional radiology removal. Embolization of the guidewire or catheter parts occurs with improper use of the equipment. Anaphylactic reactions to antibiotic-impregnated catheters have been reported. The cardiac monitors should be observed during the procedure to prevent the death of a critically ill patient from being unnoticed while the catheter is being inserted. Thrombosis of the catheter or vein may lead to pulmonary embolism.

Many of these complications can be prevented or minimized with the use of US guidance. Karakitsos et al. showed a statistically significant difference between the blind and US-guided techniques with regard to arterial puncture, hematoma formation, hemothorax, pneumothorax, and infection rate.[67] All of these were in favor of the US-guided study arm. Multiple smaller studies have shown similar results in favor of the US-guided technique.[2,68–72] There is no specific report of complication rates involving the thoracic duct, nerve injury, or thyroid injury. This is likely due to the extremely rare incidence of damage to these structures. **Overall, US guidance has been shown to significantly reduce complications and improve patient safety for internal jugular vein access.** Complications during catheterization occur in proportion to the operator's inexperience.[64] If the patient is unlikely to survive a mistake, the most experienced person available should perform the procedure!

SUBCLAVIAN VEIN CATHETERIZATION

Complications of subclavian vein cannulation are similar to those of internal jugular vein cannulation, as described above. While there is no risk of carotid artery injury if the procedure is performed correctly, the subclavian artery can be lacerated if the needle is advanced too deeply. Malposition of the catheter tip, usually due to overinsertion of the catheter, is common. Lacerations of the thoracic duct can be avoided by performing the procedure on the right side, avoiding overpenetration with the introducer needle, and avoiding directing the needle too superiorly toward the junction of the subclavian vein and internal jugular vein. Other complications, such as injury to the brachial plexus and phrenic nerve, are uncommon but possible.[73] They can be prevented by avoiding over-insertion of the needle during the procedure and avoiding needle paths superior and posterior to the subclavian vein.

A pneumothorax is a very real risk with subclavian vein catheterization. The procedure should not be performed unless personnel are immediately available who can deal with this complication.[74] The risk of a pneumothorax is probably higher in obese patients, who may have distorted anatomic landmarks and in whom a more acute angle is required to enter the subclavian vein. Patients with emphysema and COPD may have higher pleural domes and less pulmonary reserve in the event of a pneumothorax.

FEMORAL VEIN CATHETERIZATION

Deep venous thrombosis of the femoral and more distal veins is a recognized complication of femoral venous lines.[56] Inadvertent cannulation of the femoral artery may occur. This is particularly true during an episode of severe hypotension or cardiac arrest. If such an episode goes unrecognized, infusion of vasopressors into the artery may result in ischemic injury to the distal limb.

Even though US guidance for femoral vein cannulation does not currently have large studies with robust data in the literature, anatomical visualization can be useful in multiple situations. Recent research depicting the anatomical variation and overlap between the femoral artery and the femoral vein in normal patients brings to question the safety of blind or landmark based venous cannulation. In a stable patient with a palpable pulse, US guidance may aid in identifying a very small femoral vein and/or significant arteriovenous overlap. In either situation, correction with reverse Trendelenburg or proper leg positioning under US guidance may allow the Emergency Physician a better target for cannulation and reduce complications. During periods of severe hypotension or cardiac arrest, palpation of the femoral artery may not be feasible. This can lead to failed access or arterial cannulation. Hilty et al. demonstrated a higher rate of success and a decreased rate of arterial cannulation with US guidance during CPR.[75] US guidance for femoral vein cannulation may not yet be a standard practice, but it may be a useful technique that can reduce the rates of complication of central venous cannulation.

SUMMARY

Central venous access is often necessary in critically ill patients and in those with poor peripheral veins. Mastery of these techniques is essential for anyone who will be caring for acutely ill and unstable patients. While all approaches to the central circulation have acceptably low complication rates (1% to 5%) when performed by experienced providers, they all carry real risks to the patient.[39,49] Be certain that there is no safer peripheral access alternative before placing a central venous line.

The internal jugular vein is a good choice for central venous access in nonambulatory patients. The right internal jugular vein provides easy access to the superior vena cava for monitoring and for infusion of solutions too concentrated or irritating for peripheral veins. This route poses a slightly lower risk of complications than the subclavian route.[64,66]

The subclavian vein provides easy access to the central circulation. Subclavian vein catheters are more easily tolerated by awake and ambulatory patients than are internal jugular or femoral catheters. Subclavian vein cannulation does present very real risks to the patient that must be balanced against the need for the procedure and other alternatives. Subclavian vein access is the least preferred route in young children due to their small size, the proximity of the pleura, and the proximity of the subclavian artery.

Femoral vein cannulation is an essential emergency skill. It allows the easiest central venous access in most patients with the lowest risk of catastrophic immediate complications compared to jugular and subclavian access procedures.

US guidance for central venous access, specifically the internal jugular vein has rapidly become integrated into the practice of Emergency Medicine. Familiarity with US guidance is become a mandatory skill for the Emergency Physician when placing central venous lines. Refer to Chapter 50 regarding the complete details of US-guided central venous access.

50 Ultrasound-Guided Vascular Access

Srikar Adhikari

INTRODUCTION

Central venous catheterization is essential in the management of critically ill patients seen in the Emergency Department (ED). It allows for fluid resuscitation, central venous pressure monitoring, pacemaker placement, and administration of vasoactive medications. Complications such as arterial puncture, hematoma, pneumothorax, hemothorax, and air embolus have been reported to occur in 5% to 20% of patients.[1–3] Unsuccessful cannulation has

been reported in up to 20% of cases.[4,5] Central venous catheterization has traditionally been performed using surface anatomic landmarks as a guide to locate the veins. Catheterization is not always successful using the landmark method due to anatomical variations or obscured landmarks. Other factors such as obesity, shock, dehydration, intravenous drug abuse, congenital deformities, thromboses, and scarring can complicate the procedure. Ultrasound (US)-guided vascular access is widely supported in current medical practice. The use of US guidance for central venous cannulation has been endorsed by several medical societies and supported by numerous trials in the literature. **US guidance has been shown to improve cannulation success rates, reduces mean insertion attempts, and reduce placement failure rates.**[6–11] US guidance allows the Emergency Physician to more precisely locate target vessels and also provide real time visualization of needle placement.

Peripheral venous access is more commonly performed in the ED than central venous cannulation. Patients with a history of chronic kidney disease, intravenous drug abuse, vascular disease, organ transplantation, and obesity lack easily located peripheral venous sites. Obtaining peripheral intravenous (IV) access in these patients can be a challenge, even for the most experienced medical personnel. Multiple studies have shown US-guided peripheral IV access is safe and successful in these patients.[12–17] US-guided peripheral IV access prevents the need for central venous catheterization and the pain of multiple needle sticks in many "hard-to-stick" patients.

ANATOMY AND PATHOPHYSIOLOGY

It is important to recognize the differences in sonographic appearance between arteries and veins when performing US-guided vascular access. Arteries and veins can be distinguished by their size, shape, location, ability to be compressed, Doppler mode signal, and spectral Doppler waveforms. Arteries have relatively thick and hyperechoic (white) walls and anechoic (black) lumens. Veins have relatively thin and hypoechoic (gray) walls and anechoic (black) lumens. The thin-walled veins are usually oval, easily compressible, and have no pulsations on Doppler mode (**Figures 50-1 & 50-2**). Arteries are typically round in appearance and pulsatile on Doppler mode (**Figure 50-1**). Arteries and veins are often found adjacent to each other. Veins are usually larger in diameter than arteries in a well-hydrated patient (**Figure 50-1**). The anatomy relevant to the sonographic evaluation of central and peripheral veins is described in the following sections.

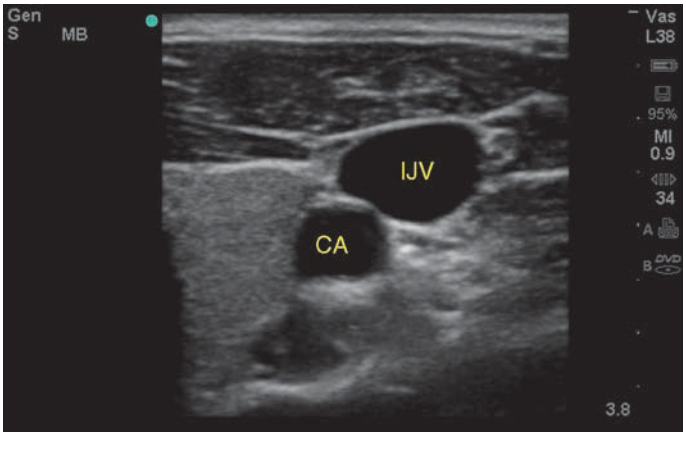

FIGURE 50-1. US image of the neck vessels. The internal jugular vein (IJV) is thin-walled and oval. The carotid artery (CA) is thick-walled and round.

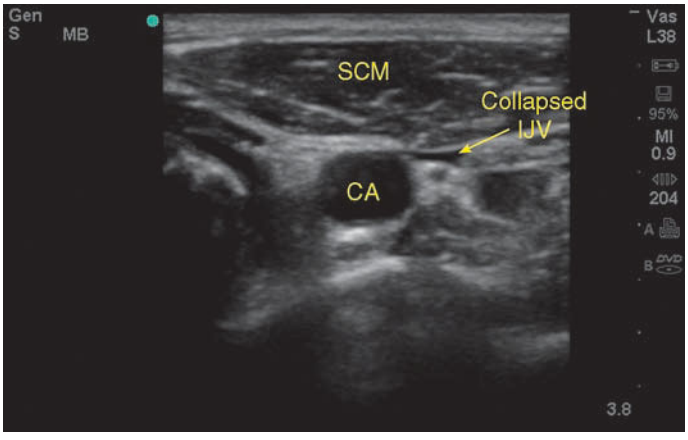

FIGURE 50-2. The US probe is used to apply external pressure to the soft tissues of the neck. The internal jugular vein collapses with gentle compression (CA, carotid artery; IJV, internal jugular vein; SCM, sternocleidomastoid muscle).

CENTRAL VEINS

The internal jugular and femoral veins are commonly used for US-guided central venous catheterization. US-guided subclavian vein cannulation is technically more challenging because the vein runs for a significant distance under the clavicle. The clavicle obstructs the US beam and produces a large acoustic shadow, which makes US visualization of this area difficult.

The internal jugular vein traverses the neck and is unopposed by bone, making it an ideal vein to visualize with US. The internal jugular vein lies underneath the bifurcation of the sternal and clavicular heads of the sternocleidomastoid muscle. It continues to run vertically downward in the neck, lying at first lateral to the internal carotid artery, and then lateral to the common carotid artery. It eventually enters the subclavian vein (**Figure 49-2**).

The common femoral vein lies medial to the common femoral artery and inferior to the inguinal ligament. In the upper thigh, the superficial femoral and deep femoral veins unite to form the common femoral vein. The greater saphenous vein joins the anteromedial aspect of the common femoral vein below the inguinal ligament (**Figure 50-3**). The common femoral vein becomes the external iliac vein after it passes under the inguinal ligament.

PERIPHERAL VEINS

The three veins of the upper extremity that are most commonly used for US-guided vascular access are the basilic, cephalic, and brachial veins. The venous drainage of the upper extremity consists of a deep system and a superficial system. The deep system includes radial and ulnar veins in the forearm that unite to form the brachial vein, which is the deep vein in the upper arm. The brachial vein lies next to the pulsatile and noncompressible brachial artery (**Figure 50-4**). It is not uncommon to find paired superficial and deep brachial veins. The two major superficial veins of the upper arm are basilic and cephalic veins. The cephalic vein arises from the radial aspect of the dorsal hand venous network, ascends proximally along the anterior border of the brachioradialis muscle, runs lateral to biceps muscle and joins axillary vein. The basilic vein begins in the ulnar side of the dorsal hand venous network, ascends along medial aspect of forearm and upper arm, and unites with the brachial veins to form the axillary vein.

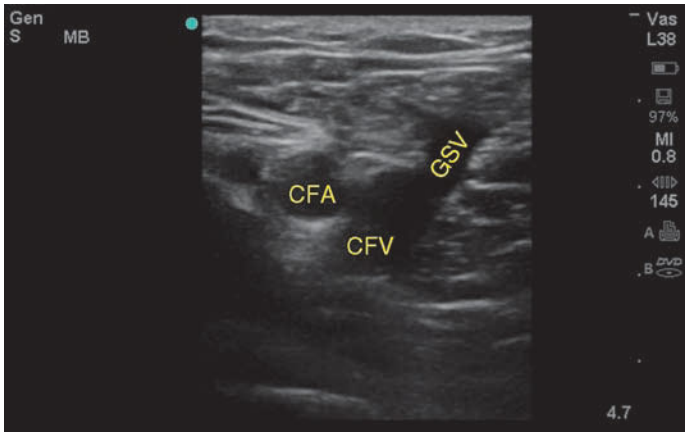

FIGURE 50-3. US image of the femoral vessels. The common femoral vein (CFV) lies medial to the common femoral artery (CFA). The superficially located greater saphenous vein (GSV) enters the common femoral vein 2 to 3 cm below the inguinal ligament.

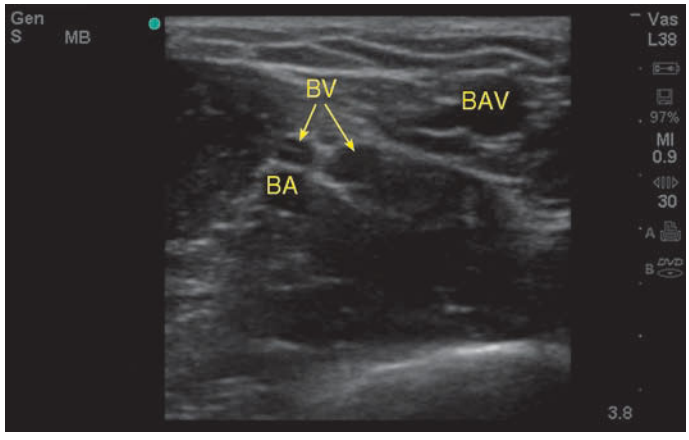

FIGURE 50-4. Transverse US view of the upper arm veins (BA, brachial artery; BAV, basilic vein; BV, paired brachial veins).

STATIC APPROACH TO VASCULAR ACCESS

The static approach to vascular access involves confirming the location of the vein prior to performing the cannulation. Place the US transducer perpendicular to the course of the vein to visualize the vein and verify compressibility. Adjust the probe so that the target vein is in the center of the US monitor screen. This places the vein directly under the center of the US probe. Place a mark on the skin at the midpoint of the US probe to mark the vein location. To assess the path of the vein, repeat this process at a point 2 cm away and along the vein. These two points marked on the skin will serve as a guide to direct the needle. Determine how deep the vein is located. Look at the depth markers on the side of the US monitor screen. Remove the probe and prepare the patient as usual.

Proceed with the catheterization. Insert the needle approximately 0.5 cm above or below the mark. Advance and direct the needle to the appropriate depth underneath the skin markings. If the patient changes position after marking the skin but before needle puncture, the patient must be re-imaged and the skin markings repeated prior to inserting the needle. The advantages of the static approach are its simplicity and that the US probe does not need to be prepared for the sterile portion of the procedure. The disadvantage of this technique is that the needle is not visualized in real time while performing the procedure.

DYNAMIC APPROACH FOR VASCULAR ACCESS

The dynamic approach to vascular access involves inserting the needle into the vein under real time US guidance. Two techniques are used for the dynamic approach and they refer to the orientation of the US probe and target vein during the venipuncture. The short axis approach visualizes the vein in a cross section. The long axis approach visualizes the vein longitudinally.

Each approach has its own advantages and disadvantages. The short axis approach provides better medial to lateral orientation of the needle in relation to the target vein and also allows for visualization of adjacent structures in the same image. Novice sonographers can learn the short axis approach more quickly and it can be performed in anatomic locations where space is limited such as the neck or the groin in an obese patient. One potential danger with the short axis approach is unseen penetration of the posterior wall of the target vein and adjacent structures. The long axis approach allows better depth and needle slope information. The entire needle can be tracked with this approach. The long axis approach provides much better visualization of the tip of the needle and its trajectory, thus avoiding inadvertent puncture of the posterior wall of the vein. The long axis approach requires more hand–eye coordination and is technically more difficult to learn.

INDICATIONS

US can be used to mark the site of needle entry or provide real time guidance. Ideally, US guidance should be used for all internal jugular and femoral vein cannulations if the equipment is available. It should also be used for peripheral IV access in all "hard-to-stick" patients or when a peripheral vein is not visible or palpable. The use of US-guided peripheral IV access in the patient with difficult peripheral IV access can prevent the need for central venous access. It is highly recommended in the patient with poor anatomic landmarks, coagulopathies, anticoagulant use, a history of difficult IV access, DIC, thrombocytopenia, prior surgical interventions or radiation in the area, scarring on the skin above veins, intravenous drug abuse, obesity, hypotension, and severe dehydration.

CONTRAINDICATIONS

There are no absolute contraindications to the use of US for central or peripheral venous access except lack of US training and experience.

EQUIPMENT

- Ultrasound machine
- Ultrasound gel
- High frequency, 5 to 10 MHz linear array US probe
- Sterile US probe cover (clear plastic cover, US gel, and rubber bands)
- Povidone iodine or chlorhexidine solution
- Equipment for peripheral IV access (Chapters 47 and 48)
- Equipment for central venous access (Chapter 49)
- Water-soluble lubricant, sterile
- Translucent dressing (e.g., Tegaderm)
- 2 to 3 inch (in) long catheter-over-the-needle, various sizes

PATIENT PREPARATION

CENTRAL VENOUS ACCESS

Position the patient the same as if performing central venous catheterization using the landmark method (**Figure 50-5**). Place the US machine across from where you will be standing to minimize the body movement required to view the US image. For internal jugular vein access, stand at the head of the patient with the US machine at the patients hips (**Figure 50-5A**). Place the patient in the Trendelenburg position with their head turned to the contralateral side or kept in a neutral head position (**Figure 50-5A**). The relationship of the internal jugular vein to the carotid artery changes with head position. In the neutral position, the internal jugular vein assumes a more lateral position to the carotid artery. This minimizes the risk of arterial puncture while accessing the target vein. For femoral vein access, stand at the bedside adjacent to the patient's hip with the US machine above the patient's shoulder (**Figure 50-5B**). Place the patient in the reverse Trendelenburg position with their hip abducted and externally rotated (**Figure 50-5B**). This position enhances the success rate of catheterization by increasing the surface area of the femoral vein available for cannulation.[18]

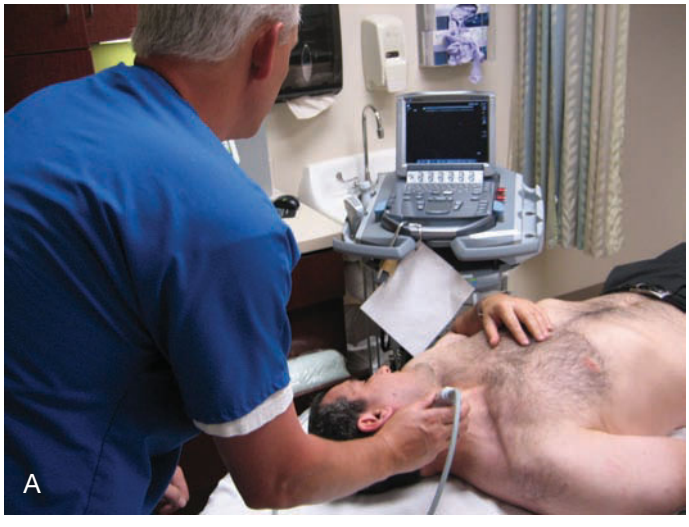

FIGURE 50-5. Patient and US machine positioning for central venous access. **A.** Internal jugular vein access. **B.** Femoral vein access.

Perform a preliminary scan prior to preparing the patient for the sterile procedure. Survey the underlying vasculature to confirm the patency of the target vein, determine the optimal site for venipuncture, and adjust the US machine settings to optimize the image. The ability of the vein to be compressed distinguishes artery from vein, confirms the patency of the vein, and reduces the risk of cannulating a thrombosed vein. Do not assess compressibility in the long axis. The US probe may slide off the vein and be seen as the vein lumen disappearing and misinterpreting it as being compressible. Clean and prep the skin at the access site as if performing a traditional central line placement. **Follow strict aseptic technique and all barrier precautions during the procedure.**

The procedure can be performed by either one person (the Emergency Physician) or two people (the Emergency Physician and an assistant). Using the two-person technique, one person stabilizes the US probe over the vein and the other performs the procedure. Prepare the US probe as discussed below.

US PROBE PREPARATION

A high frequency, 5 to 10 MHz, linear array US probe is typically used for US-guided vascular access. These US probes produce linear images and are ideal for visualization of superficial structures such as veins. **Always use a sterile US probe cover and sterile US gel when performing central venous catheterization.** Set up a sterile field on a bedside table. Open the US probe cover set onto the sterile field.

Instruct an assistant to hold the US probe upright and place standard or sterile US gel on the footprint of the US probe (**Figure 50-6A**). Apply the sterile probe cover over the US probe (**Figure 50-6B**). Smooth all the air bubbles away from the footprint of the US probe to prevent imaging artifacts. Secure the cover with rubber bands to prevent it from sliding off the US probe (**Figure 50-6C**). Place the US probe on the sterile field (**Figure 50-6D**). Apply sterile US gel onto the cover over the probe footprint just before scanning.

US PROBE ORIENTATION

Orient the US probe. In the short axis approach, the marker on the US probe and the marker on the US machine screen should be aimed in the same direction (**Figure 50-7**). If the needle moves to the right side of the US probe, the needle also moves to the right on the US machine screen. This helps to accurately move the needle right to left while directing the needle towards the vein. This makes performing the procedure less complicated. In the long axis approach, it is important to know which way the probe marker is directed (cephalad or caudad) so that the Emergency Physician knows which side of the screen the needle will come from (i.e., the right or left of the image).

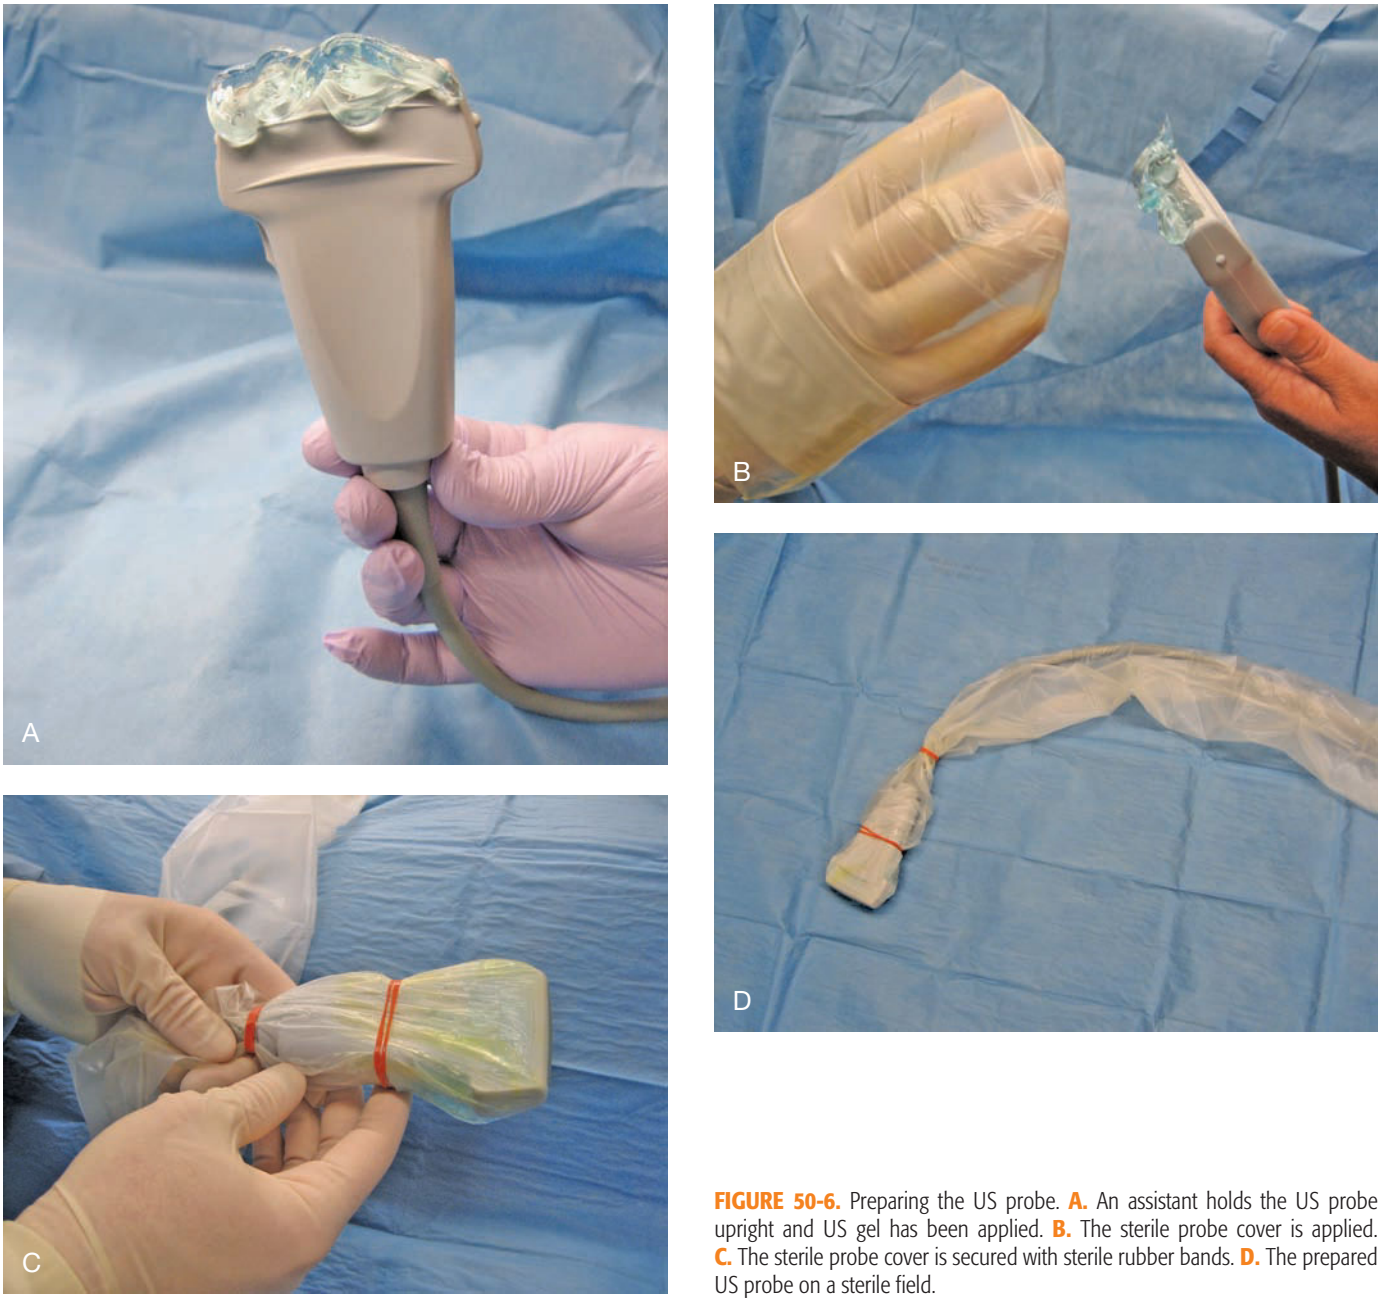

FIGURE 50-6. Preparing the US probe. **A.** An assistant holds the US probe upright and US gel has been applied. **B.** The sterile probe cover is applied. **C.** The sterile probe cover is secured with sterile rubber bands. **D.** The prepared US probe on a sterile field.

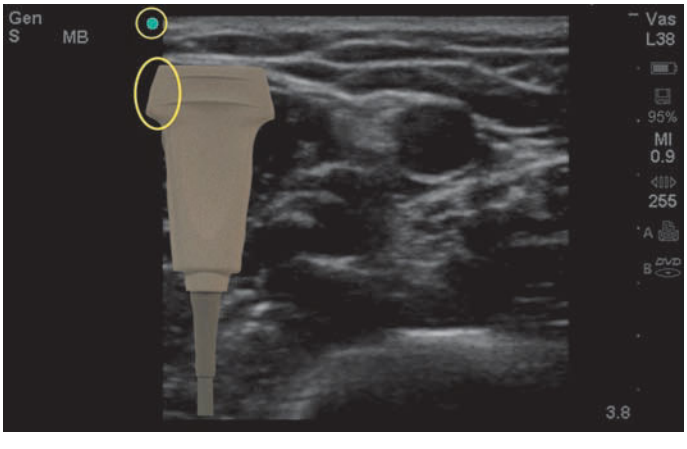
IDENTIFICATION OF VEINS

Identify and verify the vein depth, direction, and patency prior to the procedure. To locate the internal jugular vein, place the US probe in the triangle formed by the two heads of sternocleidomastoid muscle and clavicle (**Figure 50-8A**). Scan from the apex of the triangle to the clavicle. Visualize the internal jugular vein, carotid artery, and thyroid gland (**Figure 50-8B**). The internal jugular vein is an irregular and oval-shaped structure lateral to the carotid artery (**Figures 50-8B & C**). Visualize the internal jugular vein and identify its widest diameter, the depth from the skin surface, and its relationship to the carotid artery. Instruct the patient to perform a Valsalva maneuver to increase venous flow and distend the internal jugular vein while observing the US machine screen to note the changes in the US appearance of the vein.

To locate the common femoral vein, scan below the midpoint of inguinal ligament (**Figure 50-9A**). The common femoral



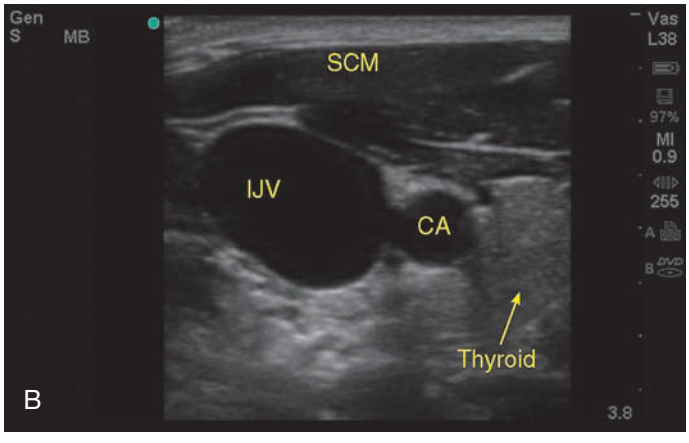


FIGURE 50-7. The US probe marker and the marker on the US machine screen are aimed in the same direction.

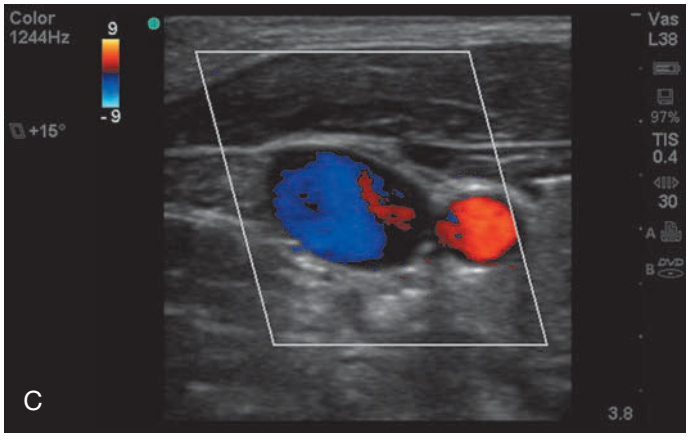

FIGURE 50-8. Identification of the internal jugular vein. **A.** Patient and US probe positioning. **B.** US image of the transverse or short axis view in B-mode. **C.** Short axis view in color Doppler mode. The large blue internal jugular vein is clearly visible adjacent to the red carotid artery (CA, carotid artery; IJV, internal jugular vein; SCM, sternocleidomastoid muscle).

artery should be clearly visible next to the common femoral vein (**Figure 50-9B**). The greater saphenous vein merges with the common femoral vein on the medial aspect. Visualize the common femoral vein and identify its widest diameter, the most superficial location, the depth from the skin surface, and a location that does not overlap with the common femoral artery.

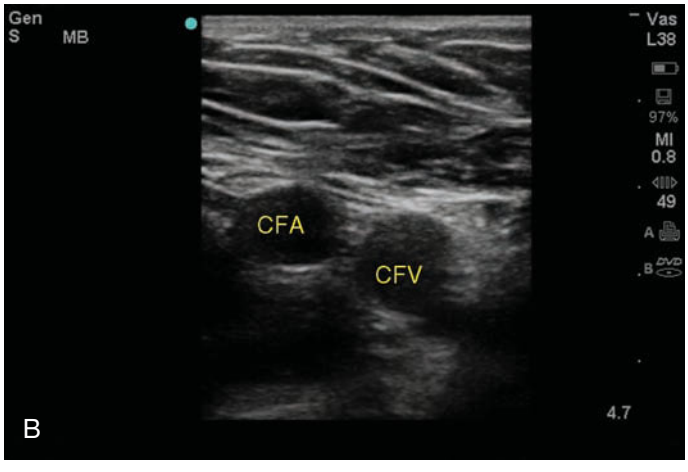

FIGURE 50-9. Identification of the common femoral vein. **A.** Patient and US probe positioning. **B.** US image of the transverse or short axis view in B-mode (CFA, common femoral artery; CFV, common femoral vein).

Do not apply excessive pressure with the US probe when assessing the vein. Excessive pressure can collapse the vein and makes it difficult to identify. Verify that the identified vessel is compressible and truly a vein (**Figure 50-2**). **The ability of the vein to be compressed distinguishes artery from vein, confirms the patency of the vein, and reduces the risk of cannulating a thrombosed vein.** Do not assess compressibility in the long axis. The US probe may slide off the vein and be seen as the vein lumen disappearing and misinterpreting it as being compressible.

Doppler US can be used to identify vascular structures. Color Doppler ensures the patency of blood vessels (**Figure 50-8C**). Spectral Doppler distinguishes blood flow patterns. Spectral Doppler demonstrates continuous venous flow in the internal jugular and femoral veins (**Figure 50-10A**). Triphasic pulsatile flow is seen on spectral Doppler in the carotid and femoral arteries (**Figure 50-10B**).

TECHNIQUES

SHORT AXIS APPROACH TO CENTRAL VENOUS ACCESS

The short axis approach allows visualization of the vein in cross section. This view is obtained by placing the US probe

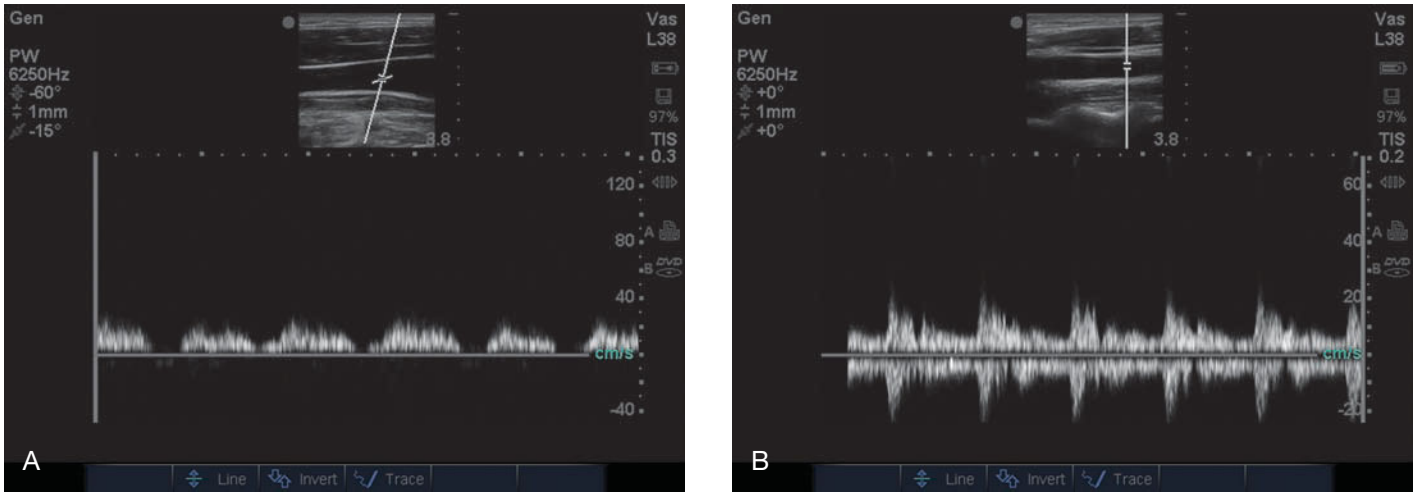

FIGURE 50-10. Long axis US images of spectral Doppler waveforms. **A.** The internal jugular vein. **B.** The carotid artery.

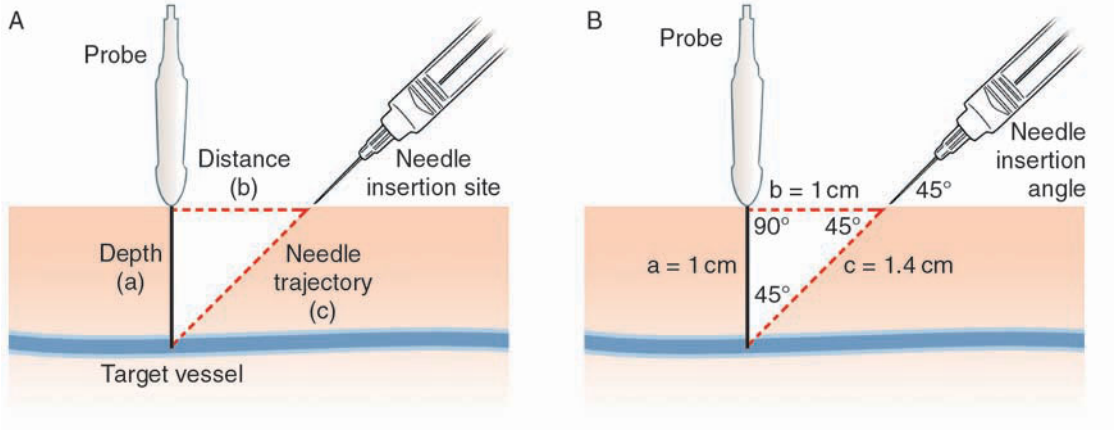
perpendicular to the long axis of the vein. The vein appears oval-shaped in this view (**Figures 50-1, 50-8B, & 50-9B**). Place sterile US gel on the skin above the vein and on the footprint of the sterile US probe. Grasp the US probe with the nondominant hand and the needle with the dominant hand. As described previously, reidentify the vein and the optimal site of needle insertion. Adjust the US probe to center the target vein on the US machine screen. The midpoint of the US probe now becomes the reference point for needle insertion.

Select the skin entry site to maximize the chances that the tip of the needle punctures the vein as well as intersect the US probe scan plane. The geometry of the Pythagorean Theorem ($a^2 + b^2 = c^2$) can be used to assess the distance to insert the needle into the skin and away from the US probe (**Figure 50-11**). Measure the distance from the skin surface to the center of the vein. This distance is equal to the distance from the probe to where the needle punctures the skin at a 45° angle. For example, if the distance from the skin surface to the center of the vein is 1 cm, make the skin puncture 1 cm from the midpoint of the US probe along the trajectory of the vein (**Figures 50-11A & B**). Insert and advance the needle at a 45° angle. The vein will then be punctured after the needle is inserted 1.4 cm. **It is very useful to assess the distances using this method before venipuncture to avoid complications.** If the vein is not punctured within the expected inserted needle length, the needle trajectory is not accurate and should be reassessed.

It is important to understand that the US beam is very narrow and only 1 to 2 mm wide despite the US probe being approximately 1 cm wide. **The needle will be visualized only when it is within this narrow beam width. The cross section of the needle in the short axis approach will be seen only when it crosses the US scan plane that is oriented perpendicular to the needle.** The needle tip or shaft will appear as a hyperechoic dot within the vein (**Figure 50-12A**). It will be seen in association with either an acoustic shadow (black) or a reverberation or ring down artifact (white echoes) posterior to the needle (**Figure 50-12B**).

Clean, prep, and anesthetize the skin after estimating the distance to the vein. Insert and advance the needle at a 45° angle (**Figure 50-13**). During the initial portion of the needle path, its location can only be identified by signs of it pushing through the tissue as soft tissue movement. This is because the needle has not yet crossed the US probe scan plane. Small, rapid, and in-line



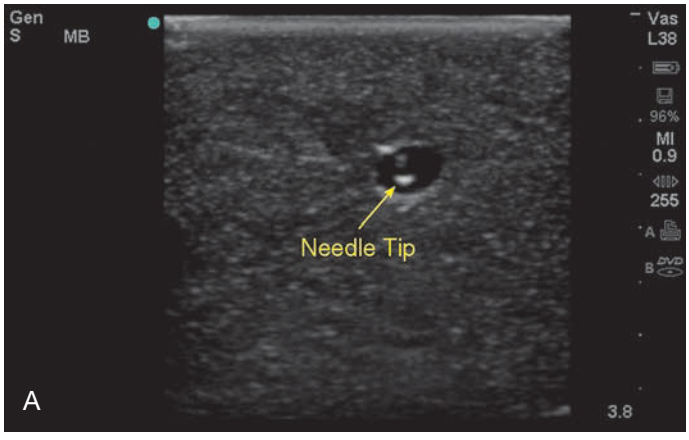


FIGURE 50-11. The short axis approach needle insertion based on the Pythagorean theorem. **A.** The depth (a) equals the distance from the US probe (b) to insert the needle at a 45° angle. **B.** A sample calculation where $a^2 + b^2 = c^2$.

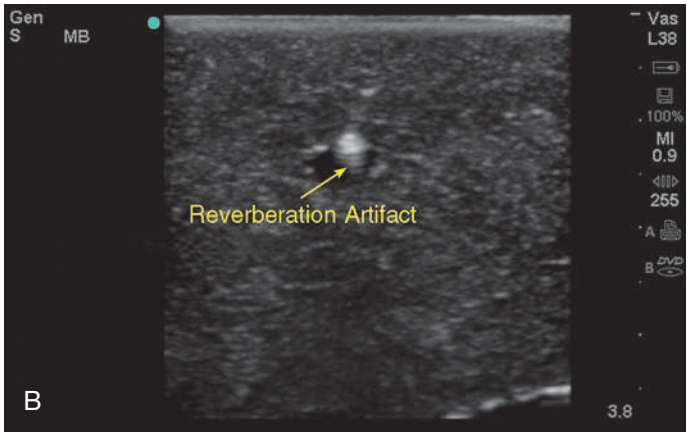

FIGURE 50-12. Short axis US image of a needle within a vein. **A.** The needle tip is visible as a hyperechoic dot inside the lumen. **B.** The reverberation or ring down artifact from the needle.

movements of the needle are helpful to locate the needle tip on the US image. **Do not mistake the needle shaft for the needle tip.** Always try to locate the needle tip by angling or fanning the US probe. As the needle contacts the anterior vein wall, it will tent or buckle the vein wall (**Figure 50-14**). The wall of the vein will first collapse downward as it is being punctured and then return to normal after the wall is punctured. Visualize the hyperechoic needle tip within the lumen of the vein to confirm the needle entered the vein (**Figure 50-12**). A concurrent flash of blood will be seen in the syringe. Place the US probe back onto the sterile field. The remainder of the procedure is as described for the landmark technique of central venous access (Chapter 49).

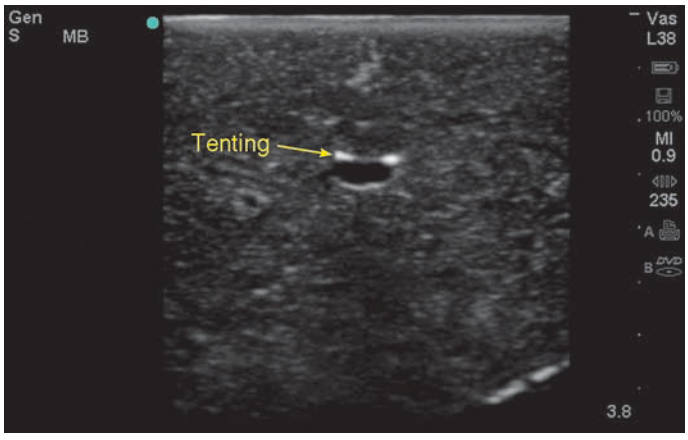

FIGURE 50-14. Short axis US image demonstrating tenting of the anterior wall of the vein as it is penetrated by the needle.

LONG AXIS APPROACH TO CENTRAL VENOUS ACCESS

The long axis approach targets the vein along its length in the longitudinal plane. Grasp the US probe in the nondominant hand and the needle with the dominant hand. Locate the target vein using the short axis approach. Verify it is compressible. Slowly rotate the US probe to visualize the vein in the long axis. The US probe should be positioned directly over the vein so that its long axis is parallel to the long axis of the vein (**Figure 50-15**). Adjust the US probe to visualize the vein at its greatest anteroposterior diameter.

Insert the needle through the skin at approximately a 30° angle adjacent to one end of the US probe (**Figures 50-15 & 50-16**).

FIGURE 50-13. The short axis approach for venous access.

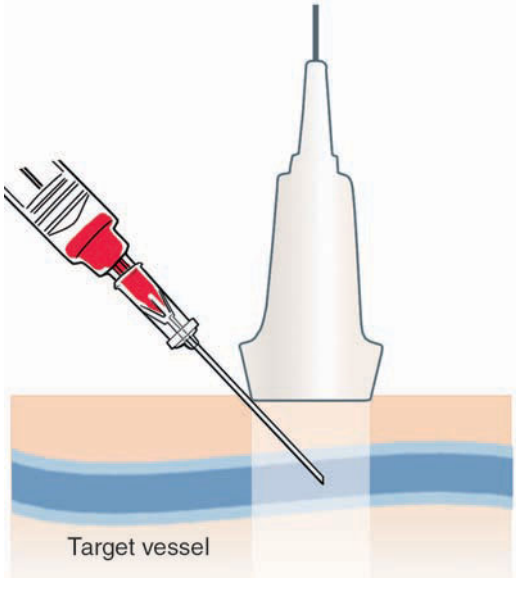

FIGURE 50-15. The long axis orientation and needle insertion.

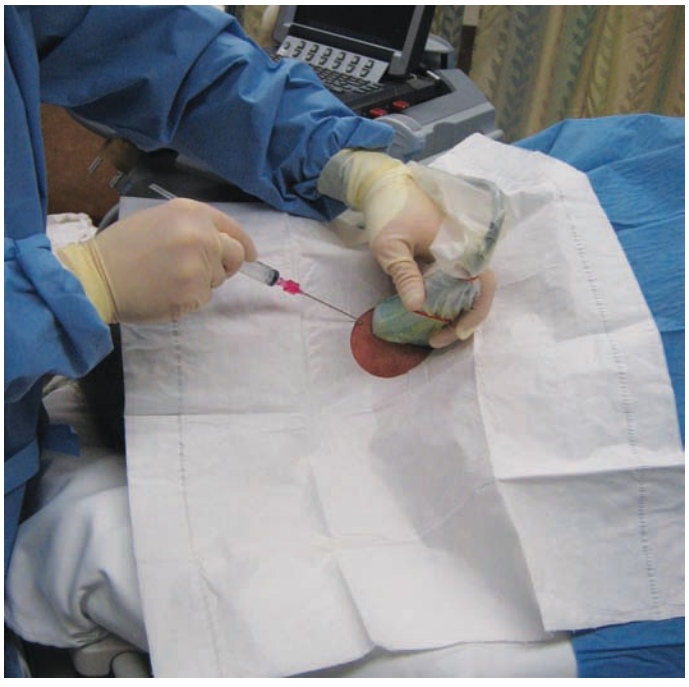

FIGURE 50-16. The long axis approach for venous access.

The needle should be in the plane that is in-line with the long axis of the US probe and in the exact same plane as the US beam. With this approach, it is crucial to keep the US probe steady and over the vein. Advance the needle. The needle tip and shaft will be visualized in real time as it travels through the subcutaneous tissues and into the lumen of the target vein (**Figure 50-17**). If it is not visualized in the US image, the needle plane and US probe scan plane are not aligned. Do not advance the needle any further. Withdraw the needle toward the skin and redirect it to align it with the US beam and the long axis of the vein.

PERIPHERAL VENOUS ACCESS

Place the patient supine with their upper extremity abducted to expose the anteromedial aspect of the upper arm (**Figure 50-18**).

FIGURE 50-18. Patient and US machine positioning for upper extremity peripheral venous access.

Place a tourniquet on the upper arm, just below the axilla, to distend the veins. Sit or stand at the patient's bedside facing the patient. Position the US machine so that the screen is easily visible (**Figure 50-18**). To locate the veins and find the ideal venipuncture site, scan the entire upper arm from just below the tourniquet to the elbow. Identify the basilic vein along the medial aspect of the upper arm (**Figure 50-19**). Move the US probe slightly laterally to visualize the brachial vein adjacent to the brachial artery. Scanning further laterally will identify the cephalic vein. Peripheral veins collapse very easily. Minimize the pressure placed upon the skin surface with the US probe. Too much pressure can collapse these veins and make them difficult to identify. Identify the segment of vein that is widest in diameter, closest to the skin surface, and not adjacent to an artery. Verify that the vein is compressible and patent as described previously.

Prepare the skin insertion site similar to peripheral IV placement. There is no need to follow any special precautions such as a sterile US probe cover. Apply a large transparent dressing (e.g., Tegaderm) onto the footprint of the linear array US probe. Make sure that no air bubbles are trapped between the transparent

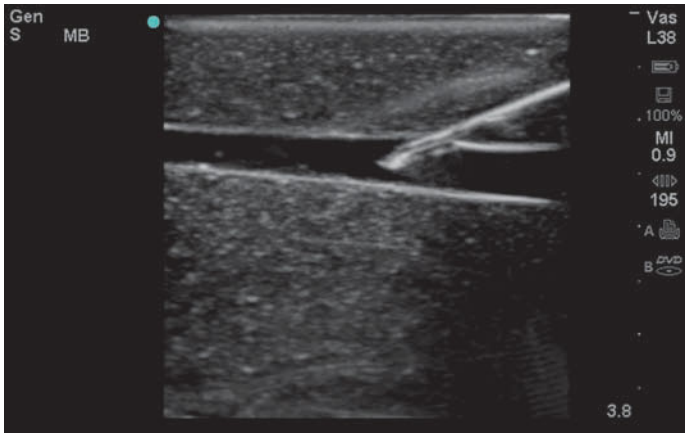

FIGURE 50-17. Long axis US image of the needle shaft in the subcutaneous tissues and the tip inside the lumen of the vein.

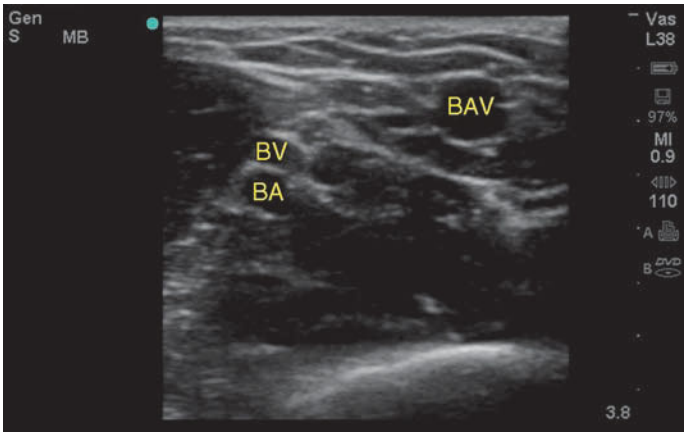

FIGURE 50-19. Short axis US image of the basilic and brachial veins (BA, brachial artery; BAV, basilic vein; BV, brachial vein).

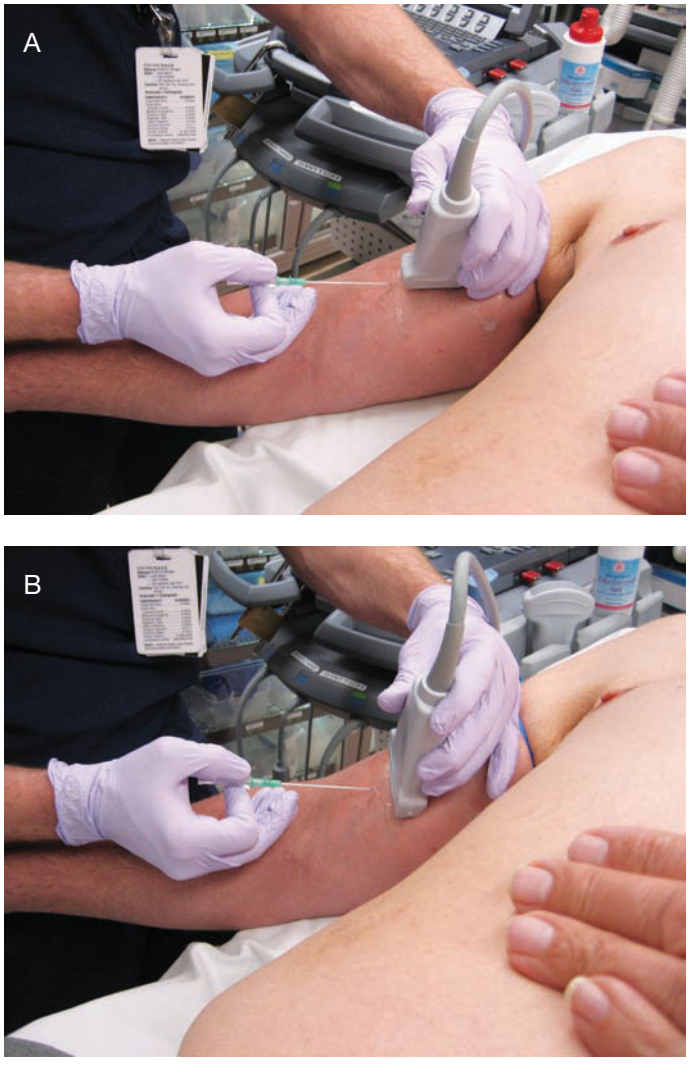

FIGURE 50-20. US probe and needle insertion for upper extremity venous access. **A.** Long axis approach. **B.** Short axis approach.

dressing and the US probe. The transparent dressing keeps the field sterile and prevents contamination of the US probe with blood. Use a water-soluble lubricant (e.g., Surgilube) instead of US gel for scanning. Use a 2.5 to 3.0 in long catheter-over-the-needle for US-guided peripheral IV access. Standard length peripheral IV catheters are too short to reach or stay within the lumen of the vein. Identify the vein in either the long axis (**Figure 50-20A**) or the short axis (**Figure 50-20B**) using the methods described previously. Insert the catheter-over-the-needle under US guidance. Once the tip of the needle is within the lumen of the vein, advance the catheter into the vein (**Figure 50-21**). Put down the US probe. Withdraw the needle, attach IV tubing onto the hub of the catheter, and secure the catheter.

ARTERIAL ACCESS

US guidance can be used to assist in obtaining an arterial blood gas and the placement of an arterial catheter. Identify the artery by its round shape, relatively thicket walls, noncompressibility, and pulsatile contractions. The procedure of cannulating an artery is the same as described above for a vein. Refer to Chapter 57 for the complete details regarding arterial puncture and cannulation.

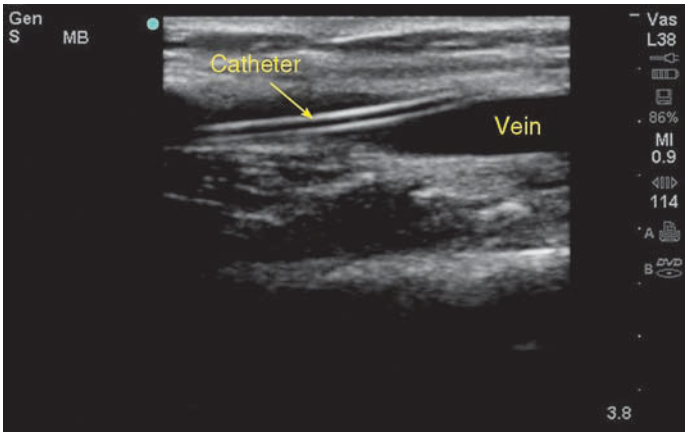

FIGURE 50-21. Long axis US image of a cannulated peripheral vein. The catheter is visible inside the lumen of the vein.

ASSESSMENT

Scan along the length of the cannulated vein in both the long axis view and the short axis view. Confirm the placement of the catheter within the lumen of the vein (**Figure 50-21**).

AFTERCARE

No specific aftercare is required following the US guidance. The aftercare procedures are related to the central venous line (Chapter 49) and peripheral IV (Chapters 47 & 48) placement.

COMPLICATIONS

Complications related to using US for vascular access are generally due to a poor technique or misinterpretation of images. An artery can be misinterpreted as a vein. There is no exposure to ionizing radiation. No increased risk of infections has been reported with the use of US when aseptic technique was followed. US guidance can be more time consuming when used for routine peripheral IV access. Its use may actually save time in the patient with difficult venous access. Using too short of a peripheral IV catheter can result in it being pulled out of the vein and the infusion solution extravasating. This can be prevented by using a longer (2 to 3 in) catheter-over-the-needle and/or inserting the catheter at a steeper angle to minimize the distance it travels in the subcutaneous tissues.

SUMMARY

US-guided vascular access is widely supported in current clinical practice. It can be used for both central and peripheral IV access. US guidance has been shown to reduce failure rates and many of the complications associated with the traditional landmark technique. The benefits of US guidance include precise localization of the target vein, visualization of adjacent structures, identification of anatomic variations, avoidance of veins with thromboses, and real time visualization of venipuncture. Knowledge of the sonographic anatomy and basic US technology combined with hand–eye coordination are essential to perform this procedure. Understanding the principles discussed in this chapter will enhance the success rate of vascular access.

51 Troubleshooting Indwelling Central Venous Lines

James J. McCarthy

INTRODUCTION

Indwelling central venous lines are an essential part of the care of both the acutely and chronically ill patients. These patients may require implanted venous access devices due to their poor peripheral venous access or for long-term intravenous therapies. When an indwelling central venous line is malfunctioning, the Emergency Physician must act quickly and thoughtfully to diagnose and correct the malfunction without further damaging the device. Understanding the different etiologies and a thorough assessment are critical to the successful management of a central venous catheter malfunction.

ANATOMY AND PATHOPHYSIOLOGY

Indwelling central venous catheters allow access to the central venous circulation from a peripheral site. This access to the central circulation is via the end of a partially implanted catheter that protrudes from the body or through the skin into a subcutaneous reservoir of a fully implanted catheter.[1,2] The proximal tip of the central venous line will typically reside in either the superior vena cava, the inferior vena cava (less commonly), or the right atrium.

Indwelling central venous access devices can malfunction for a variety of reasons. The two most common types of vascular catheter complications are thrombotic occlusions and infections.[3] The etiology of the malfunction can be divided into two main categories: external to the catheter and internal to the catheter. External malfunctions are for the most part mechanical malfunctions. Examples include catheter migration, the catheter tip abutting a vessel wall, a mural thrombus, and kinked catheters. Internal malfunctions can be further divided into thrombotic (e.g., intraluminal thrombus, fibrin sheath, and fibrin tail) and nonthrombotic (e.g., drug/drug precipitate, insoluble salts, lipid precipitate, and drug/solution precipitate).[3–5] Phenytoin and diazepam cannot be given through silicone indwelling lines as they can crystallize and permanently obstruct the catheter lumen.[4] Calcium and phosphate can form an insoluble precipitate within the catheter lumen. Infused lipids can form waxy casts within the catheter lumen.

INDICATIONS

Any catheter that cannot be easily flushed or aspirated requires further investigation. If peripheral venous access is readily available, and the patient is not acutely ill due to catheter sepsis or central venous thrombosis, catheter troubleshooting may be deferred to the Primary Care Provider. It is important to consider that delaying troubleshooting may make management more difficult and therefore necessitate line replacement. However, the Emergency Physician will have to address the problem if emergent or urgent access to the patient's central vascular system is required.

CONTRAINDICATIONS

Any device that is obviously displaced from the central circulation is not salvageable and should not be used. Dislodging a clot or septic thrombus from a catheter tip can lead to a fatal pulmonary embolism. Catheter manipulation should be avoided if signs of sepsis or central venous thrombosis are present.[6] The use of indwelling dialysis lines for purposes other than dialysis is discouraged. Manipulation of a dialysis line should only be undertaken in a true emergency or if the line is malfunctioning and is needed for hemodialysis.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile alcohol prep pads
- Thrombolytic agent
- Syringes, 5 mL and 10 mL
- 18 gauge needles
- Noncoring (Huber) needle
- 70% ethanol solution
- 0.1 N hydrochloric acid (HCl) solution
- Sterile saline
- Heparinized saline flush solution (100 U/mL)
- Sterile gauze squares
- Sterile gloves

Repair kits are available to repair some externally damaged partially implanted catheters. The kits avoid the need to remove the device and implant a new catheter. If the external tubing of the device is damaged, apply a smooth catheter clamp proximal to the damaged area and arrange to have the device repaired. The use of these kits is beyond the scope of this chapter.

THROMBOLYTIC AGENTS

The use of a specific thrombolytic agent is institution-specific and physician-specific. Streptokinase, recombinant tissue plasminogen activator (t-PA), Reteplase, and urokinase have all been successfully used to dissolve a clot within a central venous catheter.[4,7–12] Volumes and doses of the drugs differ significantly and careful attention should be paid to the medication administration. Urokinase and recombinant tissue plasminogen activator are most commonly used. Streptokinase is more likely to lead to a hypersensitivity reaction, especially if the patient has prior exposure to it, and is therefore not recommended. Urokinase is the thrombolytic agent used by most institutions because it is much less expensive than t-PA. Urokinase may be purchased in concentrations of 5000 U/mL and 250,000 U/5 mL (50,000 U/mL). The concentration of 5000 U/mL is used for dissolving a clot within a catheter. Some institutions prefer to use t-PA for this process. The Pharmacist dilutes a 50 mg vial of t-PA with 50 mL of sterile water to produce 25 syringes containing 2 mg of t-PA in 2 mL (1 mg/mL). The syringes of t-PA are then frozen until needed. It is also available from the manufacturer in 2 mg single use vials. Standard dosing for catheter obstructions is 1 mL of urokinase (5000 U/mL), 2 mL of t-PA (1 mg/ml), or 0.4 units of Reteplase.[15]

PATIENT PREPARATION

Discuss the procedure with the patient and/or their representative. Most patients with indwelling central venous access devices are very familiar with their use and idiosyncrasies. The patient will often be able to tell the Emergency Physician if the line has had problems in the past and the method used to correct the problem. Some patients will be able to suggest postural changes (e.g., raising an arm or lying in the Trendelenburg position) that will help the catheter function better. Obtain a posteroanterior and lateral chest radiograph to confirm that the tip of the catheter is in a proper location.

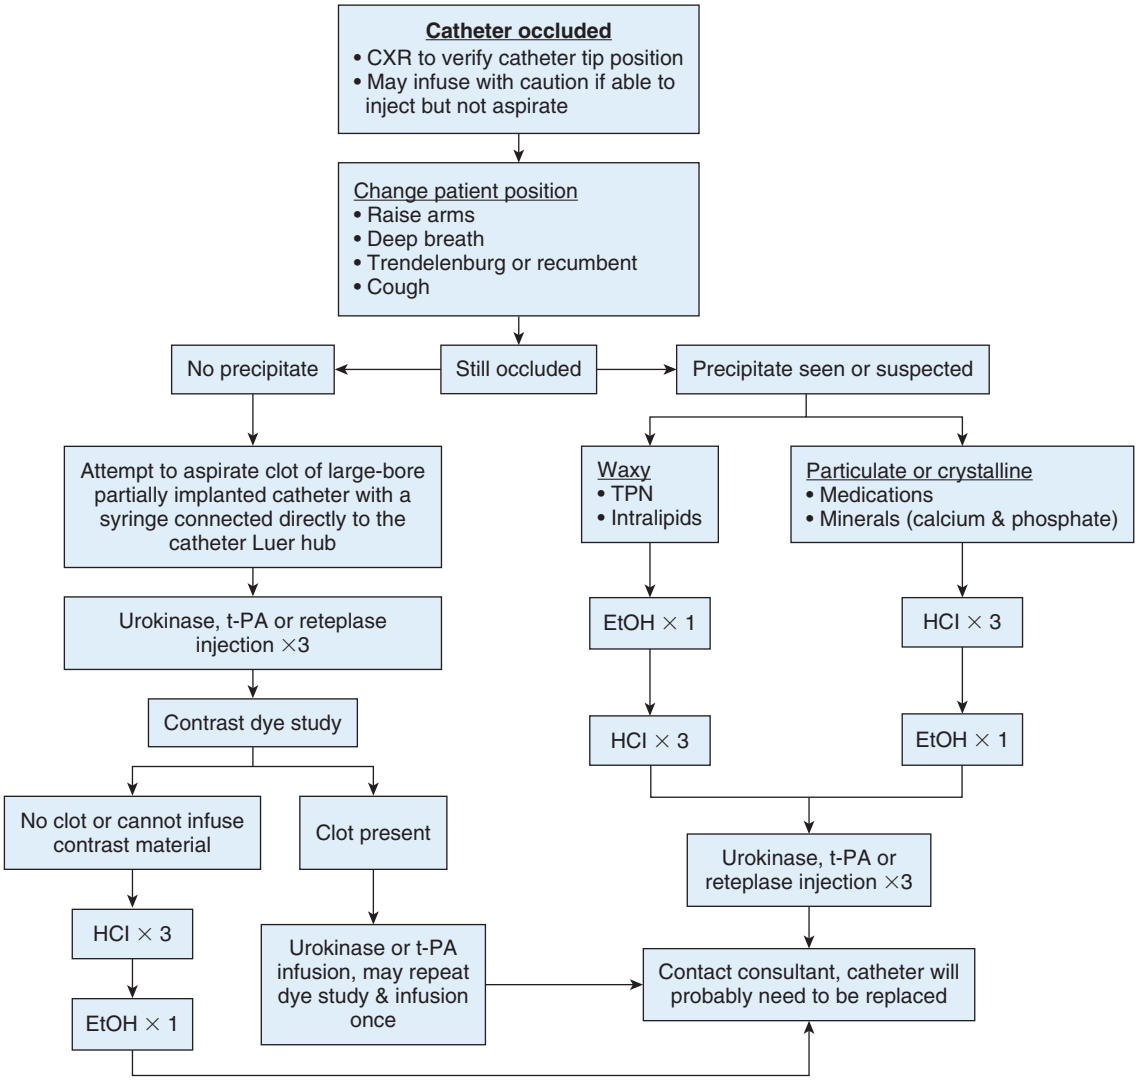

FIGURE 51-1. An algorithmic approach to the occluded central venous catheter. Continue to work down the protocol until the occlusion is resolved (CXR, chest radiograph; EtOH, 70% ethanol in water; HCl, 0.1 normal hydrochloric acid solution; TPN, total parenteral nutrition).

The chest radiograph is a good screening tool that allows the Emergency Physician to often diagnose catheter complications. A malpositioned catheter or one with the tip abutting the vessel wall must be removed and replaced. A catheter whose flow changes with patient arm position may be subject to the "pinch-off" phenomenon. This may be visible as a kinking of the catheter as it passes between the clavicle and first rib. A series of chest radiographs with the arm at the patient's side and elevated may reveal the kinking or pinching-off of the catheter. These catheters require removal. A catheter may migrate intravascularly so that it is within the contralateral subclavian vein. An Interventional Radiologist may be able to insert a wire or snare into the femoral vein to grasp and reposition the catheter. Arrhythmias associated with a catheter tip positioned within the heart require the catheter to be removed and a new one inserted. The distal catheter can curve upward so that it lies within the jugular vein. An Interventional Radiologist may be able to reposition it. Otherwise, it must be removed and replaced.

Any manipulation, injection, or aspiration of a central venous line must be done using strict aseptic techniques. Clean any dirt and debris from the distal port of a partially implanted device or the skin overlying the reservoir of a fully implanted device. Apply povidone iodine or chlorhexidine and allow it to dry. Wipe off the iodine (if used) with a sterile alcohol prep pad. **This process must be performed every time a needle is inserted into a central venous access device.**

TECHNIQUES

An algorithmic approach to the occluded indwelling central venous catheter is summarized in **Figure 51-1**.[9,14] **The key principle is that forced irrigation of the catheter, especially with a 1 mL syringe, is never performed as the catheter may rupture.**

A catheter that flushes easily but cannot be aspirated may have a fibrin sheath around the catheter tip forming a one-way valve. The tip may also be lodged against the wall of the superior vena cava or the right atrium. Repositioning the patient may alleviate the problem. The catheter may be cautiously used for an infusion if there are no signs of infection (e.g., new heart murmur, fever, erythema, or discharge at the catheter or subcutaneous reservoir

site) and the catheter tip is in good position. Refer the patient to their Primary Care Provider or a consultant for follow-up of the malfunction.

The problem is more serious if the catheter does not easily flush. Attempt to obtain peripheral intravenous access while attempting to correct the problem with the central venous catheter. If there are no signs of infection, and the catheter is not ruptured or malpositioned, the Emergency Physician must decide if a prolonged effort at resolving the occlusion is necessary. If so, proceed as described below and in **Figure 51-1**.

PARTIALLY IMPLANTED CATHETERS

A clot or small amount of precipitate within the partially implanted catheter may be able to be aspirated if the catheter bore is large enough to permit passage. Remove the Luer-lock cap from the catheter. Connect a 10 mL syringe with 2 to 3 mL of sterile saline directly to the occluded port's Luer adapter. Any clot large enough to occlude the catheter will not pass through a needle. Apply negative pressure to the syringe. The catheter is probably occluded by a clot or a precipitate if the obstruction cannot be aspirated. Remove the syringe and attach a new Luer-lock cap.

If a precipitate is seen in the catheter aspirate, determine if it is waxy or solid. Waxy precipitates are due to the lipid component of parenteral nutrition fluids. Waxy precipitates may be dissolved with a solution of 70% ethanol in water. Inject 1 to 2 mL of this alcohol–water solution and allow it to dwell in the catheter for 1 hour. Aspirate the catheter to determine patency. If still occluded, inject 1 to 2 mL of 0.1 N hydrochloric acid solution. Allow the solution to dwell in the catheter for 20 minutes. Aspirate the catheter to determine patency. Attempt to infuse 0.1 N hydrochloric acid solution two more times. The next step is to infuse a thrombolytic agent, as described below, or to replace the catheter.

Solid precipitates are due to precipitation of medications or minerals. Dilute 0.1 hydrochloric acid solution may be used to dissolve precipitated calcium and phosphate crystals. Infuse 1 to 2 mL of 0.1 N HCl and allow it to dwell in the catheter 20 minutes. Aspirate the catheter to determine patency. The process may be repeated up to three times. If still occluded, inject 1 to 2 mL of 70% ethanol in water and allow it to dwell in the catheter for 1 hour. Aspirate the catheter to determine patency. The next step is to inject a thrombolytic agent, as described below, or to replace the catheter.

If no precipitate is present, or if efforts to clear the precipitate fail, a clot may be present within the catheter lumen. Clots probably form to some extent in the majority of implanted central venous catheters. The clots may obstruct the catheter lumen.[13] Thrombosis of the central veins, superior vena cava, or right atrium may also occur. Suspect a major vein thrombosis if there is swelling, pain, or edema of anatomic structures that are drained by the cannulated vein(s).

Small clots may be dissolved by a bolus or infusion of a thrombolytic agent. Inject 1 mL of urokinase (5000 U/mL), 2 mL of t-PA (1 mg/mL), or 0.4 units of Reteplase into the catheter. Allow the solution to dwell in the catheter for 30 minutes. Aspirate the catheter to determine patency. This process may be repeated up to three times. For catheters with multiple occluded ports, the medication dosing should remain the same but divided into equal doses between the ports. If still occluded, inject 2 mL of intravenous contrast dye under fluoroscopy or inject the dye and obtain a radiograph. If no clot is present or if the contrast material will not infuse, attempt to clear the catheter with hydrochloric acid solution (up to three times) and 70% ethanol in water.

If a clot is present within the catheter, a continuous thrombolytic infusion may be considered. The infusion should occur through an intravenous line equipped with a 0.22 micron or 0.45 micron filter. A urokinase infusion may be begun over a 24-hour period. Administer the urokinase at a dose of 200 U/kg-hr mixed to run at a rate of at least 20 mL/h.[8,9] A continuous t-PA infusion may also be started. Use 2 mg/20 mL as a low dose for ports, 4 mg/20 mL as a high dose for ports, or 5 mg/50 mL as a high dose for tunneled catheters. Set the t-PA infusion rate at 10 mL/h for low and high doses for ports or 20 mL/h for high dose tunneled catheters. Thrombolytic infusions should be undertaken in consultation with the patient's Primary Care Provider as the patient will require hospital admission.

Consider consulting an Interventional Radiologist if these methods do not successfully clear the catheter or if a thrombolytic infusion is contraindicated. They can perform percutaneous fibrin sheath stripping, exchange over a wire, or removal and replacement of the malfunctioning catheter. Alternatively, the Emergency Physician may place a new central venous catheter at another site if the patient requires immediate vascular access.

FULLY IMPLANTED CATHETERS

The procedure is the same for a fully implanted central venous access device with one exception. The subcutaneous reservoir will not be able to be initially cleared by aspiration. Any clot or precipitates large enough to occlude a catheter will not pass through a noncoring (Huber) needle. **Always use a noncoring (Huber) needle when aspirating or injecting through a fully implanted catheter.**

AFTERCARE

Indwelling central venous lines must be flushed with saline, followed by the appropriate heparin solution if necessary, after clearing the obstruction. Refer to Chapter 49 for the complete details. Patients given thrombolytics must be assessed for bleeding at the catheter site and elsewhere prior to discharge, if they do not require hospital admission. The success rate for thrombolytics restoring catheter patency are greater than 80%.[16,17] Patients receiving prolonged thrombolytic infusions should be admitted for the infusion and for monitoring of potential bleeding complications. Patients and their care providers must be made aware of any catheter malfunctions and the attempts made at restoring catheter patency.

COMPLICATIONS

The complications associated with attempts to de-occlude a catheter include catheter rupture, disconnection of the catheter from any implanted reservoir, hemorrhage, and contamination of the catheter with subsequent infection. No major bleeding episodes or deaths have been associated with intracatheter thrombolysis.[15–17] Assessment for these complications is discussed in Chapter 49.

SUMMARY

In the course of their treatment, a number of patients with indwelling central venous access devices will present to the Emergency Department with malfunctioning catheters. Familiarity with the strategies for diagnosing and correcting the catheter dysfunction will enable the Emergency Physician to restore the function of some, but not all, indwelling lines. Early consultation with the patient's Primary Care Provider, Vascular Surgeon, or Interventional Radiologist is essential if the procedures outlined do not promptly restore the catheter's function.

52 Accessing Indwelling Central Venous Lines

Lisa Freeman Grossheim

INTRODUCTION

Venous access for medication administration, nutritional support, hemodialysis, and blood sampling is essential for the management of many chronic diseases. A variety of indwelling central venous access devices have been developed to avoid repeated venipunctures and permit direct access to the central circulation. These devices may be partially or completely implanted under the patient's skin. The Emergency Physician must be able to access these devices to administer medications and withdraw blood samples without damaging the device or causing it to clot off. The necessary procedures for successfully accessing indwelling central venous lines are described in this chapter.

ANATOMY AND PATHOPHYSIOLOGY

Indwelling central venous lines allow access to the central venous circulation from a peripheral site.[1,2] This is accomplished through either the end of a partially implanted catheter or through the skin into a subcutaneous reservoir of a fully implanted catheter (**Figure 52-1**). The proximal tip of the central venous line may lie in the superior vena cava or in the right atrium. Catheters designed for right atrial placement are made of softer and more pliable material than are catheters used for short-term transcutaneous central venous access. These catheters are unlikely to erode through or perforate the thin right atrial wall.

The internal jugular, subclavian, and femoral veins can all be utilized as a route for a central venous line to access the superior vena cava or right atrium. The subclavian veins are most commonly used to maximize patient comfort and mobility. When the line is initially inserted, the vein is punctured transcutaneously, the catheter is inserted into the vein, and its distal end is tunneled under the skin. If the line is partially implanted, the distal end of the catheter is brought external to the skin through a small puncture (**Figure 52-1A**). If the line is fully implanted, its distal end is connected to a subcutaneous reservoir that is placed in a pocket dissected under the skin of the chest wall (**Figure 52-1B**).

PARTIALLY IMPLANTED CATHETERS

Partially implanted central venous catheters (**Figures 52-1A & 52-2**) are those whose distal end emerges from the skin via a subcutaneous tunnel.[3] This tunnel helps prevent the spread of skin flora along the outside of the catheter and toward the central circulation. Most partially implanted catheters use a subcutaneous Dacron cuff to further insulate the proximal catheter from skin flora and help anchor the catheter in place.[4]

A variety of models are in use, including the Broviac,[5] Hickman,[6] and Groshong[7] catheters. All are available in single-lumen or multiple-lumen versions. Broviac and Hickman catheters must be flushed with heparin solution twice weekly. The Groshong catheter is unique in that it has a slit valve at its proximal end that prevents blood from reentering the catheter once it has been flushed (**Figure 52-3**). Groshong catheters need only a weekly saline flush to prevent clot formation.

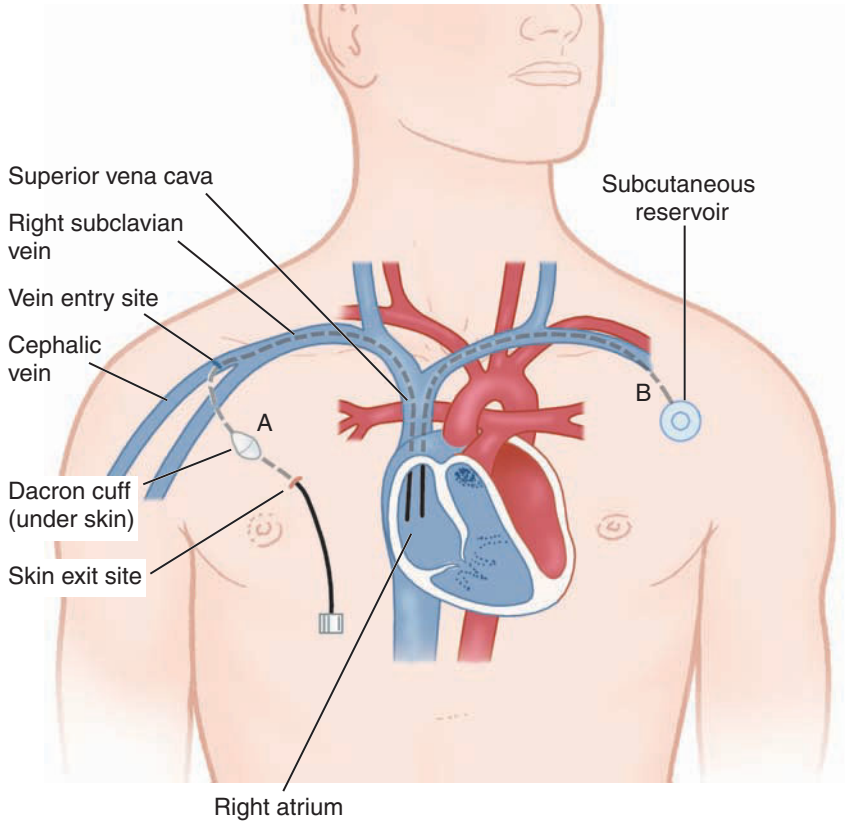

FIGURE 52-1. Indwelling central venous lines. **A.** The partially implanted central venous line. The distal end of the line emerges from the chest wall. Contamination of the implanted portion is prevented by a subcutaneous tunnel and a Dacron cuff around the catheter. **B.** The fully implanted central venous line. The catheter is connected to a reservoir that is contained in a subcutaneous pocket.

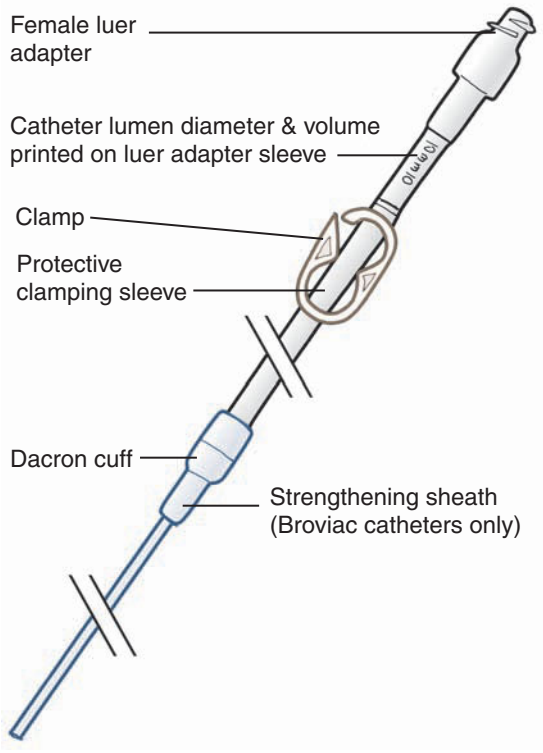

FIGURE 52-2. The partially implanted central venous catheter. A single-lumen (Hickman or Broviac) line is shown schematically. The Dacron cuff lies in the subcutaneous tissue just proximal to the skin entry site. The catheter tip lies in either the proximal superior vena cava or the right atrium.

The Hemocath or Permacath is the largest bore of the right atrial catheters. It is manufactured by Quinton and is used for hemodialysis, plasmapheresis, long-term nutritional support, and analgesia. These catheters are typically flushed during dialysis, but otherwise should be flushed three times per week with heparinized saline.

FULLY IMPLANTED CATHETERS

Fully implanted central venous catheters are those that are entirely embedded and do not exit the skin (**Figures 52-4 & 52-5**). The

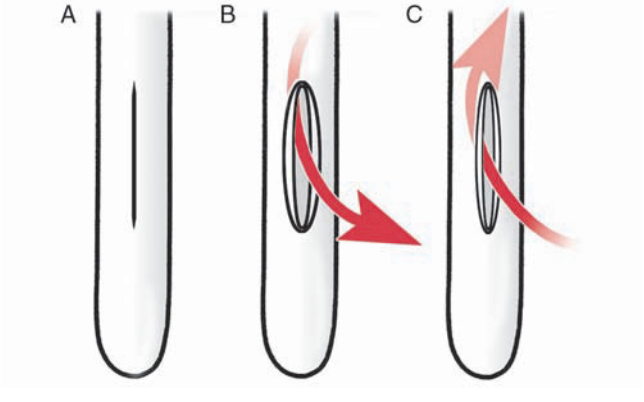

FIGURE 52-3. The Groshong central venous catheter tip. Detail of the Groshong three-position slit valve that prevents venous blood from passively entering the catheter when it is not in use. **A.** The closed or resting position of the slit valve. **B.** The valve opens outward from positive pressure when the catheter is flushed or infused. **C.** The valve opens inward from negative pressure when the catheter is aspirated.

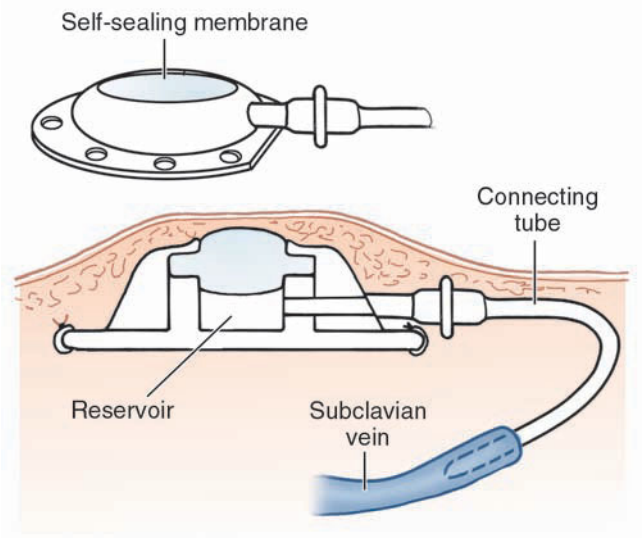

FIGURE 52-4. The fully implanted central venous catheter. The reservoir lies in the subcutaneous tissue and is anchored with sutures to keep the diaphragm facing the skin surface.

catheter's distal end is attached to a subcutaneously implanted reservoir.[4] Various catheters, including Hickman and Groshong catheters, can be attached to a subcutaneous reservoir. Most fully implanted central venous access systems are known by the brand names Port-A-Cath and Infusaport. Most manufacturers recommend that these catheters must be flushed with a heparin solution monthly when not in use.[7] However, there are some data that suggest that flushing of the port system can be done every 3 months without any increase in complications.[7] The reservoir's infusion port is covered with a self-sealing silicone rubber membrane (**Figures 52-4 & 52-5**). **Specially designed noncoring or Huber**

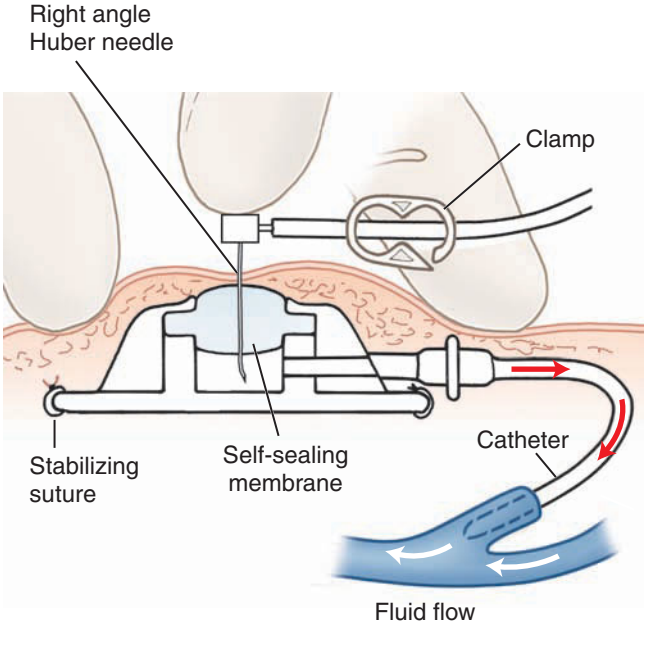

FIGURE 52-5. Accessing the fully implanted central venous catheter system. The reservoir is stabilized between the fingers of the Emergency Physician's nondominant hand as a noncoring (Huber) needle is used to penetrate the skin and reservoir.

needles must be used when accessing the subcutaneous reservoir to avoid permanently damaging the self-sealing membrane.

PERIPHERALLY INSERTED CENTRAL CATHETERS

Peripherally inserted central catheters are also known as PICC lines. They are inserted into the brachial, cephalic, or antecubital vein of the upper extremity and advanced into the subclavian vein. The greatest drawback for the use of PICC lines is the 50% risk of catheter-related thrombosis. PICC lines are made of either silicone or polyurethane. They are 50 to 60 cm long and have an outside diameter of 2 to 7 French, with the 5 French being most commonly used. They are available in both single-lumen and double-lumen versions. Some PICC catheters are equipped with a Dacron cuff similar to the Broviac and Hickman catheters.

PERCUTANEOUS CENTRAL VENOUS CATHETER

A device similar to the PICC is known as the percutaneous central venous catheter (PCVC). This catheter is often used in neonates in the neonatal intensive care unit and not in the Emergency Department. It is available in three sizes (1.1, 1.9, and 2.8 French). The 2.8 French size is used more often because the smaller sizes tend to become occluded with a thrombus. This device is only mentioned for completeness.

INDICATIONS

PATIENTS REQUIRING INDWELLING CENTRAL VENOUS LINES

Patients of all ages and with a variety of diagnoses may present with an indwelling central venous line. Some examples of such presentations are chronic painful conditions requiring parenteral analgesia (e.g., sickle cell disease), chronic infections requiring long-term parenteral antibiotics (e.g., endocarditis, osteomyelitis), the need for prolonged hyperalimentation, patients with difficult peripheral intravenous access, and cancer patients required chemotherapy and blood sampling. Any patient who will require several weeks of repeated intravenous blood sampling and/or drug administration is a candidate for an indwelling central venous line.

ACCESS OF INDWELLING CENTRAL VENOUS LINES

Fully or partially implanted central venous access devices may be accessed routinely when phlebotomy is required, medications must be administered, or intravenous fluids must be administered.

CONTRAINDICATIONS

Do not access an indwelling central venous device if peripheral intravenous access can be obtained. The use of bedside ultrasound may facilitate peripheral intravenous access and avoid accessing the indwelling device. Fully implanted devices should not be accessed through infected skin. Partially implanted catheters known or suspected to be infected should be used cautiously, as they may be a source of septic emboli, although it is sometimes possible to treat catheter sepsis without removing the device.[8,9] Phenytoin and diazepam cannot be given via silicone indwelling central venous lines as they can crystallize and permanently obstruct the catheter lumen.[10]

Devices used for hemodialysis should be accessed only in a true emergency and if no other method of venous access can be readily obtained. This guideline is intended to prevent loss of the patient's dialysis access due to device damage, clotting, or an infection. An inability to dialyze the patient will lead to significant morbidity and mortality. There are a finite number of veins available for dialysis access.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gauze, 4 × 4 squares
- 10 mL syringes
- 20 gauge needles
- Sterile saline, 0.9%
- Heparinized saline flush (100 and 1000 U/mL)
- Adhesive tape
- Luer-lock caps
- Blood collection tubes
- Infusion set
- Any intravenous fluids or medications to be injected
- Huber needle, noncoring right angle or straight angle
- Topical anesthetic (EMLA cream, ethynyl chloride spray, or ice)
- Injectable anesthetic without epinephrine, 1% lidocaine
- Sterile alcohol prep pads
- Sterile gloves
- Sterile drapes

PATIENT PREPARATION

Discuss the necessary procedure with the patient and/or their representative. Obtain an informed consent for accessing the device. Patients with indwelling central venous lines are usually very familiar with their care and use. They can often advise the Emergency Physician on the correct procedure, the appropriate flush solution, and any anatomic manipulations necessary to optimize flow through the line (e.g., raising the arms, turning the head, etc.). **Aseptic technique is required at all times when accessing indwelling central venous catheters.**

TECHNIQUES

PARTIALLY IMPLANTED CATHETERS

Accessing a partially implanted central venous catheter is simple and similar to accessing a heparin-locked peripheral intravenous catheter.[7,10] Remove any adhesive tape and gauze wrapped around the distal end of the lumen to be accessed. Fasten the catheter clamp on the desired lumen (**Figure 52-2**). Clean the catheter cap and Luer adapter with povidone iodine or chlorhexidine solution and allow it to dry. The technique for accessing the catheter will vary depending on whether blood sampling with or without a subsequent infusion is required. Both techniques are described below.

BLOOD SAMPLING FROM PARTIALLY IMPLANTED CATHETERS

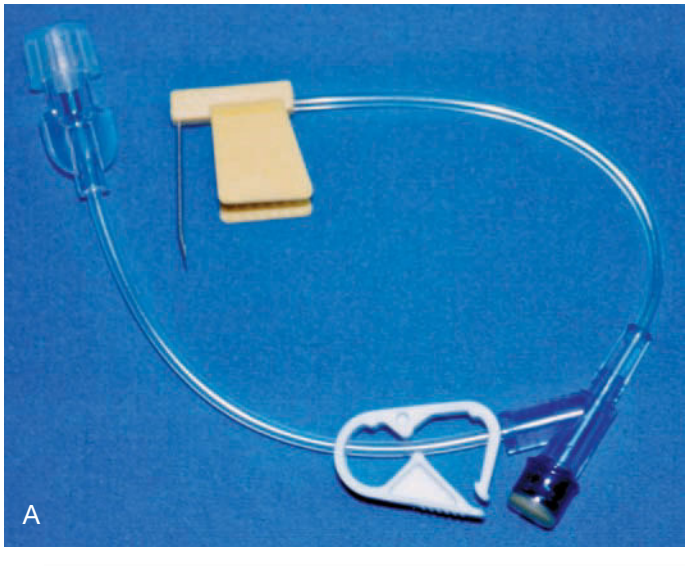
Blood samples may be withdrawn through the catheter cap using a 20 gauge hypodermic needle attached to a 10 mL syringe if blood is to be sampled without beginning an infusion. Insert the needle through the Luer cap. Open the catheter clamp. Withdraw 5 mL of blood from the catheter. Discard the blood sample, needle, and syringe. This blood sample is diluted by the catheter contents (i.e., saline or heparinized saline) and does not truly represent the circulating blood. This step is essential when accessing dialysis catheters

as they contain a dose of concentrated heparin (1000 U/mL). If unable to aspirate blood, gently flush the catheter with 2 to 3 mL of sterile saline. **Avoid using a syringe smaller than 5 mL to inject as pressure high enough to damage the catheter can be generated.** Refer to Chapter 51 for troubleshooting instructions if the catheter does not flush easily.

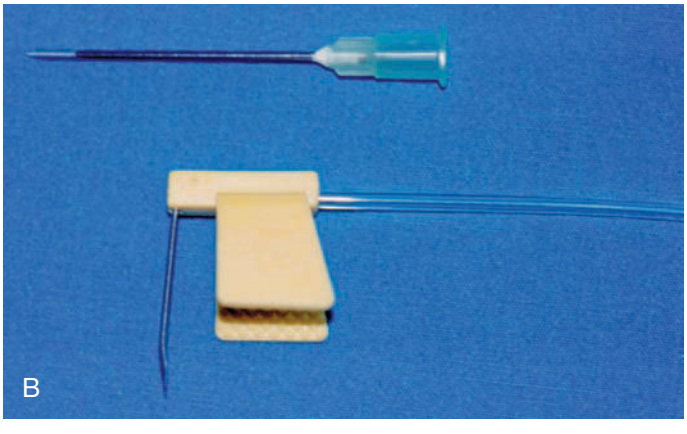
Withdraw the required blood samples using a new needle and syringe. Transfer the blood samples into collection tubes for the laboratory. The catheter must now be flushed to prevent it from clotting off. Flush the catheter with the appropriate solution in a 10 mL syringe armed with a 20 gauge needle. Inject 3 to 5 mL of heparinized saline (100 U/mL) into Broviac and Hickman catheters. Inject 5 mL of normal saline into a Groshong catheter. Inject dialysis catheters with the volume printed on the catheter, usually ≤2 mL, of heparinized saline (1000 U/mL). Wipe off the cap with an alcohol pad.

Secure the free end of the catheter. Tape the catheter to the patient's chest wall to prevent accidental traction on the catheter. Evaluate the skin puncture site. Reapply a dressing over the skin puncture site if necessary.

BLOOD SAMPLING AND INFUSION THROUGH PARTIALLY IMPLANTED CATHETERS



The Luer catheter cap can be removed entirely and the catheter lumen accessed directly with a Leur-hub syringe if an infusion is to be subsequently started. **Ensure that the catheter clamp is securely closed.** Remove the cap from the catheter. Attach a 10 mL syringe to the hub of the catheter. Open the catheter clamp. Withdraw 5 mL of blood into the syringe. Close the catheter clamp. Remove and discard the syringe with the original blood sample. Apply a new syringe, open the catheter clamp, and withdraw the blood sample. Close the catheter clamp. Remove the syringe. Continue this sequence of events until all required blood samples are obtained. **It is imperative to make sure that the catheter is clamped when the cap or syringe is removed to prevent an air embolism.** Securely attach primed intravenous tubing to the hub of the catheter, open the catheter clamp, and begin the infusion.



Clamp the catheter lumen when terminating the infusion or if no infusion is to be started. Remove the intravenous tubing or the syringe from the catheter. Attach a syringe containing the appropriate flush solution, open the catheter clamp, and flush the catheter. Close the catheter clamp. Remove the syringe. Apply a new sterile cap onto the hub of the catheter. **Never use "needle-less" caps, as they are a potential source of air emboli.** Open the catheter clamp to prevent catheter damage from long-term clamping. Secure the catheter to the patient's chest wall.

FULLY IMPLANTED CATHETERS

A noncoring Huber-type needle must be used to access subcutaneous injection ports (Figures 52-5 & 52-6). A small-gauge standard hypodermic needle can be used only in a dire emergency if a noncoring needle is not available. **The diaphragm covering the injection reservoir can be damaged by a standard hypodermic needle, leading to subcutaneous hemorrhage and necessitating surgical replacement of the implanted device.**

Clean and prep the skin overlying the injection port with povidone iodine or chlorhexidine solution and allow it to dry.

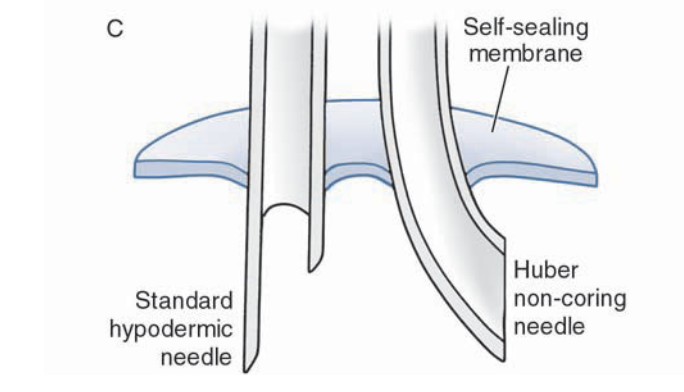


FIGURE 52-6. The Huber needle. **A.** Photo of a complete right-angle Huber needle set, including the extension tubing and clamp. **B.** Photo showing the right-angle Huber needle compared with a standard hypodermic needle. **C.** Drawing showing the key difference between a standard hypodermic needle and the Huber needle. The hypodermic needle tip can cut a cylindrical core of subcutaneous tissue and the diaphragm sealing the subcutaneous reservoir. The Huber needle pushes the subcutaneous tissue and the diaphragm material aside without removing any of it.

TABLE 52-1 Volumes and Concentrations of Heparin Flushes for Pediatric Indwelling Devices

	Children < 6 months old	Children > 6 months old
Partially implanted device	3 mL heparin (10 U/mL)	5 mL heparin (100 U/mL)
PICC line	3 mL heparin (10 U/mL)	5 mL heparin (100 U/mL)
Fully implanted device	3 mL heparin (10 U/mL)	5 mL heparin (100 U/mL)

The application of a topical or injectable anesthetic over the reservoir is optional but greatly appreciated by the patient. Remove the iodine solution (if used) with an alcohol swab. Flush the Huber needle and extension tubing with normal saline using a 10 mL syringe. Leave the syringe attached. Locate the center of the self-sealing membrane (diaphragm). Stabilize the reservoir with the nondominant hand (**Figure 52-5**). Slowly and steadily insert the needle through the skin and into the reservoir (**Figure 52-5**). Stop advancing the needle when it touches the far wall of the device. Gently flush 2 to 3 mL of saline through the needle. Refer to Chapter 51 for troubleshooting instructions if the catheter does not flush easily.

If the catheter can be flushed easily, secure the Huber needle in place by stabilizing it with gauze squares and tape. Withdraw 5 to 10 mL of blood. Close the clamp on the extension tubing (**Figure 52-5**). Remove and discard the syringe. Attach a new syringe, open the clamp, and withdraw the required blood samples. Clamp the extension tubing and remove the syringe. If an infusion is to be started, attach the primed intravenous tubing and begin the infusion. If no infusion is desired or when discontinuing an infusion, clamp the extension tubing and disconnect the intravenous tubing. Attach a 5 or 10 mL syringe containing heparinized saline (100 to 200 U/mL) to the Huber needle extension tubing. Open the clamp and flush the device with 3 to 5 mL of heparinized saline. Use only saline if a Groshong catheter is attached to the reservoir. Remove the Huber needle from the skin. Control any skin bleeding with direct pressure. Apply a sterile dressing.

PEDIATRIC CONSIDERATIONS

The management of pediatric indwelling devices is similar to those in adults with a few noted exceptions. The catheters, reservoirs, and tubing are often smaller than those used in adults or adolescents. The volumes and concentrations of heparin flushes differ in these smaller catheters (**Table 52-1**). The external portion of partially implanted devices and PICC lines must be secured with a dressing so that the child does not pull it out.

ASSESSMENT

Assessment of line function after accessing a central venous access device will not occur until the next access attempt. This procedure is described above. Troubleshooting nonfunctioning indwelling central venous lines is discussed in Chapter 51.

AFTERCARE

Secure the partially implanted catheter to the skin with tape so that the tubing will not get caught on the patient's clothing. The patient should be given a written record of how the access device was used and flushed in the Emergency Department to convey to their Primary Care Physician should problems with the line become evident at a later time. Patients must regularly assess their indwelling access sites for signs of infection (i.e., erythema, pain, purulent discharge, or serous discharge). Instruct the patient to immediately contact their Primary Care Provider or return to the Emergency Department if they develop a fever or other signs of an infection.

COMPLICATIONS

The most important elements after accessing indwelling lines are to not allow the central venous line to clot off and not to contaminate the line. Strict adherence to the procedures described above will minimize the chances of these problems occurring. Complications associated with the catheter include right atrial thromboses, right atrial erosion with pericardial tamponade (rare with implanted lines), catheter-related infections, and pulmonary embolism.[7,9,11,12] Fully implanted catheters may become disconnected from the subcutaneous reservoir or may leak into the subcutaneous tissue due to diaphragm failure. Any hematoma formation near the reservoir must be assessed promptly to prevent major hemorrhage. Infection and line sepsis can be prevented using strict sterile technique.

An air embolism should be suspected if the patient becomes confused, hypotensive, and/or tachycardic while accessing the central venous access device. This complication is 100% preventable by ensuring that the catheter tubing is clamped closed whenever the end of the tubing is without a cap. Immediately place the patient in the Trendelenburg position and on their left side (i.e., left lateral decubitus position). This will hopefully cause any air emboli to collect in the apex of the right ventricle and not enter the pulmonary artery.

Repair kits are available for damaged partially implanted catheters. These can serve to avoid the need to remove the device and implant a new catheter. If the external tubing of the partially implanted catheter is damaged, apply a smooth catheter clamp proximal to the damaged area and arrange to have the device repaired. Instructions for the use of these kits are beyond the scope of this chapter.

SUMMARY

The Emergency Physician will encounter many patients with indwelling central venous lines. Careful adherence to sterile technique as well as proper blood sampling and infusion techniques will allow access for phlebotomy, medication administration, and fluid administration while preserving the indwelling line for future use.

53 Pulmonary Artery (Swan-Ganz) Catheterization

Pratik Doshi

INTRODUCTION

The routine clinical catheterization of the pulmonary artery was made possible by the pioneering work of H.J.C. Swan and William Ganz. Together they developed the soft, balloon-tipped, flow-directed pulmonary artery catheter (PAC) that bears their names.[1] Prior to the work of Swan and Ganz, pulmonary artery catheterization was performed using a stiff catheter that required fluoroscopic guidance and was associated with a high complication rate. The Swan-Ganz PAC allows reliable and continuous measurement of hemodynamic parameters to be performed safely, even in critically ill patients.[2–4] While complications are uncommon, they can

occur. The optimal application of the PAC, both its insertion and interpretation of the data, requires appropriate training and skill.[5–7]

This chapter concentrates on the technique of PAC insertion. Obtaining central venous access is a necessary prerequisite for this technique and is discussed in Chapter 49. A detailed discussion of the interpretation of the abundant variety of data that the PAC may provide is beyond the scope of this chapter.[8] The interpretation of data is discussed primarily as it concerns PAC insertion and associated complications.

ANATOMY AND PATHOPHYSIOLOGY

The PAC is advanced into the right atrium from a venous access site in the neck, chest, upper extremity, or lower extremity. The balloon near the tip of the catheter is inflated during its insertion. The balloon follows the flow of blood through the right heart—from the right atrium through the tricuspid valve into the right ventricle, then up the right ventricular outflow tract through the pulmonic valve into the pulmonary artery, and from there into a branch of the pulmonary artery (**Figure 53-1**).

When the PAC is correctly positioned, inflating the balloon near its tip will occlude the forward blood flow to that arterial segment (**Figure 53-2**). The lumen opening at the tip of the PAC will therefore measure the downstream pressure in that vessel, rather than pulmonary artery pressure. Because the pulmonary circulation has no valves, the pressure that the PAC tip measures beyond the inflated balloon is equal to the pressure in the pulmonary capillaries. This pressure is, in turn, equal to the pressures in the pulmonary veins and the left atrium. During diastole, when the mitral valve is open, this pressure is equal to the left ventricular diastolic pressure. The left ventricular end-diastolic pressure is a very important parameter because it is the best clinical indicator of preload. Thus, measurement of the pulmonary capillary wedge pressure (or pulmonary artery occlusion pressure, as it is sometimes called) provides an excellent assessment of left ventricular filling without the need to catheterize the left side of the heart.

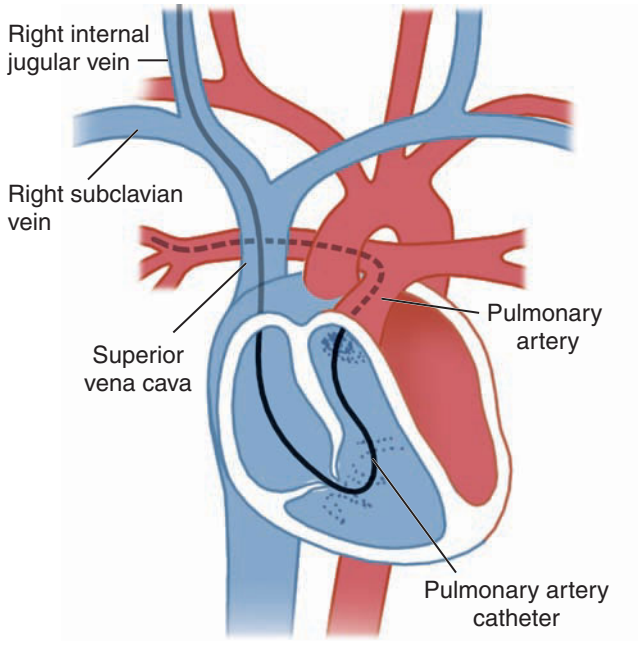

FIGURE 53-1. Cardiac anatomy as it pertains to pulmonary artery catheter insertion. The PAC enters the right atrium from the superior vena cava, crosses the tricuspid valve into the right ventricle, and then crosses the pulmonic valve into the pulmonary artery. The catheter tip lies in a branch of the right pulmonary artery.

The PAC may also be used to measure cardiac output using the thermodilution method. The tip of the PAC has a temperature-sensitive probe. When a given volume of cold saline is injected into the right atrial port of the PAC, it cools the temperature of the blood flowing past the catheter tip. If the cardiac output is high, the cold saline is mixed with and carried along by a larger flow of blood so that the temperature change detected at the PAC tip is smaller and

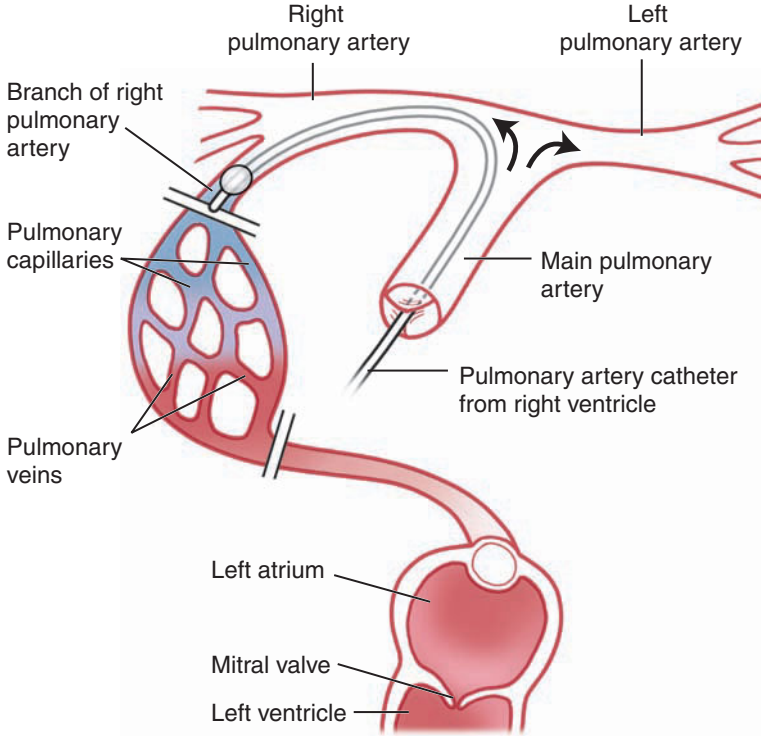

FIGURE 53-2. Diagram of the principle underlying pulmonary capillary wedge pressure. Balloon inflation blocks transmission of the forward pulmonary artery pressure to the tip of the catheter. The catheter tip therefore measures the downstream pressure of the pulmonary circulation. Because the pulmonary circulation has no valves, the pressure measured at the catheter tip is equal to the pressure in the left ventricle when the mitral valve is open (diastole).

dissipates faster. If cardiac output is low, the cold saline mixes with a smaller volume of blood and the temperature change is more apparent and slower to dissipate.

INDICATIONS

The major advantage of the PAC is that it provides accurate measurements of hemodynamic parameters such as pulmonary capillary wedge pressure and cardiac output. This is particularly useful in critically ill patients, as the clinical estimation of these parameters is frequently incorrect.[9–13] The PAC may be used for diagnostic or therapeutic purposes. Diagnostically, the PAC is usually used in situations where clinical judgment alone cannot reliably determine the physiologic basis for hemodynamic instability, pulmonary edema, or reduced urine output. Therapeutically, the PAC may help to direct therapy in patients in whom noninvasive clinical parameters are insufficient guides of treatment efficacy. The most common clinical indications for the PAC in medical and surgical patients are listed in **Table 53-1**.

It should be noted that despite the prevalence of PAC use, few prospective studies have documented improved clinical outcomes with the PAC except in perioperative surgical patients. Retrospective studies have suggested that the use of the PAC may be associated with worse outcomes.[14–17] Over the last 10 years, this question has been further studied in randomized controlled trials as a result of the retrospective data suggesting worse outcomes with the use of PAC. In all of these trials, PACs do not appear to improve survival or decrease length of stay. However, these trials also do not confirm the suggestion of worse outcomes with the use of PAC. As with any intervention, the Emergency Physician must carefully assess the potential benefits and risks in making the decision to place a PAC. There is an actual cost and potential complications associated with placement of these catheters.[21–28]

TABLE 53-1 Common Clinical Indications for Pulmonary Artery Catheter Placement in Medical and Surgical Patients

Cardiac

A. Complicated myocardial infarction
   i. Management of refractory hypotension or left ventricular failure
   ii. In the presence of hemodynamic deterioration due to a mechanical complication, to differentiate mitral regurgitation from acute ventricular septal defect
B. Other cardiac conditions
   i. Diagnose/manage cardiac tamponade
   ii. Distinguish cardiogenic from noncardiogenic pulmonary edema
   iii. Management of severe cardiomyopathy
   iv. Diagnose/manage severe pulmonary hypertension

Medical/Surgical

In the setting of sepsis, trauma, burns, multiple organ failure, pulmonary embolus, or drug overdose.

If any of the following is found to be unresponsive to conventional medical management:

A. Hypotension
B. Low urine output
C. Hypoperfusion (evidenced by cool skin, mental obtundation, and lactic acidosis)
D. Severe hypoxemia requiring high levels of PEEP (>10 cm)

Preoperative

A. High-risk cardiac surgery (e.g., CABG in elderly patients, multiple valve replacement, and ventricular aneurysm resection)
B. Complicated vascular surgery (dissecting aneurysm, resection of thoracic or abdominal aneurysm)
C. Other surgical patients with multiple risk factors
   i. Myocardial infarction within 6 months
   ii. Poor left ventricular function
   iii. Elevated Goldman or ASA score

CONTRAINDICATIONS

There are no circumstances in which PAC insertion is absolutely contraindicated. Insertion of a PAC may be relatively contraindicated in cases where the risks of obtaining vascular access (e.g., severe bleeding diathesis) or of passing the catheter (e.g., a mobile thrombus in the right heart or right-sided endocarditis) outweigh the potential benefits of obtaining the data the PAC provides.

A PAC is not indicated in situations where it will provide no diagnostic information that cannot be acquired by less invasive means. For example, while a PAC may be helpful in diagnosing or treating patients with mitral regurgitation or ventricular septal defects following myocardial infarction, echocardiography may be sufficiently diagnostic and may obviate the need for a PAC. The same can be true in cases of cardiac tamponade. The PAC may also be superfluous in situations where it will provide little or no therapeutic guidance. The insertion of a PAC is not necessary if a therapeutic trial of fluid administration restores urine output and blood pressure in a hypovolemic patient who has normal cardiac function. Other contraindications include patients with: cardiac dysrhythmias, implanted pacemakers or defibrillators, pulmonary hypertension, right-sided endocarditis, right-sided intracardiac valvular abnormalities, right-sided prosthetic heart valves, right-sided intracardiac thrombi, or severe hypotension. A PAC should not be inserted if the appropriate equipment is unavailable or if personnel experienced with the insertion and interpretation of the PAC data are not present.[19,20]

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Sterile gloves and gown
- Face mask and cap
- Saline or dextrose solution with or without heparin (1 to 2 U/mL)
- Pressure bag with manometer
- Pressure tubing
- Pressure transducer for distal port (CVP port optional)
- Stopcocks and occlusive caps for each port of PAC
- Fluid infusion tubing for sheath sideport and for PAC ports
- PAC
- Balloon inflation syringe
- Catheter sleeve
- Sterile dressing for site
- Electrocardiogram (ECG) and pressure monitor

The materials required to place a percutaneous introducer sheath are available in commercially prepared prepackaged kits. Refer to Chapter 49 for the details regarding the placement of the introducer sheath. Note that many PACs require an 8.5 French introducer sheath. In addition, it is desirable to use an introducer sheath that allows the sterile protective sleeve over the PAC to be affixed securely to the sheath.

The PAC consists of a balloon lumen that ends in a balloon just proximal to the catheter tip, a distal lumen that opens at the end of the PAC, a lumen that opens approximately 30 cm proximal to the tip, and a thermister (**Figure 53-3**). Many PACs have one or more additional lumens opening proximal to the tip. Some of these lumens are designed to accommodate a cardiac pacing wire. A 3 mL syringe with a safety stop at 1.5 mL is supplied with each PAC.

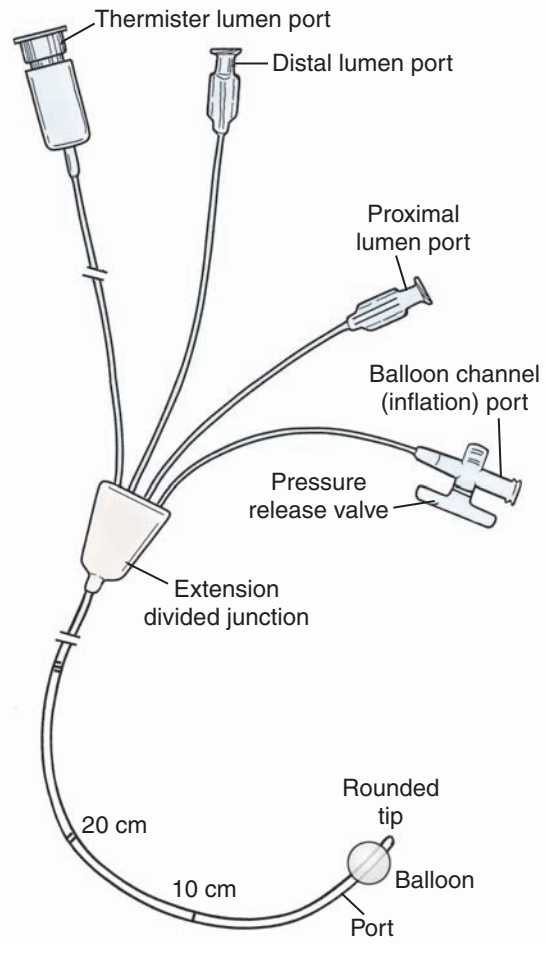

FIGURE 53-3. The pulmonary artery catheter.

This syringe is used to inject air into the balloon. Distances from the tip of the PAC are indicated by linear markings on the shaft. By the standard designation, each thin line represents 5 cm increments and each thick line 10 cm increments.

PATIENT PREPARATION

Routine laboratory studies are advisable prior to PAC insertion in nonemergent circumstances. Hematologic abnormalities (e.g., severe anemia, thrombocytopenia, and coagulation system deficiencies) can increase the risk or adverse consequences of bleeding. Electrolyte derangements (e.g., hyperkalemia, hypokalemia, and hypomagnesemia) that may predispose to arrhythmias should be identified and corrected when possible.

Explain to the patient and/or their representative the risks, benefits, and complications of the procedure. Obtain informed consent for the procedure if possible. The use of mild sedation may be advantageous in some patients. Place the patient supine if possible. Continuous ECG monitoring is essential. Pulse oximetry should be routinely monitored. Arterial pressure monitoring is often desirable in patients receiving a PAC. Apply supplemental oxygen. Equipment and personnel necessary for assisting with the PAC insertion procedure and for managing potential complications should be immediately available. This should include equipment for emergency airway management and emergency cardiac pacing.

The choice of which central venous access site to use for PAC insertion must be individualized. The preferred sites are the right internal jugular vein or the left subclavian vein. The PAC tends to float into the desired position more easily from these two sites. The left internal jugular vein and the right subclavian vein are acceptable alternatives. The femoral vein may also be used. The femoral approach may be quite difficult without fluoroscopic guidance of the catheter. The external jugular veins, basilic veins, and axillary veins are additional alternatives that carry the same difficulty.

It is essential that strict sterile technique be maintained throughout the insertion procedure. The Emergency Physician and their assistant should be wearing sterile gloves, a sterile gown, a face mask, and a cap. A large sterile field is necessary, as is close attention to the long PAC, which can easily become contaminated. It is also very important to take all necessary precautions with syringe needles, scalpel blades, and suture needles to prevent a needlestick injury.

Insert a percutaneous introducer sheath into the central venous system. Refer to Chapter 49 for the complete details regarding the insertion of the sheath. If the patient already has a single-lumen or multi-lumen central venous catheter inserted, it may be exchanged for an introducer sheath. Remove any bandages and dressings on the catheter and skin access site. Thoroughly prep the catheter, skin access site, and surrounding skin with povidone iodine or chlorhexidine solution and allow it to dry. Drape a sterile field. Discontinue any infusions through the catheter. Open an introducer sheath kit. Cut any sutures securing the catheter to the skin. Insert a guidewire through the hub of the distal port and into the central venous circulation. Withdraw the catheter over the guidewire. Insert and secure the percutaneous sheath over the guidewire as described in Chapter 49.

TECHNIQUE

Set up a bedside sterile table and open the PAC kit. Remove the protective sleeve. It allows later repositioning of the PAC while maintaining sterility. Place the sleeve over the catheter and slide it far back (>60 cm) from the catheter tip. Attach the balloon inflation syringe to the PAC. Inflate the balloon once to confirm the integrity of the balloon. It is a good idea to inflate the balloon in a full bowl of sterile saline and observe for air bubbles to ensure that there are no leaks or gross eccentricities. Allow the balloon to deflate passively. **Deflation by aspirating air from the balloon should be avoided as it places undue stress on the balloon.** Flush the PAC ports with sterile saline and attach a stopcock to each port. Attach the pressure tubing to the distal port. Flush the entire apparatus, including the PAC and the pressure monitoring system, with sterile saline to ensure that no air remains in any part of the system. Have an assistant set up, calibrate, and level the transducer. Hand the proximal end of the PAC to an assistant to attach to the ECG monitor. Finally, shake the tip of the PAC while observing the pressure waveform on the monitor to confirm that the monitoring system is operative.

Insert the PAC through the diaphragm on the introducer sheath, taking care to orient the natural curve of the catheter toward the right ventricular outflow tract. Continue to advance the PAC until it is inserted 10 to 15 cm and exits the sheath. This ensures that the balloon is not inflated within the sheath. Stop advancing the PAC. Inflate air into the balloon and lock the pressure release valve. **The PAC should never be advanced through the central venous system with the balloon deflated, as this may provoke ectopy or injure the heart or other vascular structures. Conversely, the PAC should always be withdrawn with the balloon deflated.**

Pay close attention to the distance markings on the PAC and to the pressure waveform on the monitor when advancing the PAC. Typical pressure waveforms are illustrated in **Figure 53-4**. The average distances from the different catheter insertion sites

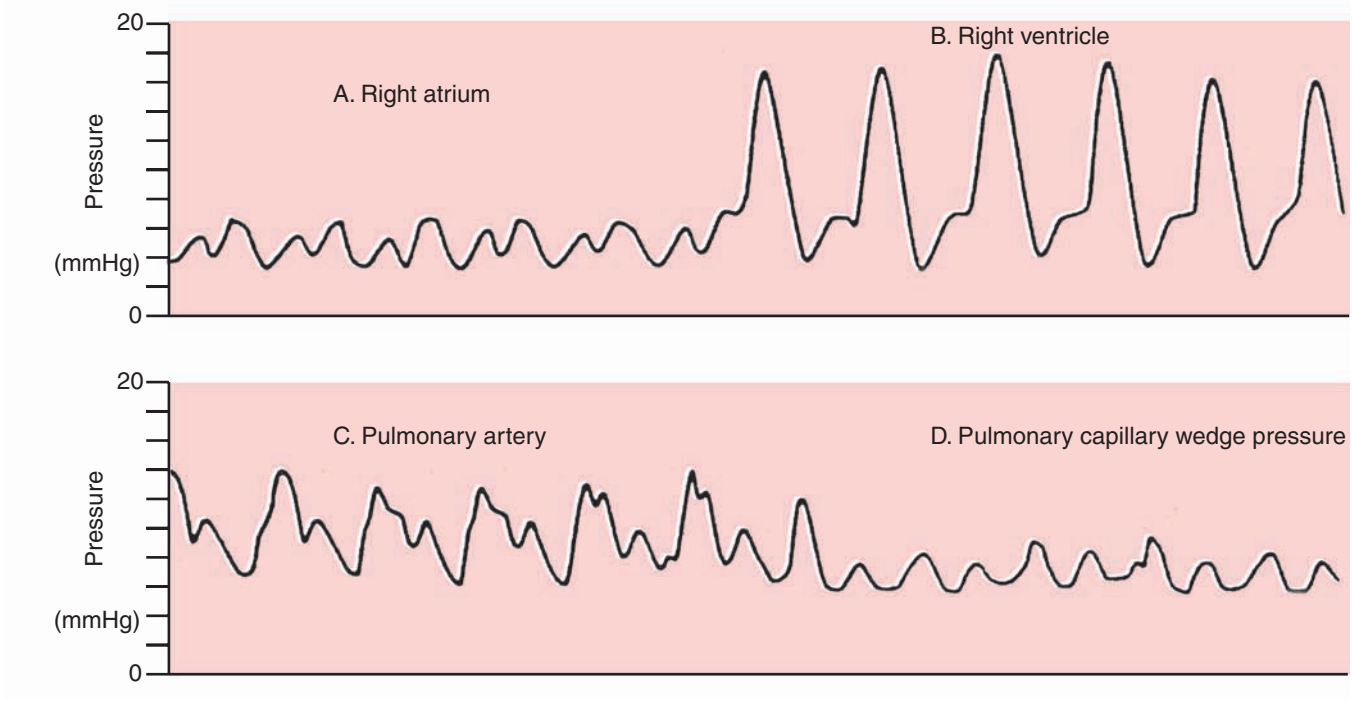

FIGURE 53-4. Typical pressure waveforms recorded by the pulmonary artery catheter during insertion.

into each chamber of the heart are listed in **Table 53-2**. Advance the PAC into the right atrium (**Figure 53-4A**). Continue to advance the PAC into the right ventricle, which will be apparent by an abrupt change in the pressure waveform (**Figure 53-4B**). Continue to advance the PAC into the pulmonary artery outflow tract, again confirmed by a change in the pressure waveform (**Figure 53-4C**). Passing the PAC through the right ventricle may produce some ventricular ectopy, which is generally uncomplicated. Advance the PAC a few centimeters further to produce a wedge tracing (**Figure 53-4D**). Deflate the balloon. This will result in the reappearance of the pulmonary artery waveform. If the wedge tracing persists, withdraw the PAC with the balloon deflated until the pulmonary artery waveform reappears. **Whenever it is unclear where the tip of the PAC is located, deflate the balloon and withdraw the PAC to a spot where the waveform is recognizable.** Take notice of the distance marking. Inflate the balloon and advance the PAC until the desired tracing is obtained.

Difficulties in passing the PAC into the pulmonary artery may occur in patients with pulmonary hypertension, significant tricuspid regurgitation, or markedly dilated right heart chambers. Instruct the patient to inspire slowly and deeply to increase venous return to the right heart. This may allow the PAC to be advanced successfully. Tilting the patient's head upward and repositioning the patient on their left side may also be helpful. Fluoroscopic guidance may be necessary if repeated attempts are unsuccessful.

Pull up the protective sleeve over the catheter and secure it to the introducer sheath. It is important not to advance the PAC itself during this manipulation. Begin any infusions through the PAC. Secure the PAC, dress the access site, and document correct positioning by obtaining an anteroposterior chest radiograph. The assessment and aftercare of the skin puncture site is described in Chapter 49.

DATA INTERPRETATION

As mentioned in the introduction to this chapter, a detailed discussion of PAC data interpretation cannot be undertaken here. However, anyone who places or uses PACs in the management of critically ill patients should be familiar with the standard information provided by the PAC. The data generated by the PAC can be divided into two categories. The first set of information comprises data that are directly measured and include the right-sided heart pressures, thermodilution cardiac output, and blood gas obtained from a mixed venous sample from the distal pulmonary artery port. These data, including normal values, are listed in **Table 53-3**. The second set of data comprises the variables that are mathematically derived from the measured data (**Tables 53-4 & 53-5**). These provide information crucial to understanding cardiac and pulmonary physiology and pathology. Today, this information is routinely available on an instantaneous basis as part of computer software packages that accompany the monitoring equipment. PAC users should become familiar with both sets of information and their application in different clinical situations. The reader is advised to consult a current textbook of cardiology or critical care medicine for a more detailed description of the hemodynamic data provided by the PAC.

COMPLICATIONS

In addition to the complications associated with obtaining central venous access and with prolonged use of indwelling catheters (Chapter 49), complications may occur during or after the insertion of the PAC. The complications directly related to the PAC may be divided into those that are associated with catheter insertion and those associated with long-term maintenance (**Table 53-6**). Both sets of complications can be further divided into those problems where there has been systematic study and the incidence of complications has been published and those that have been observed and published as case reports but the actual incidence of which is unknown.

Problems with tracing quality may occur due to problems involving the catheter itself or other parts of the system. Catheter problems include positioning too distal or not distal enough, balloon rupture, or clot formation at the tip. Problems elsewhere in the system include air in the lines, loose connections, failure of the transducer, failure of the wires, or failure of the monitor. The system should be

TABLE 53-2 Average Distances from the Catheter Insertion Site to the Catheter Tip Position*

Catheter insertion site	Right atrium distance (cm)	Right ventricle distance (cm)	Pulmonary artery distance (cm)	Wedge distance (cm)
Subclavian vein	10	20	30–40	40–45
Right internal jugular vein	15	25	35–45	45–50
Left internal jugular vein	20	30	40–50	50–55
Right antecubital vein	45	60	70–80	80–85
Left antecubital vein	50	65	75–85	85–90

* These distances are considered the common estimates for uncomplicated PAC placement in patients with normal-sized hearts. The distances will vary in patients and may be greater, especially in the patient with a dilated right ventricle. Any time there is a gross discrepancy between these distances and the actual observed placement distance, the physician should consider catheter misplacement, catheter looping, or catheter knotting. An immediate portable anteroposterior chest radiograph should be obtained to evaluate the situation.

TABLE 53-3 Variables Obtained from the Pulmonary Artery Catheter Through Direct Measurement

Variable	Normal values	Main utility	Comments
Cardiac output (CO)	4–6 L/min	Diagnosis of shock (high output vs. low output); titration of vasoactive medications	Measurement is prone to error; should be indexed to patient's size
Pulmonary capillary wedge pressure (PCWP)	5–15 mmHg	Volume status, diuresis, fluid challenges	Often overinterpreted; must be used with other values
Right atrial pressure (RAP)	0–10 mmHg	Status of right ventricle	Less useful than PCWP
Pulmonary artery pressure (PAP)	15–25 mmHg systolic; 8–15 mmHg diastolic	Status of right ventricle and pulmonary circuit	Pulmonary artery diastolic can be substituted for PCWP in most patients
Mixed venous oxygen saturation ($S\bar{v}O_2$)	70%–80%	Evaluation of oxygen delivery; pulmonary shunt fraction	Best obtained by blood gas from distal pulmonary artery

TABLE 53-4 Derived Variables Obtained from the Pulmonary Artery Catheter

Variable	Normal values	Main utility	Comments
Systemic vascular resistance (SVR)	800–1600 dynes/s/cm^{-5}	Shock states, vasodilator versus vasopressor therapy (afterload)	Unclear whether value should be indexed to patient's size
Pulmonary vascular resistance (PVR)	20–200 dynes/s/cm^{-5}	Pulmonary hypertension; acute and chronic lung disease	Unclear whether value should be indexed to patient's size
Left ventricular stroke work index (LVSWI)	56 ± 6 g m/m^2	Left ventricular performance	Clinical utility uncertain
Right ventricular stroke work index (RVSWI)	8.8 ± 0.9 g m/m^2	Right ventricular performance	Clinical utility uncertain
Oxygen DO delivery $\dot{D}O_2$	900–1100 mL/min	Shock states, anemia, low cardiac output	Often amenable to therapy, but controversial
Oxygen consumption $\dot{V}O_2$	200–250 mL/min	Sepsis, burns, trauma, ventilator patients	Affected by many variables; use is controversial
Pulmonary shunt fraction (Q_s/Q_t)	3%–5%	Acute and chronic lung disease	Underused in the evaluation of pulmonary disease

TABLE 53-5 Formulas for the Derivation of Variables

SVR = (mean arterial pressure – mean arterial pressure) × 80 cardiac output
PVR = (mean pulmonary artery pressure – pulmonary capillary wedge pressure) × 80 cardiac output
LVSWI = SV × (mean arterial pressure – pulmonary capillary wedge pressure) 0.0136 body surface area
RVSWI = SV × (mean arterial pressure – right atrial pressure) × 0.0136 body surface area
$(DO_2) = [(\text{cardiac output} \times \text{hemoglobin}) \times (13.4) \times (\%\ O_2\ \text{saturation})] + (PO_2 \times 0.0031)$
$(VO_2) = (\text{cardiac output} \times \text{hemoglobin}) \times (13.4) \times (SaO_2 - SvO_2)$
$Q_s/Q_t = (\text{pulmonary capillary } O_2 \text{ content} - CaO_2)/(\text{pulmonary capillary } O_2 \text{ content} - CvO_2)$

Key: CaO_2, arterial oxygen content; CvO_2, mixed venous oxygen content; PO_2, partial pressure of oxygen; SaO_2, arterial oxygen saturation; SV, stroke volume. Other terms are defined in **Tables 53-3** and **53-4**.

TABLE 53-6 Recognized Complications of Pulmonary Artery Catheterization

Related to catheter insertion (published incidence)
Complete heart block (0%–2.6%)
Ventricular arrhythmias requiring treatment (0%–3%)
Hematoma (0%–3%)
Air embolism (0.1%)
Pneumothorax (0.1%–1.5%)
Inability to place catheter with multiple attempts (1.7%)
Injury to great vessels (0.1%–13%)
Ventricular arrhythmias (20%–50%)
Related to catheter insertion (reported, but incidence unpublished)
Hemothorax
Hemomediastinum
Lymphatic duct perforation
Injury to trachea
Injury to phrenic or vagus nerve
Guidewire embolism
Catheter knotting (requiring surgical removal)
Cardiac perforation
Related to long-term maintenance (published incidence)
Pulmonary artery rupture (0%–0.5%)
Pulmonary infarction (0%–0.5%)
Catheter infection (1%–5%)
Related to long-term maintenance (reported, but incidence unpublished)
Catheter shearing with embolization
Misreading or misunderstanding of data provided by catheter

zeroed and calibrated again to confirm the accuracy of the pressure values if abnormally high or low values are obtained. Sometimes it is just not possible to obtain a good wedge tracing despite repeated attempts. In such cases, the pulmonary diastolic pressure may be used as a surrogate for the wedge.

A right bundle branch block may occur due to impact of the PAC with the right side of the septum during insertion. This is usually transient. Even if it persists for hours, it is well tolerated in most patients. However, superimposition of a right bundle branch block in the presence of a preexisting left bundle branch block leaves the patient with complete heart block. This complication can result in severe bradycardia and hemodynamic embarrassment. **It is important to be prepared to institute temporary transcutaneous or transvenous pacing when placing a PAC in patients with a left bundle branch block.**

Arrhythmias during insertion, most commonly premature ventricular beats, are usually due to irritation of the right ventricle. This is especially true of the outflow tract. Premature ventricular contractions are usually well tolerated unless sustained ventricular tachycardia or ventricular fibrillation occurs. Slight withdrawal and redirection of the PAC is usually adequate. Arrhythmias after insertion may be due to catheter loops in the right heart, which will be apparent on the chest radiograph and can be corrected by careful withdrawal of the PAC until the loop is removed. Arrhythmias may also occur if the PAC tip slips back into the right ventricle. In this case, the pressure tracing will show a typical right ventricular waveform. Readvancement of the PAC into the pulmonary artery should eliminate the arrhythmias.

Other potentially serious but rare complications during placement include injuries to the great vessels, trachea, lymphatic duct, vagus nerve, or phrenic nerve as well as a pneumothorax, hemothorax, hemomediastinum, and cardiac perforation. On occasion, the PAC can become knotted intravascularly or within the heart during placement. This requires an Interventional Radiologist to unknot it or surgical removal if this fails.

The most serious complications related to long-term maintenance of the PAC are pulmonary artery rupture, pulmonary artery infarction, and catheter infection. Pulmonary artery rupture is usually the result of the catheter becoming overwedged and/or the balloon over-inflated. Pulmonary infarction has been seen primarily in patients with mitral regurgitation or pulmonary hypertension and may be avoided if the duration of balloon inflation is kept to a minimum. Catheter infection occurs in 1% to 5% of PAC placements and can be minimized by strict sterile maintenance of the PAC as well as continually reevaluating the need for the PAC and keeping the placement time as short as possible. The majority of PACs should be used for 72 hours or less.

SUMMARY

Since its introduction four decades ago, the PAC was initially embraced by Emergency Physicians and Critical Care Physicians for its ability to provide real time information regarding variables such as cardiac output and pulmonary capillary wedge pressure at the bedside. PAC use had become common practice. However, over the last 15 years this has come into significant question. At this point, the utility of the PAC is unclear. The PAC has not led to improved outcomes, decreased mortality, or decreased ICU length of stay. Thus, its use as common practice cannot be supported. However, there are still many clinical situations for which the use of the PAC may benefit the Emergency Physician to make crucial decisions. The PAC is a tool in the armamentarium of any clinician taking care of critically ill patients. Therefore, it is important to be well versed in the information that it provides and its application in the clinical context of the disease state that they are managing.

54 Peripheral Venous Cutdown

Flavia Nobay

INTRODUCTION

Venous access in the critically ill patient is of the utmost importance. The literature regarding peripheral venous cutdowns extends back to 1940 when Keeley introduced this technique as an alternative to venipuncture in patients with shock.[1] Interestingly, there has been a noticeable lack of recent investigations regarding venous cutdowns, most likely due to the focus on central venous access via the Seldinger technique with ultrasound guidance and intraosseous access. Recent editions of the ATLS text refer to the saphenous venous cutdown as an optional skill to be taught at the discretion of the instructor.[2] However, despite the apparent lack of popularity of the peripheral venous cutdown, the importance of obtaining venous access in critically ill patients supports the need to know a wide variety of techniques in order to be successful in every situation. The steps outlined in 1940 by Keeley to expose and cannulate the saphenous vein remain mostly unchanged.[1]

Peripheral venous access can be extremely difficult due to vascular collapse from shock, vascular injury, obesity, or scars. Direct visualization of the vein to be cannulated can be more fruitful than indirect visualization with central venous lines without ultrasound guidance in the patient with shock. However, in a study in 1994 comparing venous cutdowns versus percutaneous femoral venous access, all times to completion of the procedure and infusion times were faster in the percutaneous femoral access group versus the cutdown

group.[3] Despite these statistics, it is not uncommon to be managing a critically ill patient who cannot be cannulated peripherally or centrally and the venous cutdown becomes a procedure of necessity for resuscitation. An additional advantage of the venous cutdown is that it does not interfere with concurrent resuscitative efforts at the head, neck, thorax, and abdomen.

Familiarity with this procedure allows for large-bore access and the rapid infusions required in the critically ill trauma or medical patient with difficult access. All Emergency Physicians should be familiar with the peripheral venous cutdown in order to effectively manage resuscitations in the trauma or medical setting. This technique can only be successfully performed if one understands the anatomy and details of venous cannulation. Practicing the cutdown technique before its critical need will help one to perform optimally in the emergent setting.

ANATOMY AND PATHOPHYSIOLOGY

There are three critical areas for venous cutdowns (**Figure 54-1**). All Emergency Physicians should be knowledgeable of the anatomy of the saphenous vein at the ankle, the saphenous vein at the groin, and the basilic vein at the elbow. **The potential injury to the patient can be significant if one approaches this procedure without regard to the clinical anatomy.**

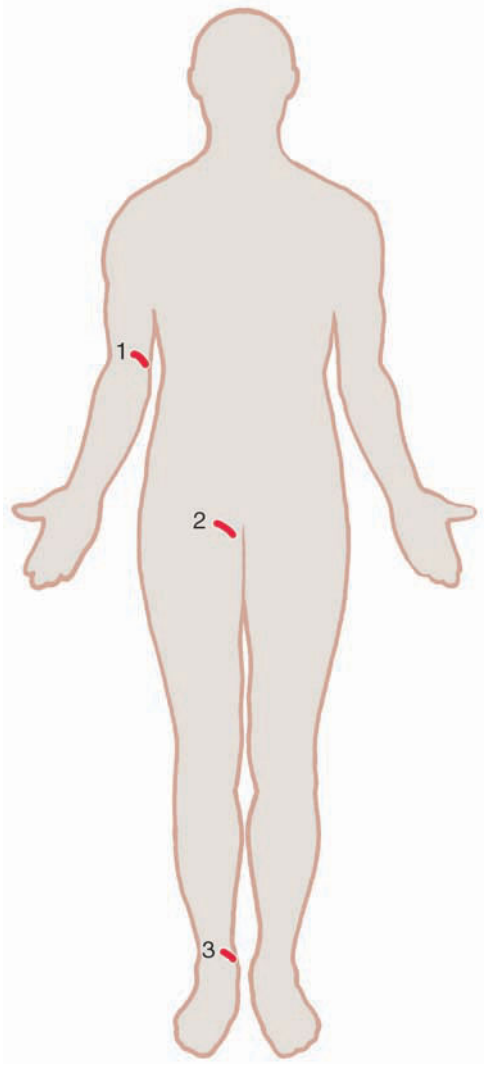

FIGURE 54-1. Common sites for peripheral venous cutdowns include the inner arm above the elbow (1), the inner thigh (2), and the inner ankle (3).

GREATER SAPHENOUS VEIN

The greater saphenous vein is the longest vein in the body. It is the ideal vein for a peripheral venous cutdown due to its anatomical regularity and superficiality (**Figure 54-2**). **The superficial and consistent position of the saphenous vein, in both adults and children, makes this the ideal vessel for a peripheral venous cutdown.** The saphenous vein begins at the medial dorsal venous arch of the foot. It passes upward and 1.5 to 2.5 cm directly anterior to the medial malleolus (**Figure 54-2A**). At the level of the medial malleolus, the saphenous vein lies just above the periosteum of the tibia.[4] It continues to ascend in the leg, along with the saphenous nerve, in the superficial fascia over the medial aspect of the leg. The vein passes posteromedially to the knee. Above the knee, it curves forward onto the anteromedial thigh. It passes over the falciform margin of the deep investing fascia to join the femoral vein approximately 4 cm below and 3 cm lateral to the pubic tubercle (**Figure 54-2B**).

The greater saphenous vein is easily identified at the ankle. It will be found, approximately, 2.5 cm anterior and 2.5 cm superior to the medial malleolus. It may be palpable if the patient is not hypovolemic or obese. The saphenous nerve, a branch of the femoral nerve, travels with the greater saphenous vein. It supplies sensory innervation to the skin of the medial leg and foot as far as the first metatarsal. This nerve is often transected when isolating the greater saphenous vein at the ankle. Fortunately, this nerve is of minimal clinical significance.

The saphenous vein in the thigh travels on the anteromedial surface and enters the fossa ovalis to join the femoral vein (**Figure 54-2B**). The femoral vein is at its largest diameter 3 to 4 cm distal to the inguinal ligament. This is approximately 2 cm distal to the approach for the placement of a femoral central venous line, at the same level where the scrotal or labial fold meets the thigh. The greater saphenous vein is also at its largest diameter in this location. At the level of the scrotal or labial fold meeting the thigh, the greater saphenous vein is easily isolated from the surrounding subcutaneous tissue. If the deep investing fascia of the thigh muscles is visible, the dissection has progressed deeper than the position of the greater saphenous vein.

BASILIC VEIN

The basilic vein is the site of choice for a peripheral venous cutdown in the upper extremity (**Figure 54-3**). It can be traced starting from the dorsal venous arch of the hand. It ascends on the posteromedial forearm to become anteromedial on the mid-to-upper forearm. It continues to ascend to the midportion of the arm where it pierces the deep fascia. The basilic vein runs in the groove between the biceps and triceps muscles in the distal one-third of the arm. The vein can always be found in the groove between the biceps and triceps muscles. A peripheral venous cutdown should be performed in this location. The basilic vein is more consistently found 2 cm cephalad and 1 to 2 cm lateral to the medial epicondyle of the humerus on the volar (anterior) surface of the arm. **The brachial artery and median nerve lie deep to the basilic vein in this location and are unlikely to be injured if the dissection remains superficial.**

Simon et al. recommend the approach to the basilic vein through the groove between the biceps and triceps muscles in the distal one-third of the arm.[5,6] These authors feel that locating the vein above and lateral to the medial epicondyle of the humerus will result in difficult cannulation secondary to the surrounding dense venous plexus. There is a significant risk of injury to the medial antebrachial cutaneous nerve and the deep brachial artery if one tries to find and isolate the basilic vein in the middle third

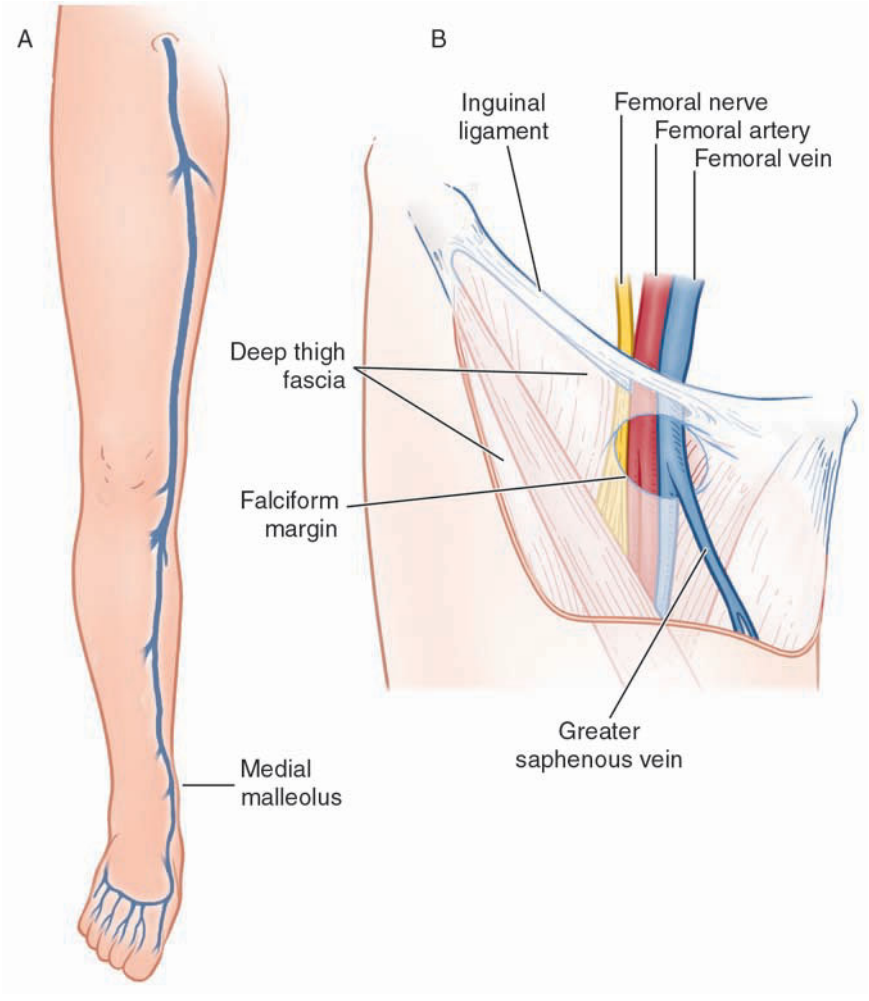

FIGURE 54-2. Anatomy of the greater saphenous vein. **A.** The subcutaneous course of the vein in the lower extremity. **B.** Detail of the greater saphenous vein at the groin.

or proximal third of the arm. Injury to the median antebrachial cutaneous nerve will result in sensory loss to the ulnar aspect of the forearm.

BRACHIAL VEIN

Brachial vein cutdowns should not be performed in the Emergency Department. The brachial vein is small in diameter. It is located relatively deep and would require significant and time-consuming steps to locate it. The anatomical structures surrounding the brachial vein include major arteries and nerves that can easily become injured while isolating the vein. Patients in hypovolemic shock will often not have a brachial artery pulse. This can lead to confusion as to which vessel is the artery and which is the vein.[4] Inadvertent cannulation of the brachial artery can result in a brachial artery thrombosis and upper extremity ischemia.

AXILLARY VEIN

The axillary vein is rarely used as a site for a venous cutdown. The axillary vein, in the axilla, is contained within the axillary sheath. Also contained within the axillary sheath are the axillary artery and brachial plexus. A venous cutdown for the axillary vein can injure these structures and is associated with a high rate of complications. It is not recommended to perform a cutdown for the axillary vein unless the Emergency Physician has specific experience with this particular technique.

INDICATIONS

The primary indication for a peripheral venous cutdown is the need for venous access in a patient with no peripheral access and in whom central access is not obtainable or contraindicated. This is the ideal procedure for the intravenous drug user with no peripheral veins and scarred central access sites, the burn patient with peripheral venous collapse and scarring, the patient in cardiorespiratory arrest, or the hypovolemic trauma patient that requires definitive and lifesaving volume resuscitation.[7] Hypovolemic shock is well treated with peripheral venous cutdowns because a unit of blood can be infused in less than 3 minutes with intravenous extension tubing inserted directly into the vein.[4]

This is also an excellent technique for emergent pediatric vascular access. Direct visualization of the vein will aid in cannulation of a vessel that may be collapsed secondary to hemorrhage, hypovolemia, and/or shock. This technique should only be used after other access attempts (i.e., interosseous access, ultrasound-guided central venous access, peripheral venous access—including scalp veins) have failed.[8]

CONTRAINDICATIONS

The absolute contraindications to a peripheral venous cutdown are vascular injury, saphenous vein removal, or long bone fractures proximal to the cutdown site. Relative contraindications include infection overlying the cutdown site, bleeding disorders, or severely

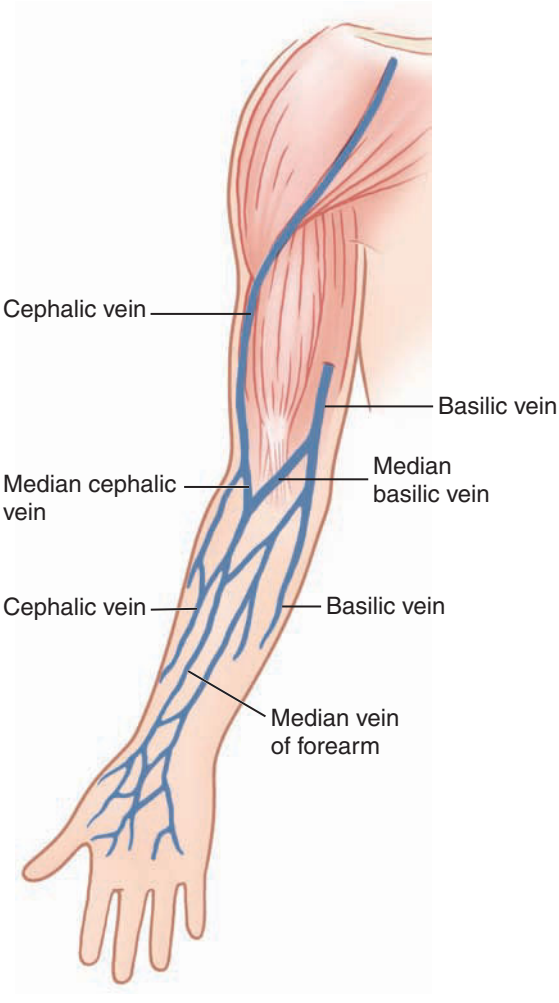

FIGURE 54-3. The superficial veins of the upper extremity.

distorted anatomy from congenital malformations, blunt trauma, or penetrating trauma in the area of the cutdown or the limb. A cutdown should not be performed unless peripheral intravenous access has failed and intraosseous access equipment is not available or has failed.

EQUIPMENT

- Povidone iodine or chlorhexidine solution
- Local anesthetic solution
- 10 mL syringe
- 22 gauge needle
- #10 scalpel blade
- #11 scalpel blade
- #3 scalpel handle
- Curved Kelley hemostat
- Small mosquito hemostat
- Vein pick
- Fine tooth forceps
- Iris scissors
- Sharp tissue-cutting scissors
- Sterile drapes
- Towel clips
- Sterile polyethylene intravenous tubing
- Sterile intravenous extension tubing
- Central line kit (for Seldinger method)
- Catheter-over-the-needle, 16 or 18 gauge
- Sterile 4 × 4 sponges
- 5 mL syringe
- 18 gauge needles
- Self-retaining skin retractors
- Small rake, two
- Needle driver
- Silk suture, 3-0 and 4-0
- Injectable sterile saline
- Intravenous tubing and solution
- Wound dressing supplies
- Antibiotic ointment

PATIENT PREPARATION

The patient is usually in extremis and positioned supine if a peripheral venous cutdown is to be performed. They may also be in the Trendelenburg position, although this is not ideal for the procedure. The limb selected for the peripheral venous cutdown should be secured to the bed with a restraint, tape, or by an assistant. **Although this is an emergent procedure, time should be taken to perform it in as sterile a manner as possible.**

Identify the landmarks for the procedure. Clean the skin of any dirt and debris. If the patient is awake and aware of the surroundings, the area of the cutdown should be anesthetized. Infiltrate local anesthetic solution into the subcutaneous tissue where the incision will be made. Prepare the skin with povidone iodine or chlorhexidine solution and allow it to dry. Apply sterile drapes to isolate a surgical field. Collect and set up all the required equipment on a bedside table covered with a sterile drape.

TECHNIQUES TO ISOLATE THE VEINS

The technique of cannulation is the same regardless of the vein chosen. The methods to isolate the saphenous vein and the basilic vein will be discussed in this section. A discussion of three different techniques to cannulate the isolated vein will be presented in the following section.

GREATER SAPHENOUS VEIN ISOLATION AT THE ANKLE

The saphenous vein is easily found and isolated at the ankle (**Figure 54-4**). Extend and externally rotate the lower extremity. Identify the medial malleolus of the tibia. Find the location 2.5 cm anterior and 2.5 cm superior to the medial malleolus. The greater saphenous vein will be found at this site. Alternatively, place your index and middle fingers at the level of the malleolus (**Figure 54-4A**). The vein will be found two finger breadths cephalad and two finger breadths in anterior of the medial malleolus. The vein may be palpable if the patient is not hypovolemic or obese. Alternatively, the vein may be visualized in patients with thin skin, superficial veins, minimal subcutaneous tissue, or dark vessels.

Stretch the skin taught over the distal tibia with the nondominant hand (**Figure 54-4B**). Note the position of the hands in the illustration. **The nondominant hand is placed with the fingertips pointing toward the Emergency Physician.** This will prevent inadvertent injury while making the skin incision. Transversely

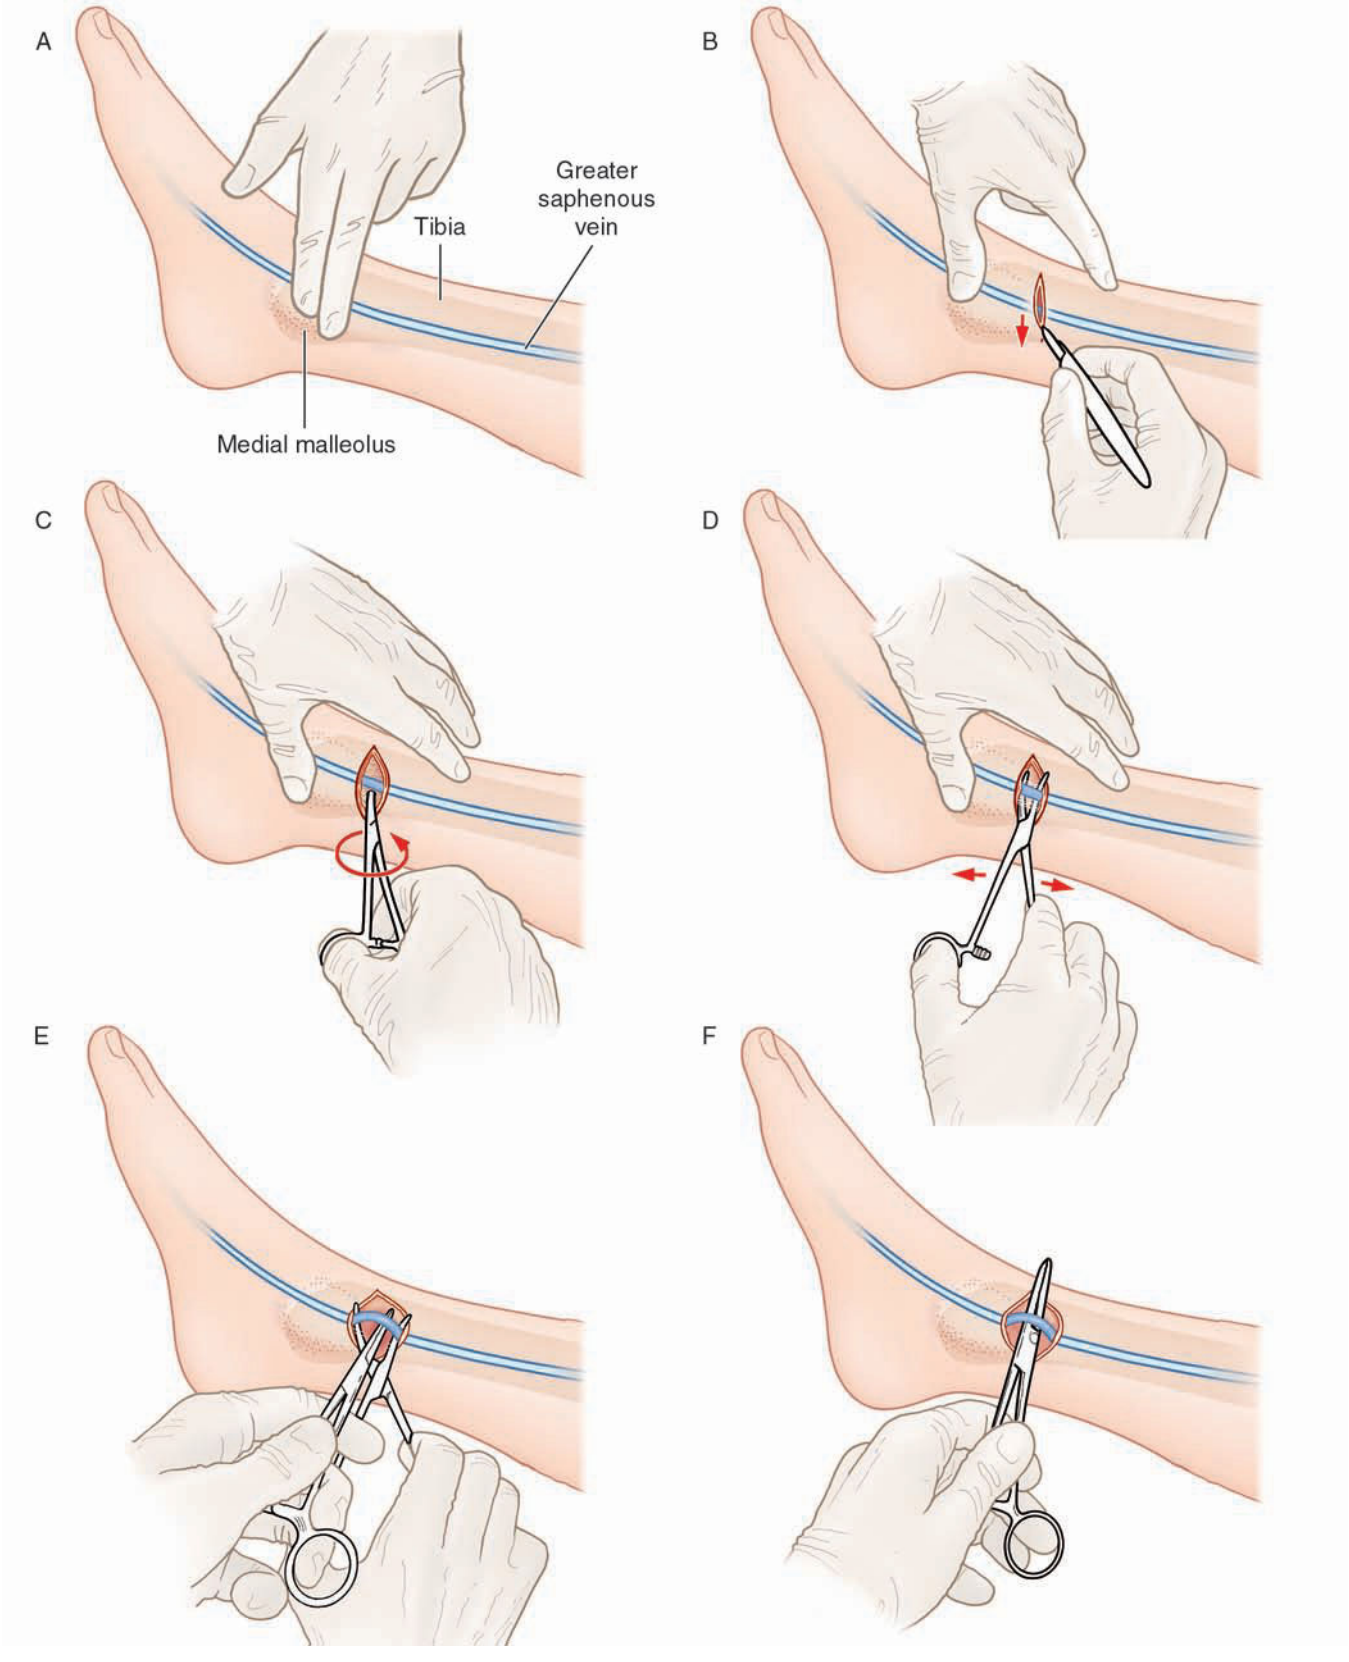

FIGURE 54-4. Isolation of the greater saphenous vein at the ankle. **A.** Identifying the vein. **B.** A transverse skin incision is made from the anterior to the posterior border of the medial tibia. **C.** The tip of a curved hemostat is scraped along the tibia then rotated 180° (*curved arrow*). **D.** The hemostat is spread to separate the tissues. **E.** A straight hemostat is inserted between the jaws of the curved hemostat to elevate the vein. **F.** The curved hemostat has been removed.

incise the skin overlying the great saphenous vein using a #10 scalpel blade, from the anterior tibial border to the posterior tibial border after appropriate anesthesia (**Figure 54-4B**). **This incision should be superficial so that the subcutaneous tissue is barely exposed.** A deep incision may transect the vein causing significant bleeding, difficulty visualizing the surgical field, and difficulty finding the ends of the vein that retract proximally and distally. Apply tension to the skin on either side of the incision to expose the underlying structures. This can be accomplished with the nondominant hand, a self-retaining retractor, or skin rakes held by an assistant.

Isolate the greater saphenous vein.[5] This may be difficult in some patients in shock or patients in the Trendelenburg position as the vein may be poorly perfused. Grasp and hold a curved hemostat (Kelly clamp) with the tip facing downward. Insert the hemostat along the posterior border of the tibia and scrape the tip anteriorly along the tibia (**Figure 54-4C**). If done properly, all of the tissue between the skin and the tibia will be above the hemostat. Rotate the hemostat 180° (**Figure 54-4C**). The tip of the hemostat will be facing upward (**Figure 54-4D**). Widely open the arms of the hemostat (**Figure 54-4D**). This will open the jaws of the hemostat and separate the saphenous vein from the saphenous nerve and fibrous strands of connective tissue. The saphenous vein should be visible between the jaws of the hemostat. If there is difficulty identifying the vein, squeeze the foot to backfill the vein with blood. Insert a straight hemostat (Kelly clamp) between the jaws of the curved hemostat and below the greater saphenous vein (**Figure 54-4E**). Remove the curved hemostat to leave the straight hemostat elevating the greater saphenous vein (**Figure 54-4F**). This straight hemostat will be useful as a "cutting board" to later transect the vein by allowing more manual control of the vein.

An alternative technique to isolate the vein is used by some Physicians. **This technique is not recommended by the editor but is briefly described for the sake of completeness.** Make the transverse skin incision. Place the jaws of a curved hemostat parallel to the greater saphenous vein. Open the arms of the hemostat to allow the jaws to dissect through the subcutaneous tissue. Continue placing the hemostat and opening the jaws until the vein is isolated. This technique is harder to perform because the vein is less likely to be identified given the white background of the periosteum.[1,8,9] Additionally, this technique takes significantly longer to find and isolate the vein.

GREATER SAPHENOUS VEIN ISOLATION AT THE GROIN

The groin vasculature offers the potential for massive infusion of blood or fluids in a matter of minutes. These vessels are closer to the central circulation and large enough to easily accommodate intravenous tubing, cut off at a 45° angle, as a catheter. The greater saphenous vein is superficial at the groin and lies in a meshwork of subcutaneous tissue. It is superficial to the femoral artery and vein. The saphenous vein travels on the anteromedial surface of the thigh and enters the fossa ovalis to join the femoral vein (**Figure 54-2B**). The greater saphenous vein is at its largest diameter 3 to 4 cm distal to the inguinal ligament. This is approximately 2 cm below the site for placement of a femoral central venous line and level with where the scrotal or labial fold meets the thigh.

Identify the location where the scrotal or labial fold meets the thigh (**Figure 54-5**). Identify the lateral edge of the mons pubis. Identify the point where a vertical line from the lateral edge of the mons pubis meets a horizontal line from the scrotal/labial fold. Make a transverse, medial to lateral, incision with a #10 scalpel blade on the patient's thigh starting where the scrotal or labial fold meets the thigh after appropriate anesthesia. Extend the incision laterally until it meets the vertical line from the lateral edge of the mons pubis.

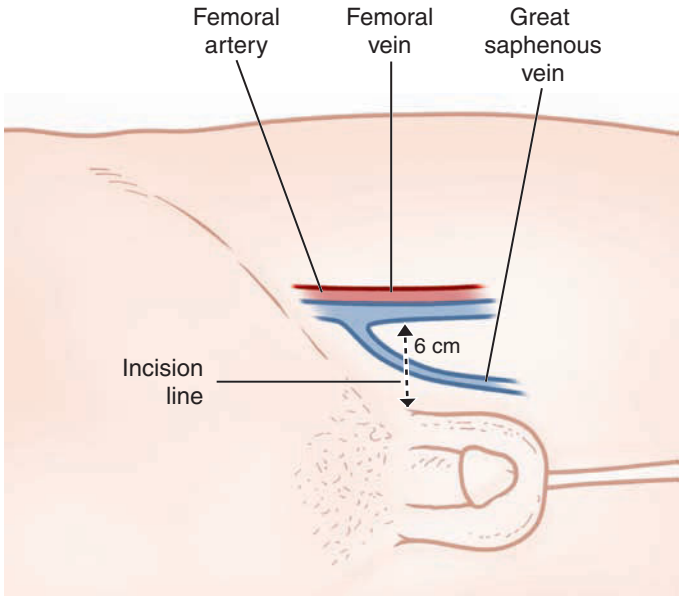

FIGURE 54-5. Isolation of the greater saphenous vein at the groin. The skin incision should begin where the scrotal or labial fold meets the thigh. Extend the incision laterally until it meets a vertical line from the lateral edge of the mons pubis.

Dissect the subcutaneous tissue to locate the greater saphenous vein. Place the jaws of a curved hemostat parallel to the greater saphenous vein. Open the arms of the hemostat to allow the jaws to dissect through the subcutaneous tissue. Continue placing the hemostat and opening the jaws until the vein is isolated. **The dissection is too deep if the deep investing fascia or the muscle bellies of the thigh muscles are encountered.** Stop, reidentify the landmarks, and adjust the skin incision and dissection as necessary.

Alternatively, the subcutaneous tissues can be bluntly dissected using 4 × 4 gauze squares. Grasp two or three gauze squares in each hand. Put the fingertips of both hands, covered with gauze, in the center of the incision. Move the hands in opposite directions, cephalad and caudad, while scraping the subcutaneous tissue with the gauze. Reapply the hands in the incision and repeat the motion until the greater saphenous vein is exposed. This technique applies pressure parallel to the greater saphenous vein and will not injure the vein.

BASILIC VEIN ISOLATION AT THE ELBOW

The basilic vein may be used for a peripheral venous cutdown. This is often performed when the greater saphenous vein cannot be accessed due to lower extremity amputation, deformity, injury, or trauma. This site is not ideal as it may interfere with resuscitative efforts while the basilic vein is being exposed. The basilic vein is consistently found 2 cm cephalad and 1 to 2 cm lateral to the medial epicondyle of the humerus on the volar surface of the arm. It may also be found in the groove between the biceps and triceps muscles. There is controversy in the literature as to where the incision for the basilic vein cutdown should be performed. The simple answer is that if one fails in isolating the vein in one location, make an incision in the second location to isolate the vein.

Position the patient to allow exposure of the basilic vein. Abduct the patient's arm 90° with the elbow flexed 90° and the palm facing upward (**Figure 54-6**). This positioning is required to access the basilic vein at either location.

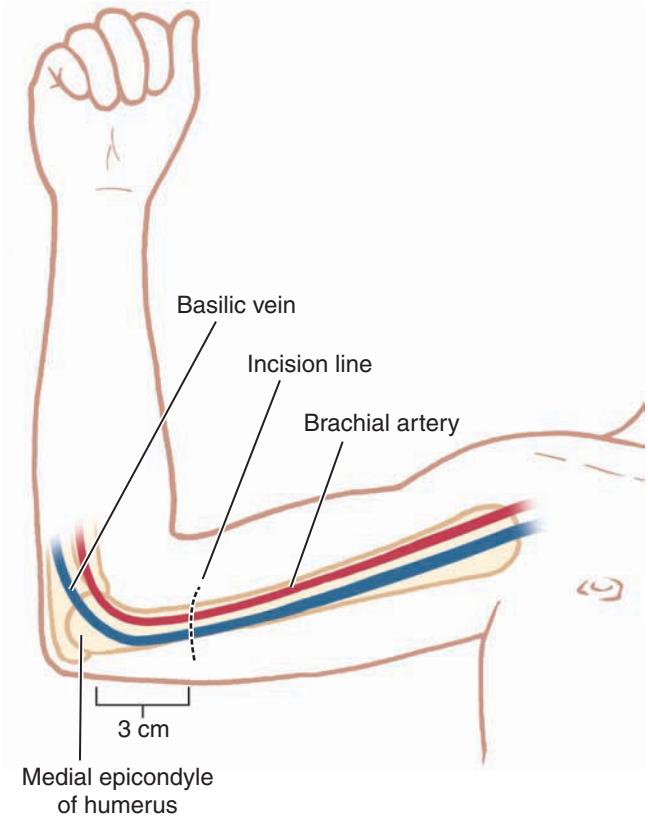

FIGURE 54-6. Isolation of the basilic vein.

Identify the point 2 cm cephalad and 2 cm lateral from the medial epicondyle of the humerus. This is the location of the basilic vein. Make a 4 to 6 cm transverse incision with a #10 scalpel blade centered on the reference point after appropriate anesthesia. The incision should only cut through the epidermis. Bluntly dissect the subcutaneous tissue with a curved hemostat or 4 × 4 gauze squares, as described previously, to locate the basilic vein. **The dissection is too deep if the brachial artery, median nerve, or muscle fibers are encountered.** Stop, reidentify the landmarks, and adjust the skin incision as necessary.

Alternatively, the basilic vein can be isolated in the middle of the distal third of the arm. Palpate the groove between the biceps and triceps muscles. This is the location of the basilic vein. Make a 4 to 6 cm horizontal incision centered about the groove after appropriate anesthesia. Bluntly dissect with a curved hemostat until the vein is located. The basilic vein is superficial to the muscle fascia and the brachial artery.

TECHNIQUES FOR CANNULATION OF THE VEIN

There are a number of techniques to cannulate a vein after it has been isolated. Either of the following techniques can be used to cannulate the greater saphenous vein or the basilic vein. It is important to realize that this may be a lifesaving procedure in an emergent setting, and the rapid and definitive cannulation of the vessel is the primary goal and not the technique chosen.

SURGICAL TECHNIQUE USING INTRAVENOUS TUBING

Isolate the chosen vein as described previously. Place a straight hemostat (Kelly clamp) under the midportion of the vein (**Figure 54-7A**). Slightly elevate the hemostat. Pass a silk suture under the vein at its proximal end and a second silk suture at its distal end (**Figure 54-7B**). Grasp the silk sutures with a hemostat to maintain the position of the tie and to allow for manipulation of the vein. Tie the distal suture to occlude inflow of blood from distal veins (**Figure 54-7C**). Do not cut either of these two sutures. The proximal suture will be left untied at this time to allow for control and manipulation of the vein.

Have an assistant prepare the catheter. Attach sterile intravenous polyethylene tubing to a bag of sterile saline. Cut the angiocatheter attachment hub off the end of the tubing at a 45° angle. Some authors suggest using a feeding tube instead of intravenous tubing.[8] This is not recommended. Intravenous tubing is ubiquitously available. With a feeding tube, the rounded tip may be more difficult to advance into the vein. The only advantage to using a feeding tube is that the rounded tip has less chance of puncturing the posterior wall of the vein.

Incise the vein. With the nondominant hand, grasp the hemostat holding the proximal suture. Raise the hemostat to flatten the vein and prevent back bleeding. Make an incision through half of the vein with the tip of a #11 scalpel blade (**Figure 54-7D**). **Do not cut the entire vein as this will cause significant bleeding and loss of the proximal end. If the incision is too large, greater than one-half the vein's diameter, the vessel may be torn completely and retract from the surgical field.**[8] The straight hemostat below the vein will act as a "cutting board" and prevent injury to underlying structures from the scalpel blade. As an alternative, the jaws of the straight hemostat can be opened and the vein cut with an iris scissors (**Figure 54-7E**).

Insert the intravenous tubing into the vein. Gently relax the tension on the proximal suture to allow the vein to open. Advance the intravenous tubing 2 to 3 cm into the vein (**Figure 54-7F**). Often times, there is considerable difficulty advancing the catheter. **Do not force the catheter through the vein as it is very delicate.** Troubleshoot by removing the catheter and make sure that the lumen of the vein has been cannulated. This is sometimes difficult to accomplish. If so, have an assistant control the proximal suture. Using a mosquito hemostat, grasp the cut edge of the vein and lift upward to expose the vein's lumen and insert the intravenous tubing (**Figure 54-7G**). For small veins, a mosquito hemostat may be too large to grasp the cut edge of the vein. Insert a vein pick or an 18 gauge needle with the tip bent into a 90° angle into the lumen of the vein (**Figure 54-7H**). Lift upward to expose the vein's lumen and insert the intravenous tubing.

After inserting the intravenous tubing, palpate the posterior aspect of the vein for penetration of the catheter. **The catheter must be removed if it penetrates through the posterior wall of the vein.** Release the proximal suture and allow the intravenous fluid to flow into the vein if the tubing has not penetrated the posterior wall of the vein. Tie the proximal suture to secure the intravenous tubing within the vein if the fluid flow is unobstructed and the fluid is not extravasating into the surrounding tissues (**Figure 54-7I**). **Do not tie the suture too tight to occlude the tubing.** Tying the suture too tightly may also result in a thrombosis.[10] If the tubing is within the lumen of the vein and the fluid is not flowing, the tubing may be against a venous valve. Gently advance the catheter 2 to 3 mm or withdraw it 2 to 3 mm and observe the fluid for flow. It is not necessary to close the skin incision at this time. Place saline moistened gauze over the incision site. Wrap a sterile dressing (e.g., Kerlix) around the extremity and the skin incision site.

If the patient survives the episode for which a venous cutdown was performed, the skin incision must be closed. If the intravenous tubing was inserted as above, the skin incision will be sutured

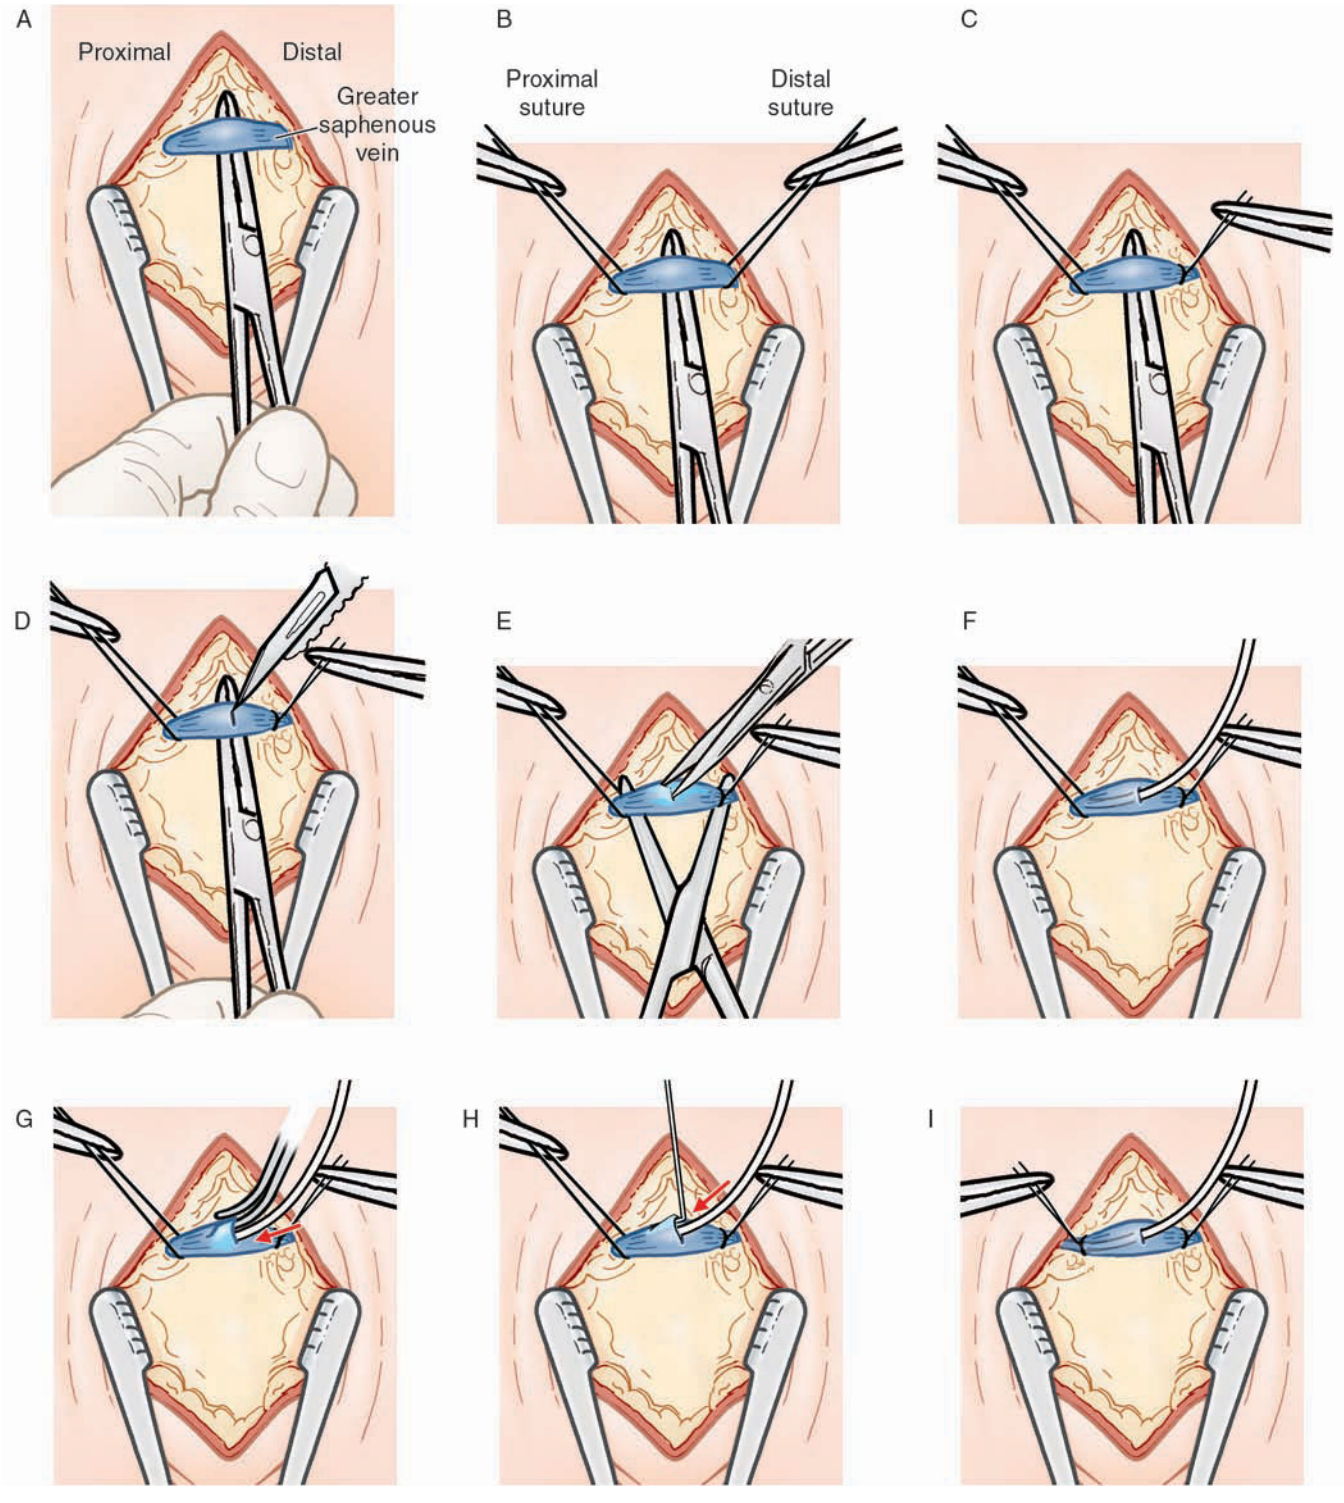

FIGURE 54-7. Venous cannulation using intravenous tubing. **A.** The vein has been isolated. **B.** A silk suture has been placed proximally and distally around the vein. **C.** The distal suture is tied. **D.** An incision is made through half of the vein with a #11 scalpel blade. **E.** Alternatively, the hemostat is opened and an iris scissors is used to cut half of the vein. **F.** The catheter is inserted into the vein and advanced. **G.** A mosquito hemostat can be used to grasp the vein and hold it open while the tubing is inserted. **H.** For small veins, a vein pick or 18 gauge needle with the tip bent can be used to hold open the vein. **I.** The proximal suture is tied to secure the tubing.

closed and the tubing will exit the incision. This is not optimal, according to some physicians, as it may allow access of bacteria through the wound and into the underlying vein. An alternative method is available (**Figure 54-8**). After exposing the vein, grasp and elevate the distal skin edge with a hemostat. Make a stab incision with a #11 scalpel blade approximately 1 cm distal to the previously made skin incision (**Figure 54-8A**). Use caution not to cut the underlying vein. Insert the intravenous tubing through the stab incision and pull it through the skin incision. Incise the vein and insert the tubing as described previously. This allows the tubing to be tunneled through the subcutaneous tissue before cannulating the vein (**Figure 54-8B**).

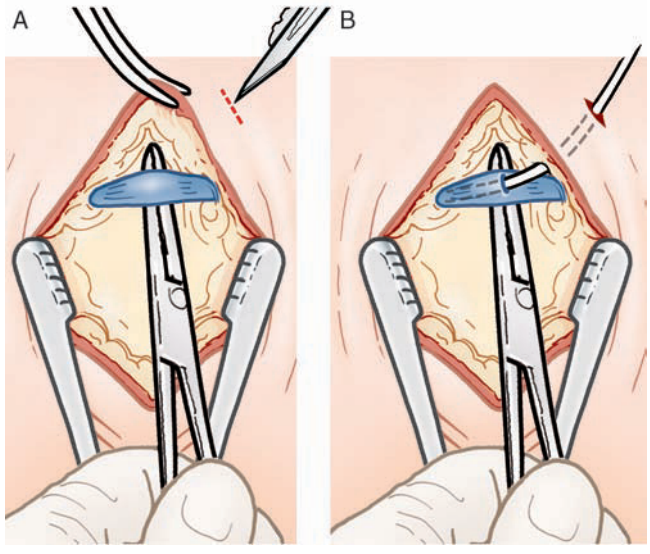

FIGURE 54-8. Alternative technique of venous cannulation with intravenous tubing. **A.** The distal skin edge is elevated. A #11 scalpel blade is used to make a stab incision in the skin and subcutaneous tissues. **B.** The tubing is fed through the stab incision and into the vein.

SELDINGER TECHNIQUE

Another technique of venous cannulation uses the Seldinger method.[9,11] This technique will insert the catheter as if cannulating a central vein. Refer to Chapter 49 for complete details. All of the required equipment can be found in a prepackaged central venous line access kit. This includes the guidewire, introducer sheath, dilator, and the venous catheter. This technique can accommodate a large caliber line, such as an 8 or 9 French introducer sheath. This technique may save 1 to 2 minutes on cannulation time by eliminating the ligature and tie off steps.

Isolate the chosen vein as described previously. Place a straight hemostat (Kelly clamp) under the midportion of the vein and open the jaws (**Figure 54-9A**). Insert the catheter-over-the-needle into the vein (**Figure 54-9A**). Stop advancing the catheter-over-the-needle when a flash of blood is seen in the needle hub. Be cautious not to puncture the posterior wall. Remove the straight clamp. Advance the catheter into the vein while securely holding the needle. Remove the needle. Insert the guidewire through the catheter. Remove the catheter by backing it out over the guidewire which will remain in the vein. Place the dilator through the introducer sheath. Feed the dilator–introducer sheath unit over the guidewire (**Figure 54-9B**). Advance the unit into the vein with a twisting motion while securely holding the guidewire (**Figure 54-9C**). Continue to advance the unit until the hub of the introducer sheath is just above the vein (**Figure 54-9D**). Remove the guidewire and dilator as a unit (**Figure 54-9D**). Attach intravenous tubing to the hub of the introducer sheath and begin instilling fluids. It is not necessary to close the skin incision at this time. Place saline-moistened gauze over the incision site. Wrap a sterile dressing (e.g., Kerlix) around the extremity and the skin incision site.

MODIFIED SELDINGER TECHNIQUE

An alternative and quicker method can be used to insert the introducer sheath into the vein (**Figure 54-10**). Isolate the chosen vein as described previously. Place a straight hemostat (Kelly clamp) under the midportion of the vein and open the jaws (**Figure 54-10A**). Assemble the unit by placing the dilator through the sheath and insert the guidewire through the dilator (**Figure 54-10B**). The guidewire should protrude 3 to 4 mm beyond the tip of the dilator. Make an incision in the lateral half of the vein (**Figure 54-10C**). While holding the proximal guidewire and sheath, insert the distal guidewire into the vein. Continue to insert the entire unit with a twisting motion into the vein (**Figure 54-10D**). Continue to advance the unit until the hub of the introducer sheath is just above the vein. Remove the guidewire

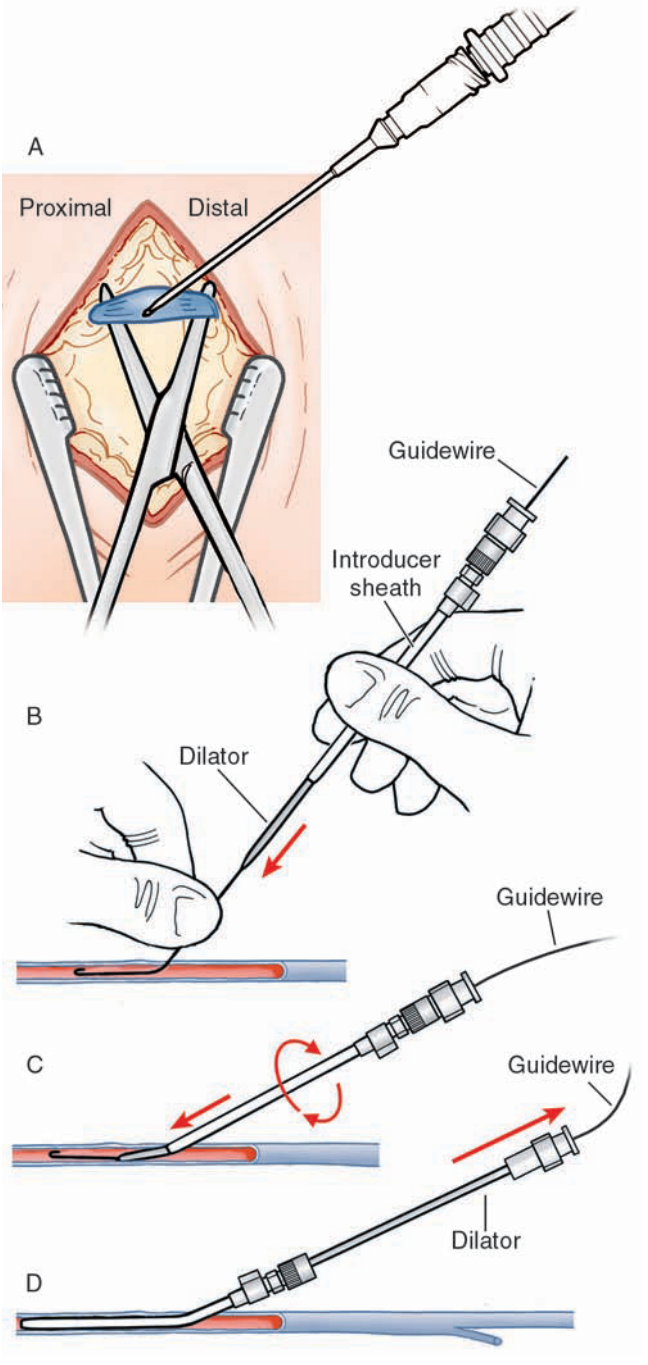

FIGURE 54-9. The Seldinger technique of venous cannulation. **A.** The vein has been isolated. The catheter-over-the-needle is inserted into the vein. **B.** A guidewire has been placed into the vein. The dilator and sheath are fed over the guidewire. **C.** The dilator and sheath are advanced into the vein with a twisting motion. **D.** The guidewire and dilator are removed as a unit.

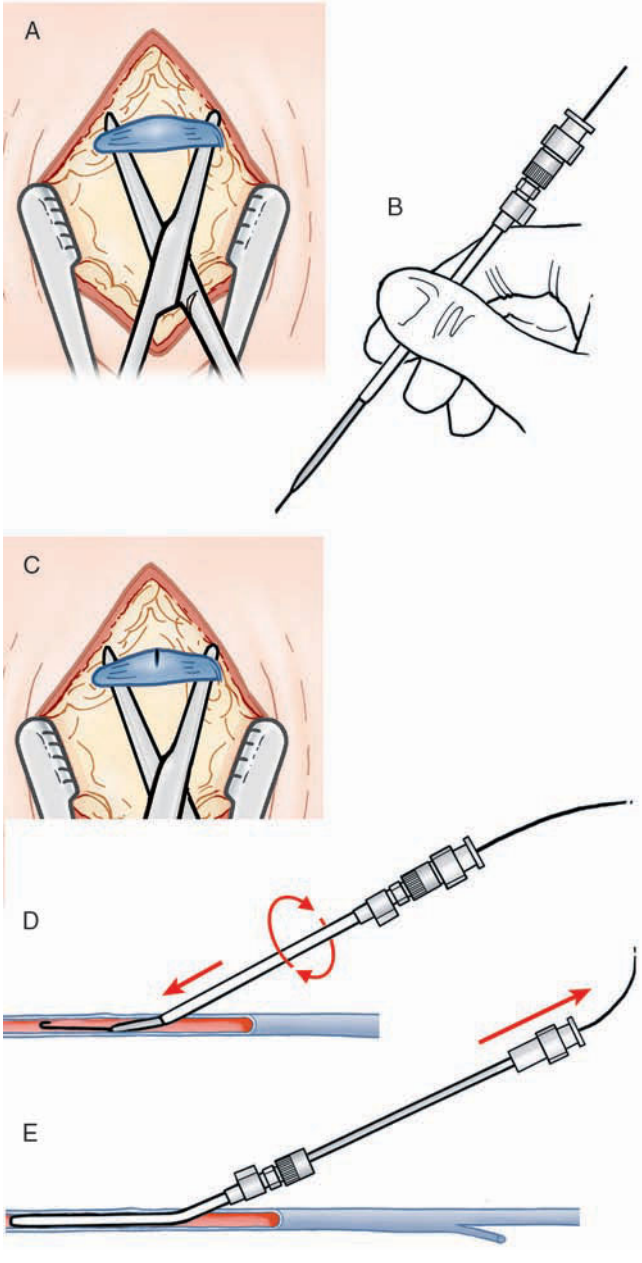

FIGURE 54-10. The modified Seldinger technique of venous cannulation. **A.** The vein has been isolated. **B.** The dilator, guidewire, and sheath are assembled as a unit. **C.** An incision has been made in the vein. **D.** The unit is inserted into the vein, guidewire first. A twisting motion will aid in its insertion. **E.** The guidewire and dilator are removed as a unit.

and dilator as a unit (**Figure 54-10E**). Attach intravenous tubing to the hub of the introducer sheath and begin instilling fluids.

INTRAVENOUS CATHETER TECHNIQUE

This final technique involves the insertion of a standard, 16 to 18 gauge, intravenous catheter-over-the-needle into the vein (**Figure 54-11**). This technique is sometimes referred to as the mini-cutdown. The vein is cannulated under direct visualization through a skin incision. This technique will insert the catheter as if cannulating a peripheral vein. Refer to Chapters 47 and 48 for complete details. This method is very quick, provides a more secure cannulation, and potentially decreases the chance of infection.

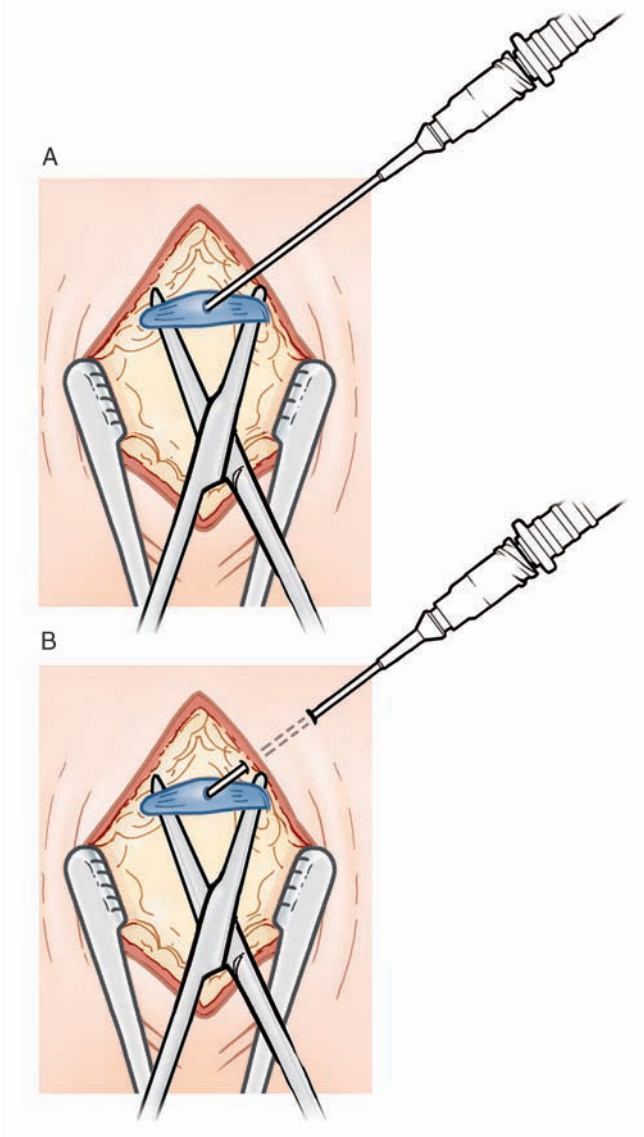

FIGURE 54-11. Intravenous catheter technique of venous cannulation. **A.** A catheter-over-the-needle is inserted into the vein. **B.** A catheter-over-the-needle is inserted through the skin and into the vein.

Isolate the chosen vein as described previously. Place a straight hemostat (Kelly clamp) under the midportion of the vein and open the jaws (**Figure 54-11A**). Insert the catheter-over-the-needle into the vein under direct visualization (**Figure 54-11A**). Stop advancing the unit when a flash of blood is seen in the needle hub. Advance the catheter into the vein while removing the straight clamp. Advance the catheter until the hub is just above the vein. Remove the needle. Attach intravenous tubing to the catheter hub and begin instilling fluids. Gently tie the proximal suture to secure the catheter within the vein. It is not necessary to close the skin incision at this time. Place saline-moistened gauze over the incision site. Wrap a sterile dressing (e.g., Kerlix) around the extremity and the skin incision site.

Alternatively, insert the catheter-over-the-needle through the skin, 1 cm distal to the distal skin edge, until the tip is visualized in the incision (**Figure 54-11B**). Insert the catheter-over-the-needle into the vein under direct visualization. Stop advancing the unit when a flash of blood is seen in the needle hub. Advance the catheter into the vein while removing the straight clamp. Advance

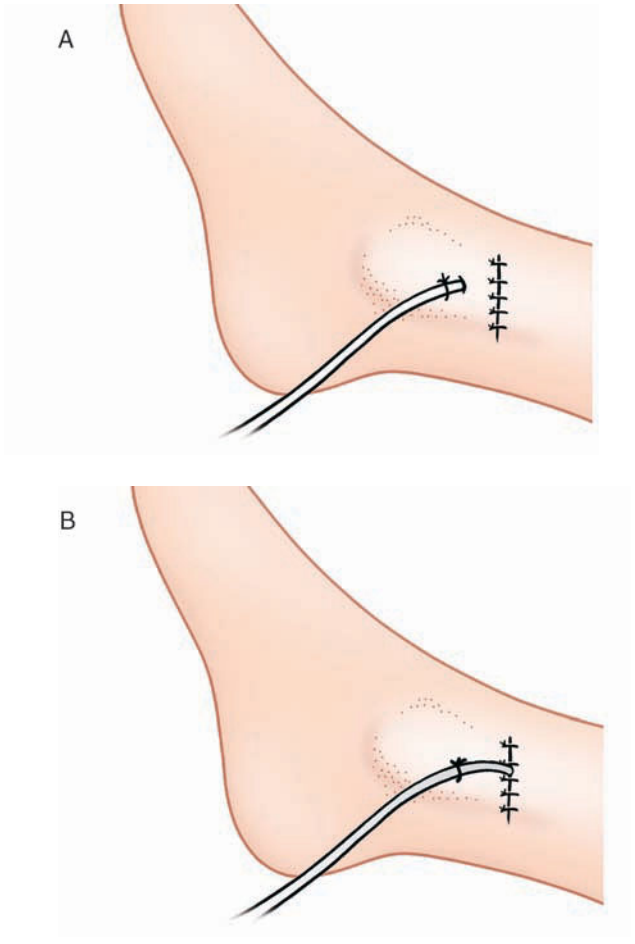

FIGURE 54-12. The skin incision is closed with interrupted 4-0 nylon sutures. The catheter exits a separate skin incision (**A**) or the original skin incision (**B**) and is secured with a suture.

the catheter until the hub is against the skin. Remove the needle. Attach intravenous tubing to the catheter hub and begin instilling fluids. The advantage of this method is that the catheter goes through the skin, which will stabilize the catheter and prevent it from becoming dislodged.

AFTERCARE

Suture the wound closed with simple interrupted 4-0 nylon sutures (**Figure 54-12**). Place a suture through the skin, wrap it around the catheter and tie it to secure the catheter to the skin. Apply antibacterial ointment to the incision, the sutures, and the site where the catheter exits the skin. Secure the intravenous tubing (**Figure 54-13**). The catheter can be looped around the toe, for a cutdown at the ankle, and secured with gauze wrap or an elastic wrap (**Figure 54-13A**). The catheter can be secured by taping it to the skin (**Figure 54-13B**). The limb can be immobilized on a board, after the catheter is secured at the ankle or elbow, for added security from inadvertent dislodgement of the catheter (**Figure 54-13C**).

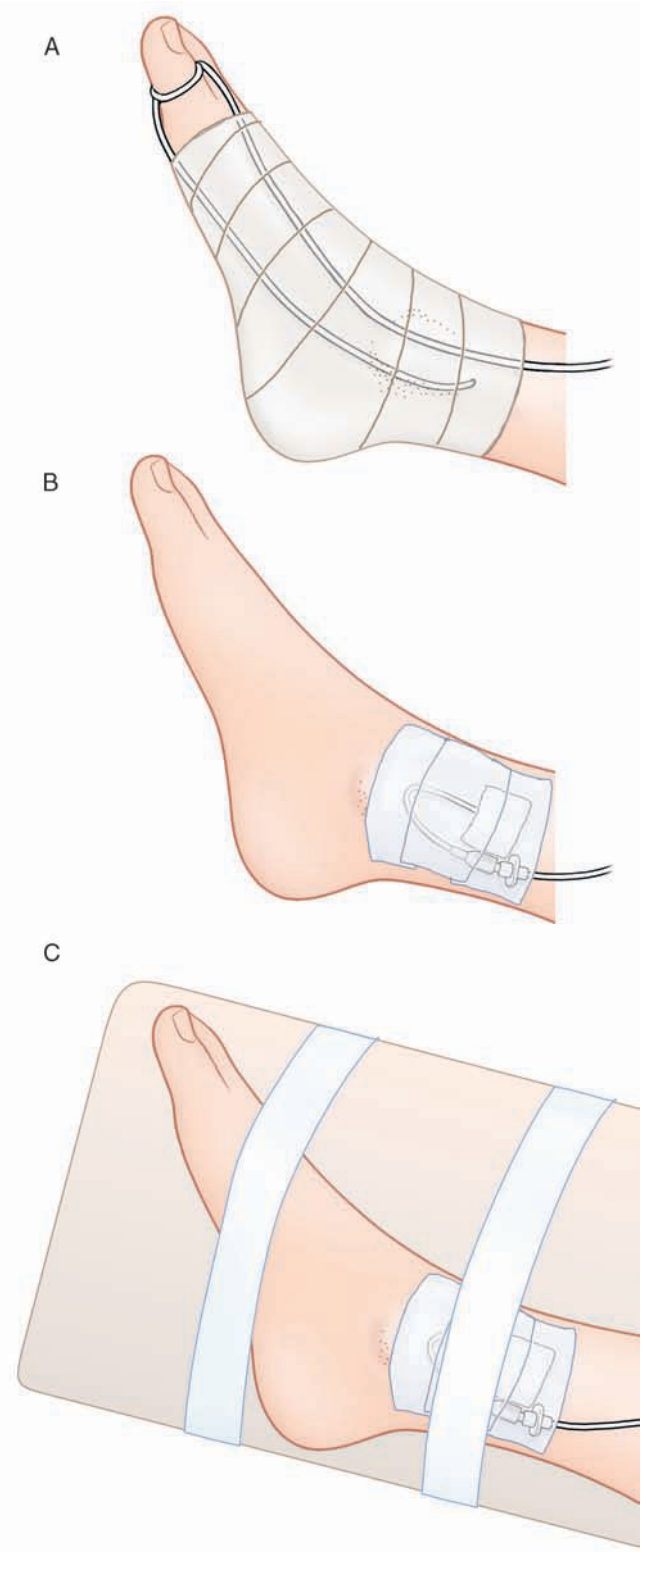

FIGURE 54-13. Securing the intravenous catheter. **A.** The catheter is looped around the great toe, for an ankle cutdown, and secured with gauze or elastic wrap. **B.** The catheter is secured with tape. **C.** The ankle or elbow can be secured to a board for additional security.

COMPLICATIONS

The complications of a peripheral venous cutdown include arterial injury, nerve injury, phlebitis, thromboembolism, wound dehiscence, and wound infection. The incidence of complications ranges from 2% to 15%.[12,16] The difficulty in reporting complications is that there is a high mortality rate in patients undergoing this procedure due to the primary problem (e.g., hypovolemia, sepsis, shock, trauma, etc.). The knowledge of the local anatomy and the technical aspects of the various cutdown techniques may avoid arterial, venous, and nerve injury. The other complications may be reduced by removal of the catheter within 12 hours after placement.[16]

PHLEBITIS

It is generally agreed that phlebitis occurs more commonly in the lower extremity than the upper extremity. However, there are little data to support this. Phlebitis usually results from prolonged catheterization. It may be seen within hours of catheter placement and as long as 18 days after the removal of the catheter.[16] In 1960, Bogen looked at 234 ankle cutdowns and found a 4% phlebitis rate.[14] He felt this was secondary to infection. The strength of the correlation was attributed to a previous nonrelated study that found *Staphylococcus aureus* on almost all catheter tips in patients with phlebitis as opposed to catheter tips in patients without phlebitis. Interestingly, these cases of phlebitis all resolved without the use of antibiotics. Moran et al. cultured 89 cutdown sites and observed that the pathogenic species causing infection were *S. aureus, Enterococcus*, and *Proteus*. These organisms were cultured more frequently in patients that had cutdowns that were left in place for longer periods of time. Moran et al. did not find a correlation between infection and phlebitis and postulated that phlebitis was due to irritation of the vein wall by the catheter.[13] Regardless of the rates and species, it is clear from all of these studies that **early removal of the intravenous catheter within 12 hours of placement will significantly decrease the incidence of phlebitis.**

INFECTION

Moran et al. did not find that prophylactic antibiotics reduced infection rates.[13] They found that daily topical antibiotic ointment, in particular Neosporin™, reduced positive local wound cultures from a rate of 78% to 18%. In 1968, Collins et al. studied polyethylene catheters and found a 2% bacteremia rate and a 1% death rate from *Pseudomonas* species in debilitated patients.[15] Rhee et al. in 1988 found only one case of cellulitis in their study of 78 patients.[11] Regardless of the rates and species, it is clear from all of these studies that **early removal of the intravenous catheter within 12 hours of placement will significantly decrease the incidence of infection and subsequent complications.** Obviously, sterile technique is also encouraged with this procedure in order to minimize complications related to infection.

ASSOCIATED INJURIES

Injury to adjacent arteries, nerves, and veins can be avoided by a detailed understanding of the local anatomy and careful procedural technique. Aggressive and forceful dissection without an understanding of the anatomy or the procedure will increase the incidence of complications. Injury to adjacent cutaneous nerves is unavoidable and inconsequential. Venous spasm, which causes nonuniform acceptance of the intravenous extension tubing, may also occur.[16]

SUMMARY

The peripheral venous cutdown is an excellent technique for rapid fluid or blood product infusion in the emergent setting. This is usually performed when other methods of venous access are unavailable or have failed. It is a relatively simple procedure. If learned properly, it can be lifesaving in the critically ill or injured patient. It is imperative to understand the relevant local anatomy and identify the clinical landmarks before this procedure is performed. Strict adherence to sterile technique and the early removal of the catheter will decrease the rate of infection and complications.

55 Intraosseous Infusion

Amanda Munk and O. John Ma

INTRODUCTION

Obtaining peripheral vascular access in the critically ill patient may be difficult and time-consuming. The vascular collapse that may accompany severe dehydration or a cardiac arrest can be profound and delay administration of essential therapies. Pediatric patients, in particular, may present a challenge due to the small size of their peripheral veins and the increased subcutaneous tissue. Administration of endotracheal medications may not provide rapid and reliable drug absorption during a cardiorespiratory arrest.[1,2]

Intraosseous (IO) access was first described in 1922 by Dr. Drinker. He referred to the medullary cavity as a "non-collapsible vein" that can be used for obtaining rapid vascular access. IO access for pediatric use was introduced in 1941. The first IO blood transfusion was documented in1942. The IO route of venous access did not become popular for many reasons. The equipment at the time was crude and did not improve until the 1970s. The technique of a saphenous venous cutdown was soon developed as an alternative method for obtaining vascular access. The development of plastic, disposable, and single use intravenous (IV) catheters revolutionized the technique of IV access.

IO access is an alternative route for blood, drug, and fluid administration. This previously abandoned technique was reintroduced in the mid-1980s in response to the need for more immediate vascular access during cardiopulmonary resuscitation.[3,4] This procedure has focused on pediatric patients due to the increased difficulty and necessity of access in critically ill children. Studies have demonstrated that peripheral venous access during pediatric cardiac arrest constituted the most expeditious manner of obtaining vascular access (mean time of 3.0 minutes). However, it was only successful in 17% of patients. This was in stark contrast to the 83% success rate for IO lines, 81% for peripheral venous cutdowns, and 77% for central venous lines.[5,6] The time required to place an IO line was 4.7 minutes compared to 8.4 minutes for a central venous line and 12.7 minutes for a peripheral venous cutdown. The insertion of an IO line was recently studied in the prehospital arena, where it was shown to be safe and effective.[7,8] IO infusion is also quick, safe, and effective in compromised neonates.[9]

IO access has been increasingly used in the resuscitation of adult patients when vascular access is unobtainable.[10,11] For prehospital providers, IO access has proved to be an invaluable procedure. One national prehospital study noted success rates for IO placement at 91%, with the majority of patients being adults.[12] In adults over the age of 80 years, success rates neared 97%. The newer powered devices make penetrating the adult cortical bone much less difficult.[12]

ANATOMY AND PATHOPHYSIOLOGY

Long bones are composed of a dense outer cortex and inner soft, spongy (cancellous) bone (**Figure 55-1**). The nutrient artery supplies the bone with a rich vascular network. It pierces the cortex and divides into ascending and descending branches that further divide into arterioles and then capillaries. Venous drainage from the capillaries into the medullary venous sinusoids, located at the proximal and distal portions of the long bone, flows into the central venous channel located in the shaft of the long bone.[13]

The IO needle is inserted through the cortex and into the bone marrow (medullary) cavity of a long bone. Numerous anatomic sites can be used to access the medullary cavity. The most traditional

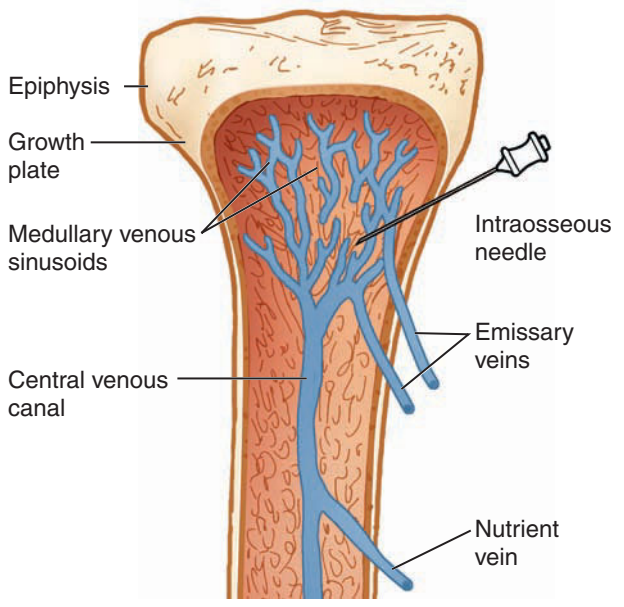

FIGURE 55-1. Venous anatomy of a long bone.

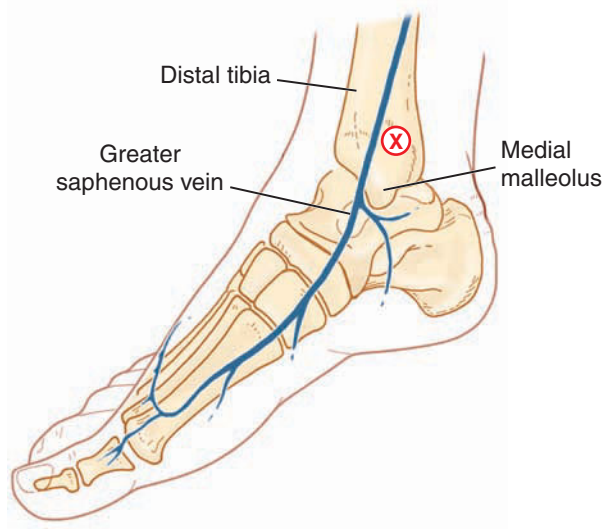

FIGURE 55-3. The distal tibia is one of the preferred sites for IO access in adult patients. The ⊗ represents the site of IO needle insertion.

site, which is favored in pediatric patients, is the flat anteromedial surface of the proximal tibia (**Figure 55-2**). The distal tibia just above the medial malleolus is the preferred site in adult patients (**Figure 55-3**). In the adult, it is easier to penetrate the cortex of the medial malleolus than the thicker cortex of the proximal tibia. Other sites for IO access include the flat anterior surface of the distal femur (**Figure 55-4**) and the anterolateral surface of the proximal humerus (**Figure 55-5**).[14]

Crystalloid infusion studies through an IO line in animals have demonstrated an infusion rate of approximately 10 to 20 mL/min with gravity and up to 40 mL/min under pressure.[15,16] Fluids and medications administered through an IO line are immediately absorbed into the systemic circulation. Sodium bicarbonate infusion, even during a cardiac arrest, was shown to have superior buffering capacity when administered via an IO line than by a peripheral IV line.[17] Medications and fluids that may be administered by the IO route are listed in **Table 55-1**.[18,19] **The medication concentrations, dosages, and infusion rates through an IO line are the same as those through a peripheral IV line.** Succinylcholine has been effectively infused by the IO route for muscle paralysis prior to endotracheal intubation.[20]

INDICATIONS

The placement of an IO line is indicated when vascular access is rapidly required for the resuscitation of a patient and standard vascular access is unobtainable or delayed. It may be operationally useful to define a specific time frame or a specified number of peripheral IV attempts before proceeding to IO access. Situations that may require the placement of an IO line are cardiac arrest, shock, sepsis, trauma, severe dehydration, extensive burns, status epilepticus, or any condition that requires urgent administration of fluids, medications, or blood products.[18] Current American Heart Association Advanced Cardiac Life Support guidelines recommend IO access if IV access is unobtainable within 90 seconds or two attempts and for the administration of medications over endotracheal medication administration.

In addition to resuscitation, IO access can provide blood samples for typing, crossmatching, and laboratory analysis. Electrolytes, creatinine, blood urea nitrogen (BUN), glucose, calcium, and arterial blood gas values from blood samples obtained through an IO needle

TABLE 55-1 Medications and Fluids that may be Administered Through an IO Line[16–19,43,44]

Medications

Adenosine	Diazoxide	Lorazepam
Amiodarone	Digoxin	Mannitol
Antibiotics	Dobutamine	Morphine
Antitoxins	Dopamine	Naloxone
Anesthetics	Ephedrine	Norepinephrine
Atracurium besylate	Epinephrine	Pancuronium
Atropine	Heparin	Phenobarbital
Calcium gluconate	Insulin	Phenytoin
Calcium chloride	Isoproterenol	Propranolol
Contrast media	Ketamine	Sodium bicarbonate
Dexamethasone	Levarterenol	Succinylcholine
Diazepam	Lidocaine	Tenecteplase
		Thiopental
		Vecuronium

Fluids

Blood products
Dextrose solutions
Iodinated contrast agents
Lactated Ringer's solution
Packed red blood cells
Plasma
Sodium chloride solutions

are similar to those from samples taken via traditional routes.[21,22] Laboratory values may be less accurate after five or more minutes of active resuscitation, or if drugs or fluid have been infused through the IO site.[22]

CONTRAINDICATIONS

Placement of an IO line is contraindicated in diseased or osteoporotic bone. The placement of an IO line through areas of cellulitis, abscesses, or burns should be avoided.[23] Fractures in the ipsilateral bone increase the risk of an extravasation-induced compartment syndrome and nonunion of the fractures.[24] Failed placement of an IO line in the same bone is a relative contraindication. Do not use a bone that has had a previous orthopedic procedure, contains hardware, or may contain hardware (i.e., pins, plates, screws, and artificial joints). An IO line should not be inserted if the patient is morbidly obese as the needle is too short to enter the medullary cavity or if the patient is so obese that the bony landmarks cannot be palpated.

There are contraindications specific to sternal IO access. Do not attempt sternal IO access in patients who weigh less than 50 kg, are small in stature, have a small sternum, have congenital sternal malformations, or have chest wall malformations. The blunt trauma patient with a suspected sternal fracture or soft tissue injury over the sternum should not be considered for sternal IO access. A history of a sternotomy or osteoporosis is also a contraindication.

EQUIPMENT

- Sandbag or towels
- Povidone iodine or chlorhexidine solution
- Local anesthetic solution, 1% or 2% lidocaine
- Syringe, 5 to 60 mL
- Primed intravenous tubing with normal saline
- Tape
- Plastic protective cup
- Leg board for immobilization
- IO access device

IO needles are available in a number of sizes and styles (**Figure 55-6**). **Only specifically designed IO needles should be used for this procedure.** Spinal needles often bend and do not penetrate the cortex of the bone. Their long length causes increased resistance to fluid flow. Standard hypodermic needles also often bend and do not penetrate the cortex of the bone. Both these types of needles may break while being inserted and injure the healthcare provider.

Available models of manually inserted IO devices include the hand-driven threaded-needle SurFast and Cook Intraosseous needle (Cook Critical Care, Bloomington, IN), the Jamshidi bone marrow needle (Baxter Healthcare, Valencia, CA), and the MedSurg Industries Illinois sternal/iliac aspiration needle (MedSurg Industries, Rockville, MD). The typical unit consists of a detachable

FIGURE 55-6. IO infusion needles. *From left to right*: the Cook Intraosseous infusion needle, two models of the Illinois sternal/iliac aspiration needle, and the Jamshidi bone marrow needle.

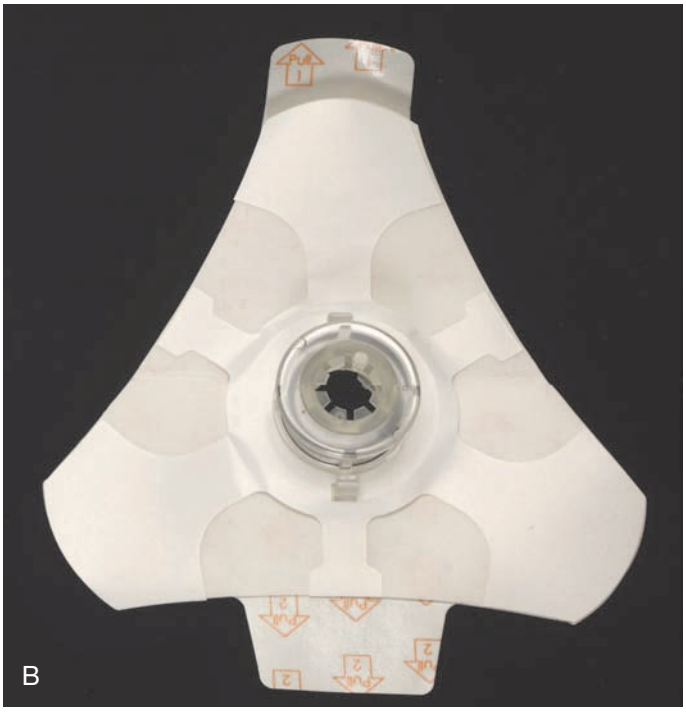

FIGURE 55-7. The EZ-IO. **A.** The driver and three lengths of IO needles. **B.** The EZ-Stabilizer (Photos courtesy of Vidacare, San Antonio, TX).

handle, an IO needle, an obturator, and a sleeve to prevent the needle from penetrating too deeply. The IO needle ranges in size from 12 to 20 gauge. The IO needles available today are variations of the basic unit and include adjustable-length shafts to decrease the risk of penetrating too deeply, a variety of tips on the obturator (e.g., lancet, pencil point, and trocar), threaded versus nonthreaded shafts, needle side ports to increase flow rates, numerous lengths, and numerous handle types.

New powered and spring loaded injection devices have evolved. Two currently available devices are the EZ-IO Intraosseous Driver (Vidacare, San Antonio, TX) and the Bone Injection Gun (BIG, Wais Medical, Kress USA Corporation). The EZ-IO uses a battery-powered driver to insert the needle to a preset depth (**Figure 55-7**).[14] The BIG incorporates a loaded spring to inject the IO needle, and the desired depth of injection may be adjusted (**Figure 55-8**).[25] Both devices are available in adult and pediatric needle sizes. The EZ-IO and the BIG have numerous advantages when compared to

FIGURE 55-8. The BIG in adult and pediatric sizes (Photo courtesy of Wais Medical, Houston, TX).

the manual devices. They are easier to use, quicker to establish IO access, require less or no force to insert the IO needle, and do not bend during insertion.

Sternal access devices include the MONOJECT™ I-Type Sternal-Iliac Aspiration Needle (Covidien, Mansfield, MA), the First Access for Shock and Trauma (FAST1™ and FASTX™, Pyng Medical, Richmond BC), and Life/form® Adult Sternal Intraosseous Infusion System (Nasco, Modesta, CA). The F.A.S.T.1™ is a multiple-component kit to be used for sternal IO access in the adult patient. A special introducer limits the depth to which the needle can be inserted. This prevents injury to the underlying great vessels, heart, lung, and mediastinum. This system was evaluated in Special Forces military settings, and found to be equally useful and safe in terms of IO access.[27] Sternal IO access devices are used less often than the previously described powered devices due to the possible interference with resuscitation attempts and their incomplete removal on occasion requiring surgical removal.

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative if time permits. This procedure is often performed in emergencies; therefore, informed consent can often be waived. Currently, the primary site of choice for IO line placement is the proximal tibia. Alternate sites include the distal tibia, distal femur, proximal humerus, and the sternum. Even with sternal access, it is possible to perform a cricothyroidotomy and cardiopulmonary resuscitation (CPR).[25] The proximal humerus allows more central access, while the proximal tibia is often accessible without disrupting airway management and CPR.[14]

Place the patient supine with the lower extremity supported behind the knee with a towel or sandbag. Identify by palpation the landmarks required to perform the procedure. Palpate the bony landmarks with the nondominant hand. The bony landmarks for the proximal tibia approach are the tibial tuberosity and the flat anteromedial surface of the proximal tibia. The site of IO needle placement is approximately 2 cm below the tuberosity on the flat anteromedial surface of the proximal tibia (**Figure 55-2**). The bony landmark for the distal tibia approach is the junction of the medial malleolus and the flat anteromedial surface of the distal tibia just posterior to the greater saphenous vein[18] (**Figure 55-3**). This is the preferred site in the adult patient. The bony landmarks for the distal femur approach are the medial and lateral condyles of the femur

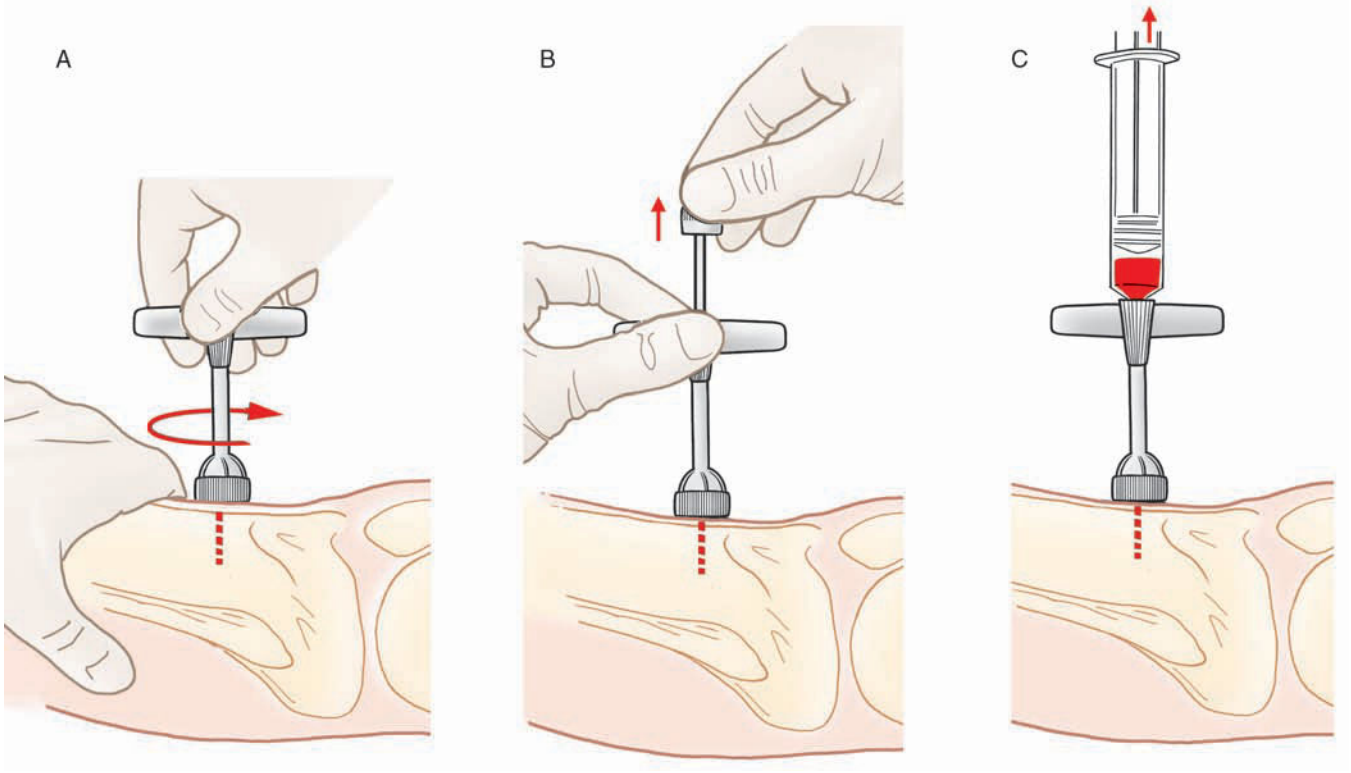

FIGURE 55-9. Placement of an IO line. **A.** The nondominant hand is used to support the extremity. The IO needle is inserted with a twisting motion to cut through the cortex of the bone. **B.** The handle and obturator are removed. **C.** A syringe is attached to the hub of the IO needle and bone marrow is aspirated.

and the patella. The IO needle should be positioned approximately 2 cm above these structures (**Figure 55-4**). This site is utilized less often due to the abundance of muscle and soft tissue structures. The bony landmarks for the humeral approach are slightly anterior to the lateral midline of the arm, with care to avoid the bicipital groove (**Figure 55-5**). The arm should be adducted and internally rotated for optimal positioning.[14]

Prepare the patient. Clean any dirt and debris from the skin. Apply povidone iodine or chlorhexidine solution to the skin and allow it to dry if time permits. This procedure is extremely painful. If time permits, the use of a local anesthetic solution in the conscious or semiconscious patient will be greatly appreciated. Infiltrate local anesthetic solution into the skin, subcutaneous tissues, and periosteum overlying the bone puncture site. Additionally, in the alert patient, consider infusing 3 to 5 mL of 2% lidocaine intravenously both initially and at regular intervals to minimize patient discomfort.[11]

TECHNIQUE

MANUALLY INSERTED IO DEVICES

Examine the IO needle to ensure that it appears to have been manufactured properly. Reidentify the landmarks with the nondominant hand. Stabilize the extremity with the nondominant hand (**Figure 55-9A**). Grasp the IO needle firmly with the dominant hand. The handle of the IO needle should be firmly planted in the palm of the dominant hand. Insert the needle perpendicularly or slightly angulated (at a 10° to 15° angle) to the long axis of the bone (**Figure 55-9**). **The IO needle should always be directed away from the growth plate to avoid injuring it.** Direct the needle caudad in the proximal tibial approach and cephalad in the distal tibial and distal femoral approaches.

Advance the IO needle through the skin and subcutaneous tissue until the bone is contacted. Advance the IO needle through the bone. A twisting or rotary motion with the simultaneous application of downward pressure should be used to cut through the cortex of the bone (**Figure 55-9A**). A significant reduction in the resistance to forward motion will be encountered when the cortex is penetrated and the needle enters the medullary canal. This distance is rarely greater than 1 cm in most patients. An index finger may be placed 1 cm from the bevel of the IO needle prior to advancement. This will help prevent overpenetration into and through the cortex on the opposite side of the bone.[28] Alternatively, adjust the sleeve so that only 1 cm of the IO needle is exposed. **Stop advancing the IO needle when it enters the medullary canal.**

Remove the stylet when the medullary canal is entered (**Figure 55-9B**). Attach a 5 or 10 mL syringe onto the hub of the IO needle (**Figure 55-9C**). Aspirate blood from the medullary canal to confirm proper placement of the IO needle. Any samples obtained may be sent to the laboratory for subsequent analysis. The aspiration of more than 2 to 3 mL of blood may not be possible in cardiac arrest situations. Attach IV tubing to the hub of the IO needle and begin the infusion of fluids. Medications can be administered through the injection port of the IV tubing. Place a sterile dressing around the skin puncture site and apply pressure for 5 minutes.[29]

IO ACCESS USING THE EZ-IO

The EZ-IO is a reusable, nonsterile, battery powered driver that uses sterile, disposable, single patient use IO needles. The IO needles are available in three lengths (15, 25, and 45 mm). Choose the proper IO needle for the patient, their body habitus, and the insertion site. Assess the tissue depth by palpation. Choose an IO needle so that at least one black line on the IO needle shaft will be

FIGURE 55-10. Using the EZ-IO. **A.** An IO needle has been applied onto the driver. **B.** Insert the IO needle at a 90° angle to the skin. **C.** The driver has been removed. **D.** The stylet is removed. **E.** The EZ-Stabilizer and tubing have been applied.

above the patient's skin when the tip is against the bone. The IO needle tip is designed to cut the bone and create a hole the same size as the needle.

Identify the IO insertion site and prepare for the procedure. Clean and prep the skin at the site and surrounding area. The procedure requires aseptic technique. Select the appropriate size IO needle. Open the cover of the case that holds the sterile IO needle. Insert the bit on the EZ-IO driver into the base of the IO needle (**Figure 55-10A**). **Leave the cap on the IO needle until it is ready to be inserted.** Open the EZ-Connect tubing and flush it with a syringe containing 10 mL of sterile normal saline. Leave the syringe attached to the tubing after it is flushed.

Reidentify the landmark for the insertion site. Inject local anesthetic solution subcutaneously and down to the periosteum. Remove the cap from the IO needle. Insert the IO needle perpendicular or at a 90° angle to the skin (**Figure 55-10B**). Advance the IO needle through the skin and subcutaneous tissues until the tip is against bone. At least one black line on the needle shaft should be visible above the patient's skin. If a black line is not visible on the needle shaft, withdraw the needle and replace it with a longer

IO needle. Press the trigger to start the driver shaft and IO needle rotating. **Apply gentle and minimal downward pressure to advance the IO needle into the medullary canal. Stop advancing the driver when a loss of resistance is felt.**

Grasp and firmly hold the hub of the IO needle. Remove the driver (**Figure 55-10C**). **Do not allow the IO needle to move while removing the driver.** Twist the stylet counterclockwise and remove it while securely holding the IO needle hub (**Figure 55-10D**). Attach the EZ-IO stabilizer (**Figures 55-7B & 55-10E**), if using it, followed by the primed EZ-Connect tubing. Aspirate bone marrow to confirm proper needle placement. **Do not attach a syringe directly to the IO needle hub.** A syringe attached to the hub can result in a fracture of the hub. **Always attach the EZ-Connect tubing then aspirate and inject through it and not directly through the IO needle hub.** Begin using the IO access.

IO ACCESS USING THE BIG

The BIG is an automatic, spring loaded device that does not require a power source. It is available in two sizes, adult and pediatric. The insertion site is different for adults and children. Always start at the tibial tuberosity as the initial landmark. For adults, move 2 cm medially toward the inner leg and then 1 cm proximally toward the patient's head. For children, move 1 to 2 cm medially toward the inner leg and then 1 to 2 cm distally toward the patient's foot. Mark this final location as the insertion site. It may also be inserted in the proximal humerus in the adult patient.

Prepare for the procedure. This procedure requires aseptic technique. Clean and prep the skin at the insertion site and surrounding area. Open the package and remove the sterile BIG. Rotate the base of the unit to adjust the IO needle penetration depth according to the pediatric patient's age: 0 to 3 years at 0.5 to 1.0 cm, 3 to 6 years at 1.0 to 1.5 cm, and 6 to 12 years at 1.5 cm (**Figure 55-11A**). Use the adult BIG for patients over the age of 12 years. Reidentify the landmark for the insertion site. Inject local anesthetic solution subcutaneously and down to the periosteum.

Position the BIG at the insertion site with the base perpendicular or at 90° to the skin (**Figure 55-11B**). Firmly grasp the BIG with the nondominant hand. Squeeze and pull out the red safety latch while firmly holding the BIG against the insertion

FIGURE 55-11. Using the BIG. **A.** Adjust the penetration depth. **B.** Apply the BIG at a 90° angle to the skin. **C.** Remove the safety latch. **D.** Grasping the BIG in preparation of triggering the unit.

FIGURE 55-11. (*continued*) **E.** Remove the BIG. **F.** Attach and secure the safety latch. **G.** Pull the stylet-trocar from the IO cannula. **H.** Attach IV tubing onto the hub and aspirate bone marrow (Photos courtesy of Wais Medical, Houston, TX).

site (**Figure 55-11C**). **Do not discard the safety latch as it will be used later to secure the IO needle.** Grasp the upper part of the BIG with the dominant hand (**Figure 55-11D**). Place two fingers under the wings and the palm on the top of the BIG (**Figure 55-11D**). Continue to firmly hold the base against the patient's skin with the nondominant hand.

Insert the IO needle. Trigger the BIG by gently pressing down with the palm. The device will eject the spring loaded IO needle into the bone. The IO needle should be standing upright, firmly in the bone, and stable. If not, it has been placed into muscle or soft tissue. Gently lift and remove the BIG device without catching on the IO needle hub (**Figure 55-11E**). Attach the safety latch onto the cannula between the patient's skin and the IO cannula hub (**Figure 55-11F**). Secure the safety latch to the skin with tape (**Figure 55-11F**). Gently remove the stylet-trocar, leaving the cannula in place (**Figure 55-11G**). **If the stylet-trocar is "stuck" and not easily removable, do not pull or try to forcefully remove it.** The IO needle did not penetrate all the way into the medullary cavity and is embedded in the cortex. Insert the square end of the safety latch into the hub of the IO needle and gently twist to remove the IO needle. Repeat the procedure at another site. Attach the IV tubing onto the hub of the cannula (**Figure 55-11H**). Aspirate bone marrow to confirm proper placement (**Figure 55-11H**). Flush the IV tubing and cannula with 5 to 10 mL of sterile saline. Begin using the IO access.

ASSESSMENT

Assess whether the IO needle is correctly positioned within the medullary cavity. First aspirate blood from the marrow cavity. This may not be possible because of poor circulation in patients with a cardiac arrest. A second sign of correct placement is to assess whether the IO needle will stand erect without support. Finally, flush the IO line. The ability of the fluid to flow without inducing soft tissue swelling can also be used to confirm proper placement. Ultrasonic visualization of flow within the medullary cavity using color flow Doppler can also confirm proper placement.[45] A reassessment must be performed again at regular intervals to ensure that extravasation does not occur.[30] Circumferential pressures of the involved extremity may be used for serial examination.[30]

A C-arm fluoroscopic imaging device may be used at the bedside to confirm accurate placement of the IO needle.[31]

AFTERCARE

Secure the IO needle. Secure the manually inserted IO needle by taping it in place. It may be easier to apply 4 × 4 gauze squares on two sides of the IO needle to support it and then tape the needle and gauze in place. Secure the EZ-IO needle in the same manner. Tape the safety latch of the BIG to the skin to secure it. Tape the IV tubing securely at several points. This will prevent traction on the tubing from pulling the IO needle out of the bone. Tape a plastic cup over the IO needle to avoid inadvertent disruption during patient resuscitation or positioning. Immobilize the extremity, if necessary, to help secure the IO line.

Remove the IO line once the resuscitation is complete and another form of secure vascular access has been obtained. Manually inserted IO devices can be removed by gently twisting it and pull it straight out. **Do not rock the device.** To remove the EZ-IO, attach a 5 or 10 mL Luer lock syringe onto the IO needle hub. Rotate the syringe clockwise and pull it straight out. It may take several rotations of the syringe before the IO needle can be removed. **Do not rock the IO needle or syringe.** To remove the BIG cannula, insert the square end of the safety latch into the hub of the cannula and gently twist and pull to remove it. Bleeding at the insertion site can be controlled with a sterile pressure dressing followed by cleansing the skin and a simple bandage.

COMPLICATIONS

The most common complication of IO infusions are subcutaneous and subperiosteal extravasation of fluid due to technical difficulty.[4] Under ideal circumstances, the type of IO needle used should not affect extravasation rates.[30,32] Extravasation is usually due to under- or overpenetration of the cortex. There have been cases of tibial fracture due to overpenetration of the cortex.[33,34] A compartment syndrome may occur when there is extravasation or when IO lines are placed in fractured bones.[26] Necrosis and sloughing of the skin at the insertion site of the IO needle are due to extravasation of fluid or medication.[35]

Localized infections may occur after IO needle placement. Cellulitis or the formation of subcutaneous abscesses occur in 0.7% of patients.[24] Osteomyelitis has been reported in less than 1% of patients with IO needles.[25] Risk of osteomyelitis increases with prolonged IO use, administration of hypertonic fluids, and bacteremia.[25,36]

Injury to the growth plate is a commonly mentioned complication; however, the literature does not support this.[37,38] Additionally, in recent animal studies, the rate of the IO infusion and the osmolarity of the infused fluid did not adversely affect the bone marrow or bone development.[42] Fat embolism has also been mentioned as a possible complication.[41] Consider a fat embolism if the patient becomes hypoxic or experiences respiratory difficulty shortly after beginning an IO fluid infusion or bolus. The use of an IO line for the infusion of emergency drugs and fluids does not increase the magnitude of fat embolization during CPR.[39,40] Animal studies have shown no significant increase in fat emboli in lung tissue when IO infusion is used.[39]

The flow rate of fluid through an IO line is slower than that through a peripheral intravenous line. This may be due to a small marrow cavity, a fibrous marrow cavity, and/or the replacement of red marrow with yellow marrow. Fluid flow rates can be significantly increased by applying a pressure bag onto the intravenous fluid bag or using a level-one infuser. The placement of a second IO line may be required to further increase the amount of fluid that can be infused.

The complications specific to the EZ-IO include hub fracture after insertion and separation of the needle from the hub upon removal. Too much downward pressure upon IO needle insertion can result in it penetrating the back of the bone. The other general complications are described above.

The complications associated with the BIG are primarily from incorrect use. **Never remove the safety latch until the BIG is against the patient's skin over the insertion site.** Removal of the safety latch activates the device. The IO needle can be forcefully ejected and injure someone if the BIG is squeezed after the safety latch is removed. Never place a finger over the distal end of the BIG. **Always grasp the BIG properly. Grasping it upside down can result in the IO needle penetrating the Emergency Physician's hand.** Incorrectly adjusting the penetration depth can result in the IO needle penetrating the back of the bone. The other general complications are described above.

SUMMARY

The placement of an IO line is a viable option in the resuscitation of a patient when traditional vascular access techniques have failed. The procedure is technically straightforward and has been demonstrated to be successful in the hands of trained healthcare workers, including prehospital personnel. Complications have been related mostly to technical mistakes and can be avoided if care is taken to correctly identify landmarks, avoid the growth plate, regulate the depth of IO needle placement, and ensure the early removal of the IO line.

56 Umbilical Vessel Catheterization

Eric F. Reichman, Amy Noland, and Antonio E. Muñiz

INTRODUCTION

Umbilical vessel catheterization was first described by Diamond in 1947 for an exchange transfusion in a neonate.[1] Umbilical vessel catheterization serves many important functions in the ill neonate. Umbilical vessel catheterization can be used as a reliable method of obtaining rapid vascular access in the neonate. Umbilical vessel catheters may be used for fluid resuscitation, blood transfusion, medication administration, frequent blood sampling, and cardiovascular monitoring.[2–5] **However, the use of these catheters also carries significant risk of permanent morbidity and even death.** Either the umbilical artery or vein may be used for vascular access. The artery can usually be accessed within the first 24 hours of life. It is occasionally possible to use the umbilical artery up to 7 days after birth.[2] The umbilical vein can be accessed for up to 2 weeks of age.[2,6]

Umbilical artery catheterization is more desirable than umbilical vein catheterization because it allows frequent arterial blood gas sampling and continuous blood pressure monitoring, in addition to fluid, blood, and medication administration. Unfortunately, umbilical artery catheterization is more difficult and time consuming to perform, especially in unskilled hands. Therefore, umbilical vein catheterization is the preferred procedure for the infant in shock and in need of rapid resuscitation. Arterial access can be obtained later in a more controlled environment, such as in the neonatal intensive care unit. **Umbilical vessel catheterization can lead to serious complications and**

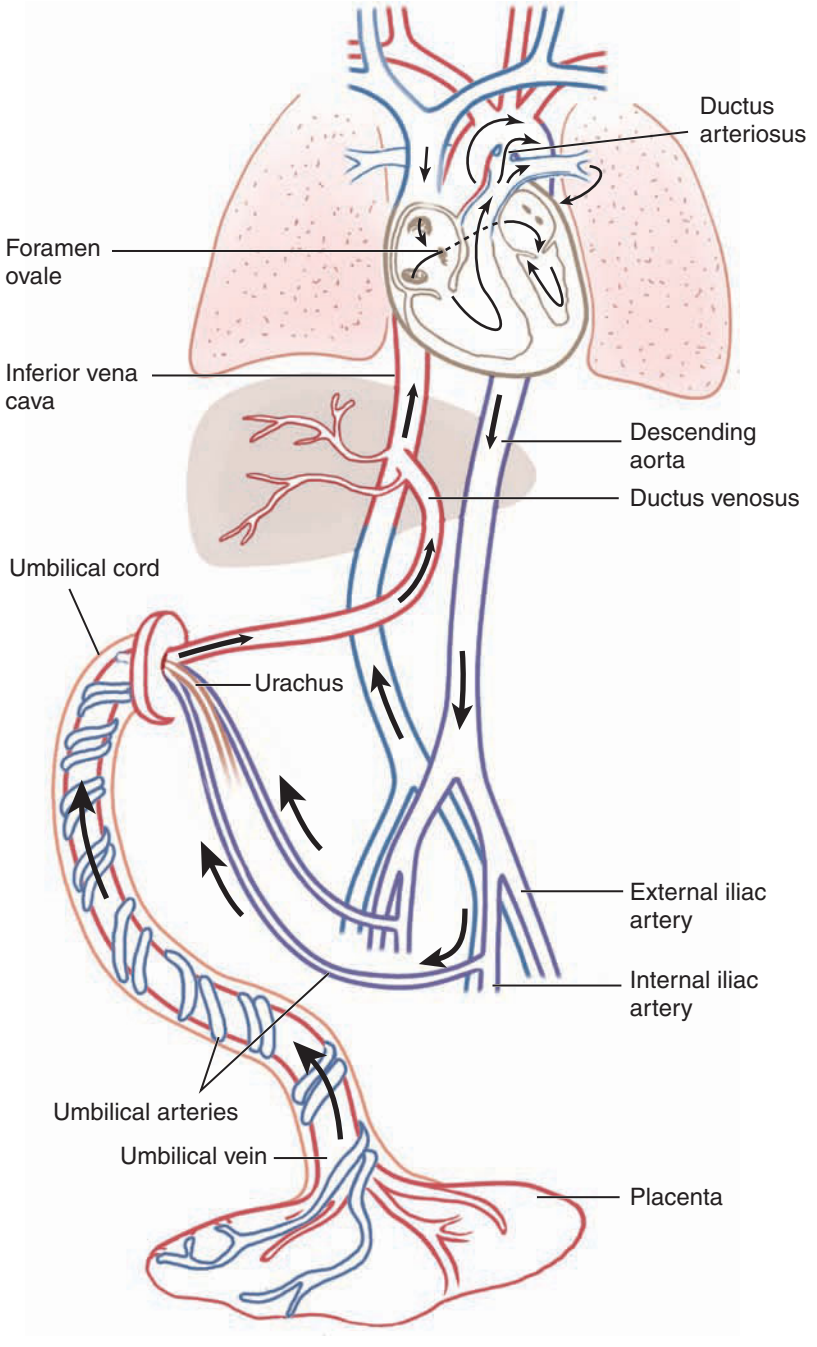

FIGURE 56-1. The fetal circulation.

should be reserved for the patient in whom peripheral venous access attempts have been unsuccessful.[5,7]

ANATOMY AND PATHOPHYSIOLOGY

The fetal circulatory system is quite different from that of the neonate or infant (**Figure 56-1**). Oxygenated blood from the placenta travels via the umbilical vein, through the ductus venosus in the liver, to the inferior vena cava (IVC), and into the right atrium. Oxygenated blood from the IVC preferentially enters the left atrium through the foramen ovale. It then enters the left ventricle, then the aorta. This oxygen-rich blood supplies the brain prior to mixing with the oxygen-poor blood coming through the ductus arteriosus. Deoxygenated blood from the superior vena cava (SVC) enters the right ventricle and is pumped to the pulmonary artery. It then passes through the ductus arteriosus to meet the oxygenated blood in the aorta.

Pulmonary vascular resistance decreases dramatically as the infant takes its first breaths. The systemic vascular resistance increases when the umbilical cord is clamped. The foramen ovale closes with the combination of decreased pulmonary artery pressure and increased systemic resistance. The ductus arteriosus closes within 24 to 48 hours due to the release of prostaglandins and increased blood oxygen tension. The ductus venosus closes when the umbilical cord is clamped.

The umbilical vein and arteries can easily be differentiated by examination of a cross section of the umbilical cord (**Figure 56-2**). The umbilical vein is a single vessel with thin walls and a large

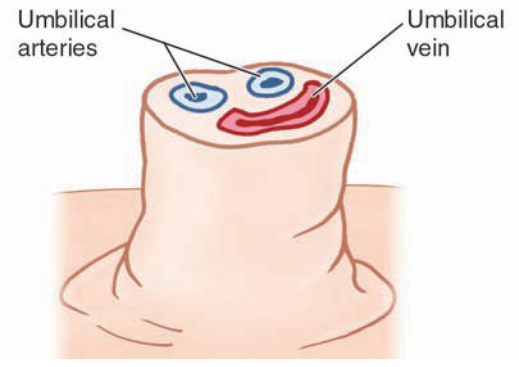

FIGURE 56-2. Anatomy of the umbilical cord.

lumen. It is usually flattened in one direction. There are two thick-walled umbilical arteries that are significantly smaller in diameter than the umbilical vein. Occasionally, only a single umbilical artery is present.

INDICATIONS

Umbilical artery catheterization is indicated when frequent arterial blood gas determinations and continuous monitoring of blood pressure are required in the first few days of life in critically ill neonates.[4] Umbilical artery catheters can be used for delivering blood, fluids, total parenteral nutrition, medications, and for exchange transfusions.[2,3] It reduces the need for multiple venipunctures and heel prick capillary blood sampling in the critically ill neonate.[8] Neonates under 24 hours of age can usually be catheterized without much difficulty. Skilled Emergency Physicians can sometimes perform this in neonates up to 7 days of age.[2]

Umbilical vein catheterization is easier to perform than umbilical artery catheterization. It is the preferred procedure for the neonate in shock needing rapid administration of intravenous fluids, blood, or medications.[1] In critically ill neonates, the umbilical vein can be used to monitor central venous pressure. This procedure is possible in neonates up to 2 weeks of age.[2] Recently, the umbilical vein has been used to perform invasive cardiac procedures.[9]

CONTRAINDICATIONS

Umbilical vessel catheterization in the Emergency Department should be performed only on severely ill neonates in whom peripheral vascular access attempts have failed. The contraindications are similar for the umbilical vein and umbilical artery catheterization. These include gastroschisis, an omphalocele, omphalitis, and peritonitis.[2,10] Never insert an umbilical catheter if there are any signs of infection on or around the remnant of the umbilical cord. Umbilical vessel catheterization is contraindicated if a neonate is older than the previously stated ages. An alternate route of vascular access is required if the possibility of an abdominal abnormality exists, as manifested by a distended abdomen or visible defects.[2] Relative contraindications for placement of an umbilical artery catheter include decrease perfusion to the lower extremities or buttock and suspicion of necrotizing enterocolitis.

EQUIPMENT

- Umbilical vein catheters, 5.0 French and 3.5 French
- Umbilical artery catheters, 5.0 French and 3.5 French
- Umbilical tape
- Povidone iodine or chlorhexidine solution
- Sterile gauze
- Sterile drapes
- Sterile gown and gloves
- Cap and face mask
- Adhesive tape
- Radiant warmer with a light
- Cardiac monitor
- Pulse oximeter
- 3-0 or 4-0 silk suture with a needle
- Needle driver
- Smooth-curved iris forceps
- Iris scissors
- Two small, smooth-curved hemostats
- Straight Crile forceps
- #10 or #11 scalpel blade on a handle
- Three-way stopcock
- 10 mL syringe filled with normal saline
- Heparinized sterile saline solution, 1 unit of heparin/1 mL of saline

Umbilical artery and vein catheters are available in a variety of sizes. Umbilical vein catheters are available as a single-lumen or double-lumen catheter. They should not have side holes unless it is to be used specifically for an exchange transfusion. Use a 5.0 French umbilical venous catheter in neonates weighing >1200 g and a 3.5 French catheter in neonates weighing <1200 g. Use a 5.0 French umbilical artery catheter in neonates weighing >3500 g and a 3.5 French catheter in neonates weighing <3500 g.

Umbilical vessel catheterization kits are commercially available from several manufacturers. One example is the Argyle Neo-Sert™ Umbilical Vessel Catheter Insertion Tray (Tyco Healthcare, Mansfield, MA). The kits are sterile, disposable, and intended for single patient use. They contain all the equipment required including the instruments and catheters.

PATIENT PREPARATION

Attempts at peripheral venous access should have failed in a sick neonate prior to attempting umbilical vessel catheterization. All equipment should be readily available on a pre-prepared sterile tray. Place the tray with the instruments on a Mayo stand next to the neonate's bed. Place the neonate under a radiant warmer with a light source. Place the neonate on a cardiac monitor, continuous pulse oximeter, and supplemental oxygenation if needed. Place the neonate supine with the lower extremities in the frog-leg position (**Figure 56-3**). Their arms and legs may need to be restrained to prevent contamination of the sterile field.

This procedure requires strict sterile technique. The Emergency Physician performing the procedure should wear a cap, mask, sterile gloves, and sterile gown. Scrub the umbilical cord, umbilical cord clamp, and the neonate's abdomen with povidone iodine or chlorhexidine solution and allow it to dry. Place sterile drapes to form a sterile field around the umbilical area, ensuring the neonate's head is exposed for observation.

TECHNIQUES

Sterile technique must be maintained throughout the entire procedure. Loosely tie a piece of umbilical tape around the base of the umbilical cord (**Figure 56-4**). Place a 3-0 or 4-0 silk purse-string suture through the base of the umbilical cord and just above the

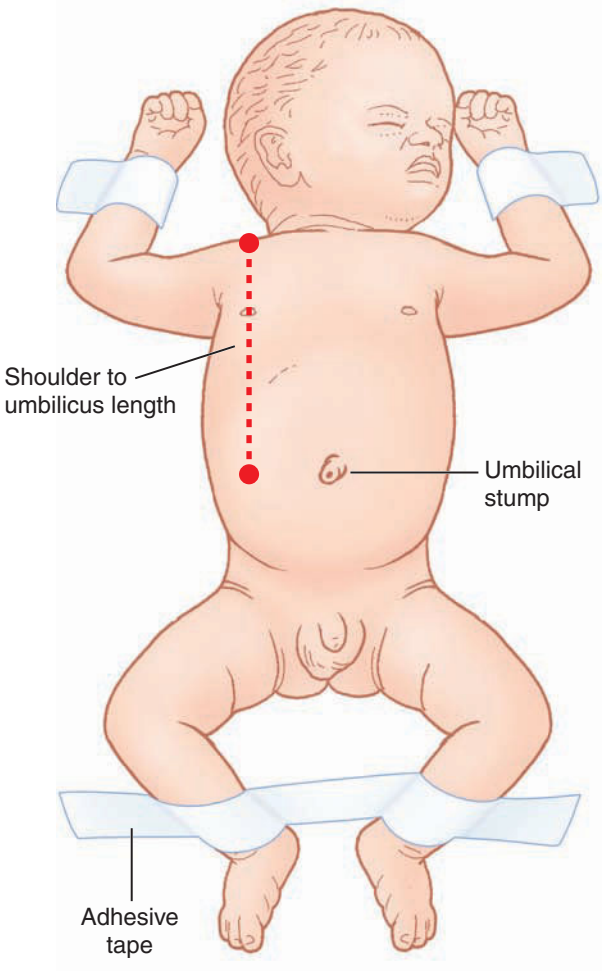

FIGURE 56-3. Positioning of the neonate. The dotted line represents the shoulder-umbilical length.

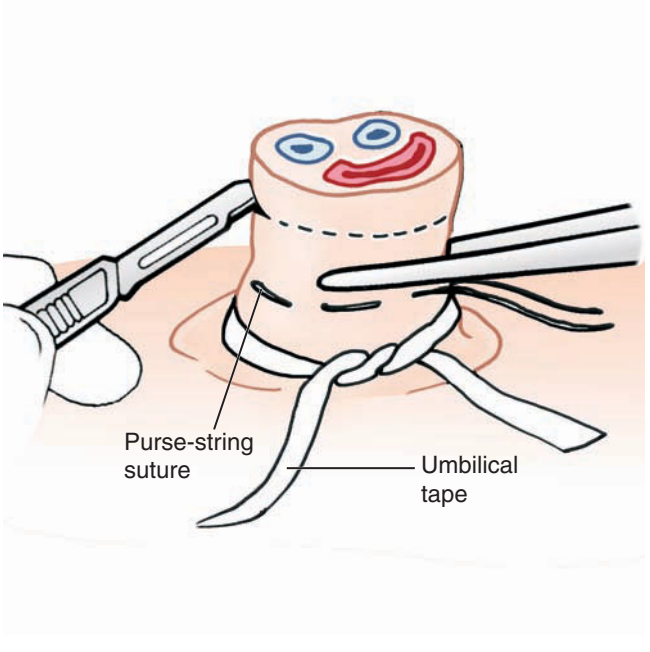

FIGURE 56-4. Preparing the umbilical cord stump. Umbilical tape has been placed at the base and tied loosely. A purse-string suture has been placed through the stump and just above the umbilical tape. The distal end of the umbilical cord is removed along the dotted line.

umbilical tape (**Figure 56-4**). **Avoid piercing the umbilical vessels and the skin of the abdominal wall.** Leave the suture untied and the ends uncut. This will be used later to secure the umbilical vessel catheter. Gently grasp the umbilical cord clamp. Use an #10 or #11 scalpel blade to cut the umbilical cord just beneath the clamp to expose a smooth, clean surface of the umbilical cord (**Figure 56-4**). **Do not cut the cord too close to the base in case it needs to be re-cut for a repeat attempt.** Tighten the umbilical tape if blood is oozing from the cut umbilical cord. **Blot the blood with gauze squares. Do not rub the gauze against the umbilical cord to prevent damaging the fragile umbilical cord.** Grasp the umbilical cord with forceps or fingers and identify the three vessels, two arteries, and one vein. The arteries are smaller, round, and have thick muscular walls. The vein is larger, has thinner walls, and is less round than the arteries. The umbilical artery or vein may now be catheterized as described in the following sections.

UMBILICAL ARTERY CATHETERIZATION

Determine the desired position of the catheter tip (**Figure 56-5**). There are two possible positions for the umbilical artery catheter tip, the high or low position. In the low position, the catheter tip is placed between the third and fifth lumbar vertebrae, a level corresponding to just above the aortic bifurcation.[2,11] In the high position,

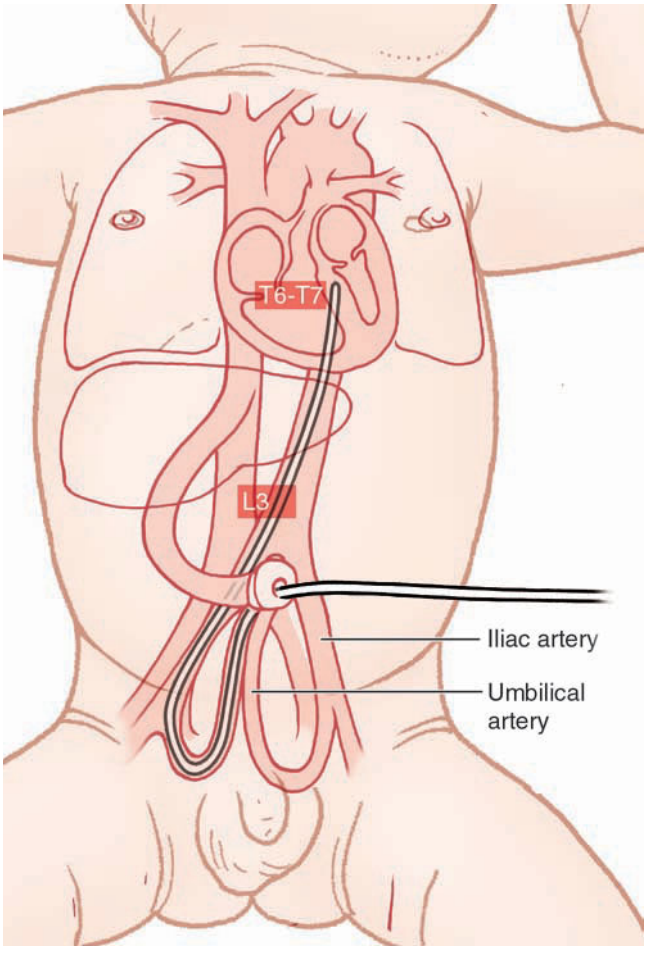

FIGURE 56-5. Positioning of the tip of the umbilical artery catheter. The low position, between L3 and L5, is just above the aortic bifurcation. The high position, between T6 and T9, is above the diaphragm, between the ductus arteriosus and the mesenteric arteries. The shaded boxes represent the vertebral bodies in the midline.

the catheter tip is placed between the sixth and ninth or tenth thoracic vertebrae, a level corresponding to just above the diaphragm, between the ductus arteriosus and the origins of the mesenteric arteries.[2,11–13] Controversy exists over which position is the preferred site for the catheter tip.[14] A recent Cochrane Database review of six controlled trials demonstrated that the high position was associated with a lower occurrence of clinical vascular complications, removal, and adverse sequelae.[4,5,21]

A variety of methods have been used to determine the insertional length of umbilical arterial catheters. Some of these include electrocardiographic changes during placement, echocardiography-guided insertion, and ultrasound-guided insertion.[15–19] However, these are hard to perform in clinical practice. Other methods for determining the appropriate depth of catheter insertion are based on the shoulder-to-umbilicus length and the neonate's birth weight. There are also standardized graphs for determining the appropriate catheter insertion depth.

Most centers use a calculation derived by Dunn on post-mortem infants where the length of insertion to the high position is measured from the external shoulder to the umbilicus (**Figure 56-3**).[20] Measure the shoulder to umbilicus length by measuring the distance between the top of the shoulder to the level perpendicular to the umbilicus (**Figure 56-3**). Using the shoulder-umbilical length and the desired position of the catheter tip, determine the umbilical catheter length to be inserted into the artery (**Figure 56-6**). Add the length of the umbilical stump to the umbilical artery catheter length found on the *y*-axis of the graph to determine the corrected length of catheter to be inserted.

Another popular way to measure the length of insertion is the formula derived by Shulka and Ferrara.[21] The insertion length (cm) at the high position = (3 × body weight [kg]) + 9 + the length (cm) of the umbilical cord stump. To place it in the low position, use this value divided by 2. For neonates <1000 g body weight, another formula seems to be more accurate.[22] The insertion length (cm) at the high position = (4 × body weight [kg]) + 7 + the length (cm) of the umbilical cord stump.

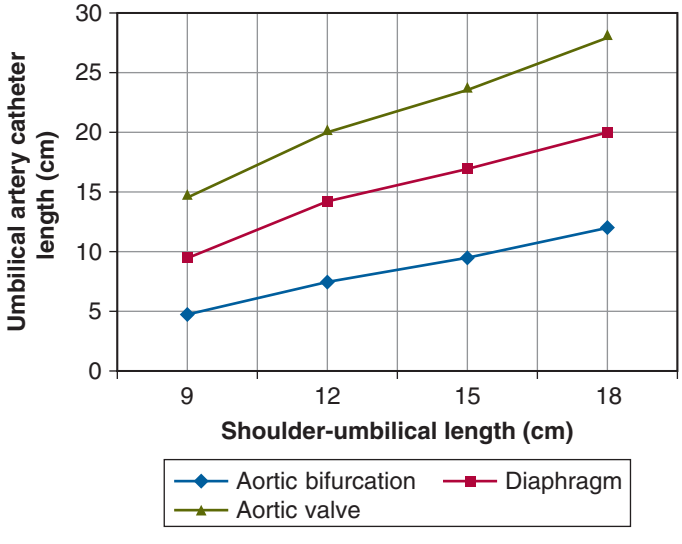

FIGURE 56-6. Graph to determine the correct length of catheter to insert into the umbilical artery. Using the shoulder-umbilical length and the desired position of the catheter tip, determine the length of catheter on the *y*-axis to be inserted into the artery. Add the length of the umbilical stump to the umbilical artery catheter length found on the *y*-axis of the graph to determine the corrected length of catheter to be inserted. (Modified from Shilkofski.[11])

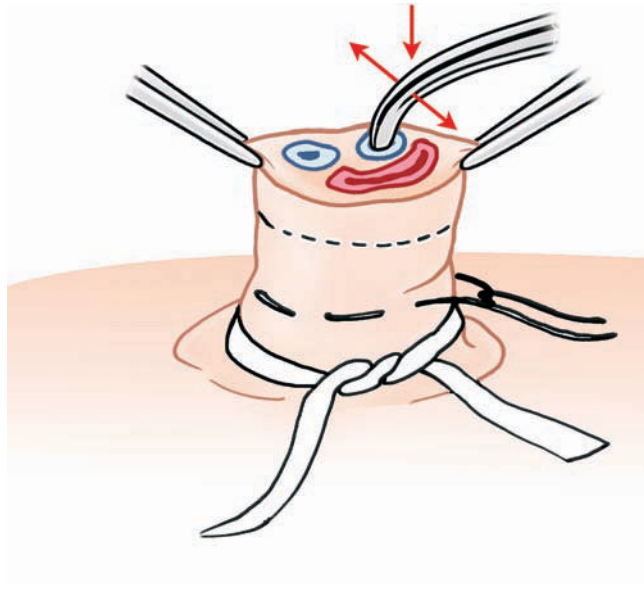

FIGURE 56-7. Preparation for catheter insertion. The upper edges of the umbilical cord stump are stabilized with two smooth-jaw curved hemostats. A smooth-jaw curved iris forceps is placed into one umbilical artery and allowed to open and dilate the artery.

Flush the catheter with the heparinized saline solution, if there are no contraindications to heparin. Attach the three-way stopcock, in the closed position, to the hub of the catheter. Identify the arteries and choose one for catheterization. Grasp the distal portion of the umbilical cord with the two smooth-curved hemostats to stabilize the end of the umbilical cord (**Figure 56-7**). Instruct an assistant to hold the hemostats. **Do not apply traction to the hemostats to prevent injury to the umbilical cord.** Insert the tips of the smooth-curved iris forceps approximately 0.5 cm into the lumen of the artery and gently allow the jaws of the forceps to open (**Figure 56-7**). This will dilate the arterial lumen. Repeatedly insert and open the tips of the curved iris forceps within the arterial lumen to a depth of 0.5 to 1.0 cm.[2]

Grasp the umbilical catheter approximately 1.0 cm from the tip. Gently insert the tip of the catheter into the artery (**Figure 56-8**). Apply gentle pressure for about 30 seconds. The muscles of the artery may spasm and prevent the catheter from advancing. If the spasm persists, remove the catheter. Place 0.1 mL of a 2% lidocaine solution into the catheter tip.[2] Reinsert the catheter and flush the lidocaine into the artery at the level of the spasm. If the catheter still will not advance, a gentle twisting motion may allow it to advance. Catheterize the other umbilical artery if this fails. Advance the catheter to the predetermined length. Increased resistance will be felt as the catheter goes through the base of the umbilical cord and navigates the curve of the umbilical artery entering into the femoral artery. Tighten the umbilical tape to temporarily secure the catheter.

Obtain fluoroscopic, plain radiographic, or ultrasonic confirmation of placement prior to using the catheter. The single lumen catheter may not be properly positioned. The catheter may pass into the aorta but curve distally into the iliac or femoral artery. This can result in cyanosis, blanching, or necrosis of the extremity and/or buttock.[23,24] This occurs more frequently when a 3.5 French catheter is inserted in a large neonate. Using a larger catheter (i.e., 5 French) will usually allow the catheter to go cephalad in the aorta. If the catheter goes distally, it can be partially withdrawn, twisted 90°, and re-inserted only if done during the procedure with real-time fluoroscopy or ultrasound during the procedure. **Never advance a catheter**

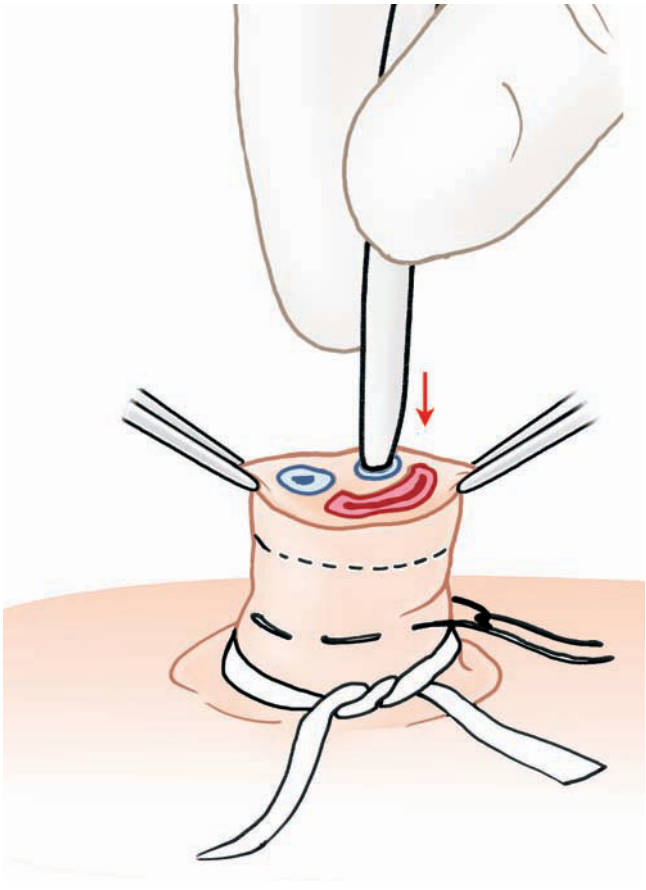

FIGURE 56-8. The catheter is inserted into the umbilical artery and advanced to the desired depth.

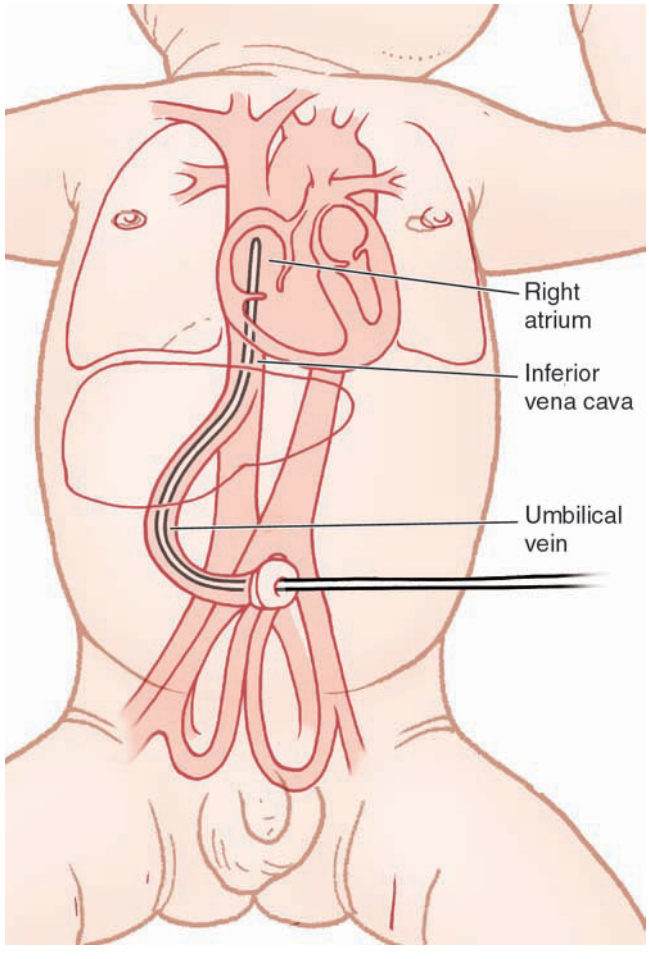

FIGURE 56-9. Positioning of the tip of the umbilical vein catheter. The tip should be above the diaphragm, at the junction of the inferior vena cava and the right atrium.

that has been previously placed as it can introduce an infection. The catheter may also enter the aorta, turn 180° to reverse itself, and enter the iliac or femoral artery. This also occurs more often when a smaller (i.e., 3.5 French) catheter is used in a large neonate. The catheter must be removed if it is placed correctly but there is persistent lower extremity cyanosis, blanching, or decreased distal perfusion.

UMBILICAL VEIN CATHETERIZATION

Catheterizing the umbilical vein is much easier than the umbilical artery. The lumen is larger and easier to negotiate. This quality makes the umbilical vein more desirable for vascular access in emergency situations.[7,25]

First determine the desired position of the catheter tip. Ideally, it should be located at the junction of the IVC and the right atrium (**Figures 56-9 & 56-10**). Measure the shoulder-umbilical length (**Figure 56-3**). Using the shoulder-umbilical length and the desired position of the catheter tip, determine the umbilical catheter length to be inserted into the vein (**Figure 56-10**). Add the length of the umbilical stump to the umbilical vein catheter length found on the *y*-axis of the graph to determine the corrected length of catheter to be inserted. Another method to calculate the depth of insertion is length (cm) = (3 × body weight [kg]) + 9, divided by 2, then add 1 cm.

Umbilical vein catheterization is similar to that of the artery with three exceptions. Any visible clots must be removed from the lumen of the vein prior to inserting the catheter. **The vein requires no dilating. In an emergency, when awaiting radiographic confirmation is not feasible, the umbilical vein catheter should only be inserted 3 to 5 cm until there is free flow of blood. It is imperative that the catheter not be inserted too deeply in order to prevent entry into the hepatic vessels via the ductus venosus, since medications could potentially cause hepatocellular damage.**[2,5–7,26] The catheter can be replaced with a more permanent line once the patient has been stabilized.[25] The nonemergent umbilical venous catheter should be placed with the tip above the diaphragm, at the junction of the IVC and right atrium as determined previously. Tighten the umbilical tape to temporarily secure the catheter. Obtain fluoroscopic, plain radiographic, or ultrasonic confirmation of placement prior to using the catheter.[18]

UMBLICAL MULTIPLE-LUMEN CATHETERS

Reliable vascular access can be problematic in the sick neonate.[27] Insertion of a double-lumen or triple-lumen catheter into the umbilical vein can provide additional venous access for the administration of incompatible drugs such as vasopressor agents, calcium, or sodium bicarbonate solutions.[28] It is also useful for drugs requiring continuous infusions, leaving other ports for blood sampling, central venous pressure measurements, maintenance fluids, or medication administration. Infuse all these solutions into the proximal lumen(s), allowing measurements of central venous pressures from the distal port. Multi-lumen catheters can be placed directly by the same methods as a single-lumen catheter or using the Seldinger

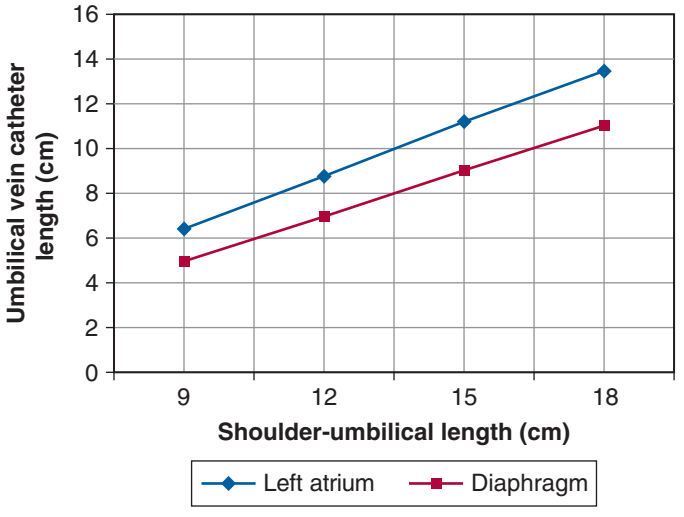

FIGURE 56-10. Graph to determine the correct length of catheter to insert into the umbilical vein. Using the shoulder-umbilical length and the desired position of the catheter tip, determine the length of catheter on the *y*-axis to be inserted into the vein. Add the length of the umbilical stump to the umbilical vein catheter length found on the *y*-axis of the graph to determine the corrected length of catheter to be inserted. (Modified from Shilkofski.[11])

technique similar to inserting a central venous line (Chapter 49). The increased pliability of the multi-lumen catheter makes passage into the hepatic veins more likely.

A wire exchange technique may be used to place a multiple-lumen catheter in neonates with an indwelling single-lumen catheter. This method decreases the probability of loss of vascular access during the exchange. It has the risk of the guidewire entering the heart and causing a cardiac dysrhythmia and/or myocardial perforation. This technique should only be performed by those familiar with the Seldinger technique.

The catheter exchange over a guidewire requires strict sterile technique. Insert a guidewire through the catheter. Firmly hold the guidewire. Withdraw the catheter over the guidewire. The guidewire must always remain within the vein. Advance the multi-lumen catheter over the guidewire and into the vein while securely holding the guidewire. Remove the guidewire while maintaining the catheter in the umbilical vessel. Advance the multi-lumen catheter to the predetermined length. Tighten the umbilical tape to temporarily secure the catheter. Obtain fluoroscopic, plain radiographic, or ultrasonic confirmation of placement prior to using the catheter.

ASSESSMENT

Confirm the proper placement of the catheter tip. The umbilical tape has been tightened to temporarily secure the catheter within the umbilical cord. **Do not infuse anything through the line until proper placement is confirmed.** This can be accomplished with fluoroscopy, plain radiographs, or ultrasonography. If the catheter is in too far, withdraw it and reevaluate the new catheter tip position. **If the catheter is not in far enough, do not advance the catheter. Withdraw the catheter and restart the procedure with a new catheter.**

AFTERCARE

Secure the catheter more permanently after confirming that the catheter tip is in the desired location (**Figure 56-11**). Tighten and tie a knot in the previously placed purse-string suture. Wrap the loose ends of the suture around the catheter as it enters the umbilical vessel, then secure it with several square knots (**Figure 56-11**). **Loosen and remove the umbilical tape to avoid umbilical cord necrosis.**[4] Secure the catheter to the abdominal wall with adhesive tape. Antibiotic ointment may be applied at the junction of the umbilical cord and the catheter.

COMPLICATIONS

Significant morbidity can be associated with umbilical artery and vein catheterization.[29] Prevention of complications requires strict adherence to sterile technique, flushing of the catheter prior to insertion, gentle catheter manipulation during insertion, and accurate positioning of the catheter. It is essential that no air be allowed to enter the catheter. An air bubble can enter the

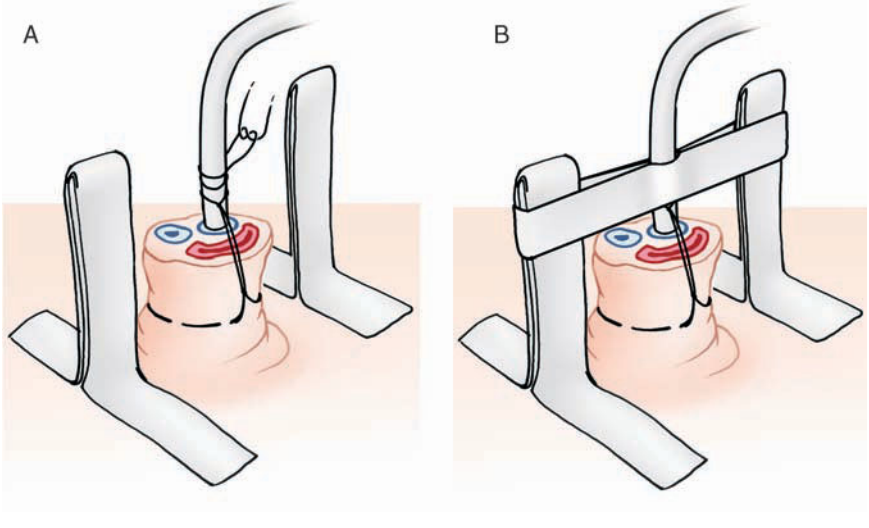

FIGURE 56-11. Securing the umbilical vessel catheter. **A.** The purse-string suture is tied about the umbilical cord and the umbilical tape is removed. The ends of the suture are wrapped around the catheter, as it enters the umbilical vessel, and secured with square knots. **B.** Tape is applied to secure the catheter to the abdominal wall.

central circulation, pass through the foramen ovale, and lodge in an end artery. This air embolism can cause a stroke if it ends up in a central nervous system artery, a myocardial infarction if it ends up in a coronary artery, and it may lead to death.[30,31]

Even if all precautions are observed, complications are still unavoidable.[5] Complication rates as high as 20% for venous catheters and 10% for arterial catheters have been reported.[32] A venous catheter placed in the portal system may lead to hepatic necrosis, hemorrhage, and thrombus formation, which may lead to a pulmonary embolus or portal hypertension.[3–6] Neonates are at higher risk for thromboembolic events because of their underdeveloped clotting mechanisms, small vessel diameters, and critical underlying diseases when compared with older children and adults.[29] Phlebitis or nosocomial sepsis can ensue if strict aseptic technique is not followed.[32] Rarely, the catheter can be transected or form a knot intravascularly.[33,34] Vessel and bowel perforation from forceful manipulation of the catheter, an air embolus from an unflushed catheter prior to insertion, false track formation, cardiac arrhythmias, damage to cardiac valves, and myocardial perforation have all been reported.[3,6,7,32,58] Necrotizing enterocolitis, biliary venous fistula, pericardial effusion, hypoglycemia from high positioning of an umbilical artery catheter, bladder rupture, congestive heart failure, hypertension, transection of an omphalocele, transection of the catheter, intravascular knots in the catheter, and Wharton's jelly embolus have also been reported.[58–65] Occasionally, a persistent urachus in the umbilical cord stump may be mistaken for an umbilical vein. Catheterization of the urachus will result in the flow of urine, and not blood, from the catheter. This is easily identified and corrected.

Malpositioning of the umbilical vein catheter has resulted in rare complications such as pneumopericardium, cardiac tamponade, pleural effusion, pulmonary hemorrhage, pulmonary edema, pulmonary infarction, pulmonary abscess, cardiac thrombosis, endocarditis, myocardial perforation, atrial flutter, hyponatremia, perforation of the peritoneum, perforation of a Meckel's diverticulum, perforated urachal remnant, ascites from intraperitoneal extravasation of total parenteral nutrition (TPN), esophageal varices, hepatic laceration, hepatic necrosis, hepatic abscess, hepatic calcifications or bladder calcifications with infusion of calcium gluconate, biliary fistula, perforation of the IVC, gastric outlet obstruction, or bladder rupture.[8,34–54]

Malpositioning of the umbilical artery catheter has rarely resulted in sciatic nerve damage, refractory hypoglycemia from infusion into the celiac axis, or spinal cord injury with paraplegia from infusion into the artery of Adamkiewicz.[2,23,32,56,57] Umbilical artery catheterization may be complicated by vasospasm, thrombosis or embolism, causing ischemia of the lower extremities or intraabdominal organs.[2,5,6,32,55] Vasospasm can occur within moments of catheter insertion or up to several hours following placement. The signs include progressive ischemia resulting in discoloration or mottling of the lower extremities and/or buttocks. Embolization of clots can cause loss of digits, hematuria, kidney failure, hypertension, necrotizing enterocolitis, bowel infarction, cyanosis or blanching of the skin (of the back, buttocks or legs), or skin ulceration.

SUMMARY

Umbilical vessel catheterization is a readily available method of obtaining vascular access in the sick newborn. These vessels can be used for fluid resuscitation, blood transfusion, medication administration, frequent blood sampling, and cardiovascular monitoring. Because serious complications may result from using this route, it should be reserved for infants in whom peripheral vascular access is unsuccessful.

57 Arterial Puncture and Cannulation

Zak Foy and Susan Stroud

INTRODUCTION

Arterial blood gas (ABG) sampling is an essential component of the care of many Emergency Department patients. It provides key information regarding a patient's oxygenation and acid-base status. Arterial cannulation allows for continuous and accurate blood pressure monitoring and frequent blood gas sampling in the care of the critically ill patient.

ANATOMY AND PATHOPHYSIOLOGY

Knowledge of the arterial anatomy is a key factor in the success of arterial puncture and cannulation. It is important to recognize that nerves and veins are located in close proximity to the desired arteries in order to avoid complications. The anatomy and positioning for radial, brachial, femoral, and dorsalis pedis artery access is described below.

RADIAL ARTERY

The radial artery is the preferred site for arterial puncture and cannulation. One reason is the comparative ease of identifying the anatomical location of this artery. A second reason is the collateral nature of the arterial blood supply to the hand provided by the radial and ulnar arteries. The ulnar artery is not often used due to its smaller size. Terminal branches of these two arteries meet in the palm of the hand to form the deep and superficial palmar arterial arches (**Figure 57-1**).

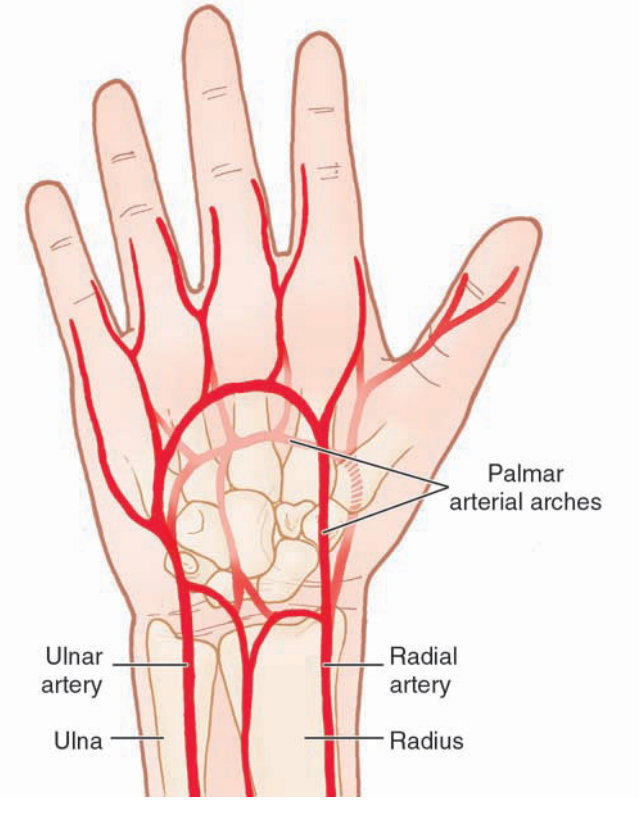

FIGURE 57-1. Anatomical location of the radial and ulnar arteries. Collateral circulation is provided by the superficial and deep palmar arches.

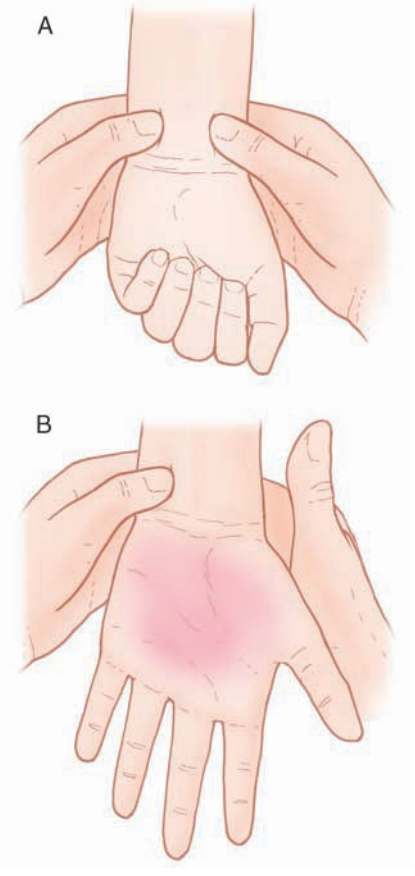

FIGURE 57-2. The modified Allen test. **A.** The distal radial and ulnar arteries are occluded. **B.** The ulnar artery remains occluded while determining if the radial artery can supply adequate blood flow to the hand.

The radial artery can be found just medial and proximal to the radial styloid process on the ventrolateral wrist (**Figure 57-1**). Dorsiflexing the wrist approximately 60° can aid in palpating the arterial pulse. Another notable landmark is the flexor carpi radialis tendon that runs immediately medial to the radial artery. The recommended point of needle or catheter insertion is at the proximal flexor crease of the wrist and directly above the radial artery pulse.

An Allen test should be performed to assess the adequacy of the collateral circulation to the hand prior to radial artery puncture or cannulation (Figure 57-2).[1,2] Ask the patient to repeatedly close their hand tightly into a fist and open it, to force blood out of the fingers, while manually occluding the radial and ulnar arteries (**Figure 57-2A**). Continue this process for 1 minute. Ask the patient to open their hand. The fingers should be blanched and pale due to the occlusion of the arterial inflow. Release the finger occluding the ulnar artery. Measure the time it takes for blushing of the palm to occur. It is considered normal if it is <7 seconds, equivocal at 8 to 14 seconds, and abnormal if >14 seconds.[1] Repeat the test, but this time release the radial artery compression to confirm arterial flow into the hand (**Figure 57-2B**). The purpose is to confirm arterial inflow from both the radial and ulnar arteries.

An alternative method of evaluating the collateral circulation involves the use of a pulse oximeter with a visual pulse waveform display.[3] This is useful in the young, unconscious, or uncooperative patient. Place the pulse oximeter sensor on the patient's thumb. Observe the visual display to confirm a waveform is present. Occlude the radial artery and examine the waveform on the monitor. Either an ulnar dominant system or a radial dominant system with adequate collateral circulation is likely if the waveform remains unchanged during radial artery occlusion.[3]

The performance of an Allen test to confirm adequate collateral circulation to the hand is generally advocated before radial artery puncture or cannulation. There is concern that radial artery occlusion from an intraluminal clot or an external hematoma can result in hand ischemia if the ulnar artery cannot provide adequate collateral blood flow. Some authors have questioned the utility of performing an Allen test.[1,2,4,38] The Allen test is subjective, often improperly performed, and has poor sensitivity and specificity to predict complications.[39] The relative safety of radial artery cannulation without the Allen test has been demonstrated in a large case series of patients without major peripheral vascular disease.[4] Although an abnormal Allen test may not preclude radial artery puncture or cannulation, it may indicate a greater need for caution and alert the Emergency Physician to potential problems after the procedure is performed.[2] This can include arterial thrombosis, hand ischemia, and hand necrosis. **Thus it is recommended, but not required, to cannulate another site if the Allen test is abnormal.**

BRACHIAL ARTERY

The brachial artery courses along the medial side of the antecubital fossa just lateral to the median nerve (**Figure 57-3**). The brachial artery divides at approximately the level of the neck of the radius to become the ulnar and radial arteries. In the antecubital fossa, the brachial artery is located lateral to the medial epicondyle of the humerus and medial to the biceps brachii muscle. The brachial artery is more easily identified when the elbow is fully extended. In order to locate the artery, start by palpating the medial epicondyle of the humerus. Move laterally until the medial edge of the biceps

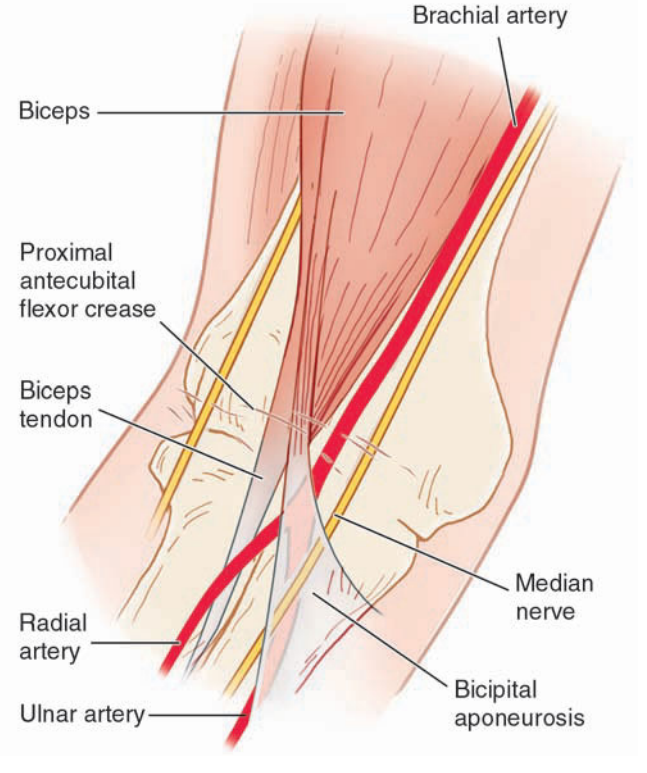

FIGURE 57-3. Anatomical location of the brachial artery. Note the median nerve running just medial to the artery and the biceps brachii muscle just lateral to the artery.

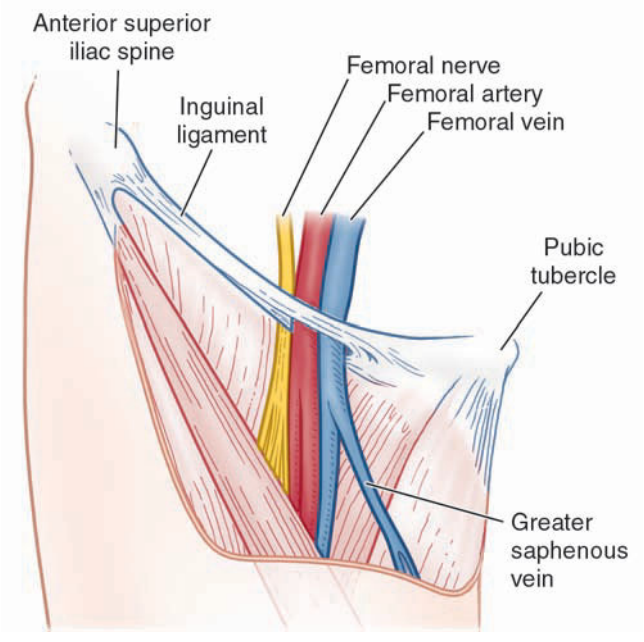

FIGURE 57-4. Anatomical location of the femoral artery. Note the proximity to the femoral nerve and vein.

muscle is palpated. The brachial artery pulse should be palpable just medial to the biceps muscle. The arterial pulsation is most easily identified at the level of the proximal flexor crease of the antecubital fossa. The preferred location for puncture or cannulation of the brachial artery is in, or just proximal to, the antecubital fossa and directly above the brachial artery pulse. If the artery is to be cannulated, the arm should remain in extension while the cannula is in place.

FEMORAL ARTERY

The bony anatomic landmarks used to identify the femoral artery are the anterior superior iliac spine and the tubercle of the pubic symphysis. The artery lies approximately midway between these two points after it courses under the inguinal ligament to enter the thigh (**Figure 57-4**). The femoral nerve and vein are found running in parallel and adjacent to the artery. The vein lies just medial to the artery and the nerve just lateral. The femoral artery is larger than other arteries commonly cannulated and lies significantly deeper than the radial or brachial arteries. This makes it necessary to use a longer cannula and, depending on the patient's body habitus, may require a longer needle for a simple arterial puncture to be successful. Extension and slight abduction of the hip maximizes access to the femoral triangle, improves the ability to palpate the artery, and provides a maximal work area for the procedure.

DORSALIS PEDIS ARTERY

The dorsalis pedis artery is a continuation of the anterior tibial artery on the dorsal surface of the foot. Puncture and cannulation of the dorsalis pedis artery is a good second choice if the radial artery is unsuccessfully cannulated or unavailable. The pulse is often easily palpable between the first and second metatarsal due to its superficial location. Its distal location does not interfere with other resuscitative efforts and is convenient for the patient. The risk of foot ischemia is minimal due to the abundant collateral circulation to the foot and ankle. There are no significant structures to injure adjacent to the dorsalis pedis artery. This artery can be absent in some people or have significant variability in its anatomic location. It may be difficult to identify the pulse in the hypotensive patient.

ALTERNATIVE ARTERIAL SITES

There are several alternative sites that are occasionally used for arterial puncture and cannulation. These include the superficial temporal artery, the axillary artery, and the ulnar artery. The superficial temporal artery is often used in neonates and young infants in the intensive care unit. Cannulation of this artery is rarely performed in the Emergency Department because of its location and the ability to maintain access.

The axillary artery is a continuation of the subclavian artery after the first rib. The axillary artery crosses the teres major tendon to enter the arm as the brachial artery. The axillary artery can be deep to the skin surface. The advantages of this artery include the ease of locating a the palpable pulse, even in the hypotensive patient. An accurate blood pressure, devoid of the effects of vasoconstriction, can be obtained. Unfortunately, the disadvantages of cannulating the axillary artery are significant. The axilla is poorly accessible. The patient's arm must be abducted, externally rotated, and immobilized during and after the procedure. The course of the artery changes with arm position. The artery is contained within the axillary sheath along with the axillary vein and brachial plexus. There is a significant risk of nerve injury if the needle penetrates the brachial plexus. The risk of an arterial embolus is higher in central arteries when compared to peripheral arteries.

The ulnar artery, along with the radial artery, is one of the terminal branches of the brachial artery. It is superficial at the wrist and the pulse is easily palpable. The ulnar artery is significantly smaller in most people when compared to the radial artery, making the procedure more technically difficult. An ulnar artery may be absent or extremely small in some patients. The ulnar artery lies adjacent to the ulnar nerve. This increases the possibility of nerve injury if the needle penetrates the ulnar nerve. It can be difficult to identify the artery in the patient with anasarca, obesity, peripheral edema, or peripheral vascular disease.

INDICATIONS

The principal indications for arterial blood sampling include the determination of the blood carbon dioxide (CO_2) content, oxygen (O_2) content, and acid–base status.[5,6] The need for ABG sampling for determination of oxygenation has decreased substantially with the advent of pulse oximetry. Pulse oximetry may poorly reflect true oxygenation in the setting of severe hypoxia or severe hypotension. Therefore, ABG analysis persists as the true measure of arterial oxygenation.[7] End-tidal CO_2 (E_TCO_2) monitoring has decreased the utilization of ABG samples for CO_2 measurement. In patients who have large dead space ventilation or low cardiac output, E_TCO_2 measurements may grossly underestimate the true CO_2 contents of the blood.[8]

Arterial blood gas samples are useful for accurate pH monitoring of patients with shock, obstructive lung disease, and other pulmonary disorders. Possibly the most important indication for ABG sampling in the critically ill patient is the determination of the patient's acid–base status. Venous sampling may occasionally suffice for monitoring the pH in a few illnesses such as diabetic ketoacidosis.[9] The measurement of venous blood pH is much less reliable as a surrogate for arterial pH in patients with shock and other critical illnesses.[10] Arterial blood samples are still used for the measurement of carboxyhemoglobin and methemoglobin level. One study found that venous and arterial co-oximetry carboxyhemoglobin values are closely correlated and may be used to screen a patient thought to have been exposed to carbon monoxide.[11]

The three principal indications for arterial catheter placement are the need for continuous monitoring of arterial blood pressure, the need for frequent ABG sampling, and the need for frequent blood sampling for laboratory analysis in the critically ill patient. Cycled oscillometric blood pressure measurement may be insufficient to gauge rapid hemodynamic changes in critically ill hypertensive or hypotensive patients. Continuous blood pressure monitoring facilitates titration of rapid-acting vasodilators and vasopressors. The accuracy of auscultated or oscillometric blood pressure readings under conditions of severe shock or malperfusion are suspected.[1,2] Centrally measured aortic pressure is the true gold standard.[1,2] However, given the impracticality of measurement of aortic pressure, peripheral arterial pressure measured with an intraarterial catheter connected to a pressure transducer is the next best gauge.

CONTRAINDICATIONS

Contraindications to arterial puncture and catheter placement relate primarily to abnormalities at the insertion sites. Avoid skin and arteries that are already compromised by trauma, burns, infection, severe dermatitis, severe peripheral vascular disease, or previous surgery in the area.[1,5] Puncture or cannulation of synthetic vascular grafts is also relatively contraindicated. **Do not puncture where the artery "should be" if the arterial pulsation cannot be palpated.** Attempts at cannulation of nonpalpable arteries are generally fruitless and sometimes hazardous. Arterial puncture or catheterization is relatively contraindicated in patients with bleeding diatheses and those who have received, or may receive, thrombolytic therapy.

EQUIPMENT

Arterial Puncture for Single ABG Sample

- Povidone iodine or chlorhexidine solution
- Dorsal wrist extensor splint or small rolled up towel
- 1% lidocaine, 1 mL in a tuberculin syringe
- 5 mL syringe for blood collection with cap retained
- Prepackaged blood gas syringe with lyophilized heparin pellet
- 20 to 22 gauge needle for arterial puncture
- 1 to 2 mL of heparin (1000 U/mL)
- Gauze pads
- Adhesive tape
- Specimen collection bag or cup with 2 to 3 inches (in) of ice

Arterial (Brachial, Radial, Dorsalis Pedis) Cannulation

- Povidone iodine or chlorhexidine solution
- Dorsal wrist extensor splint or small rolled up towel
- 1% lidocaine, 1 mL in a tuberculin syringe
- 4 × 4 gauze squares
- Adhesive tape
- Nylon suture, 3-0 or 4-0 and needle drivers
- 20 or 22 gauge, 1¾ in polyurethane angiocatheter or catheter-over-the-needle
- 0.45 mm diameter, 5¼ in spring wire guide compatible with above catheter

Femoral Artery Cannulation

- Povidone iodine or chlorhexidine solution
- 1% lidocaine, 3 mL in a syringe armed with a 25 gauge needle
- 4 × 4 gauze squares
- #11 scalpel blade
- Nylon suture, 3-0 or 4-0 and needle drivers
- Femoral artery needle, approximately 18 gauge, 2 7/8 in.
- 4 French single lumen catheter, at least 15 cm in length
- 30 cm guidewire compatible with above needle and catheter

Ultrasound Guidance

- Ultrasound machine
- 5 to 10 MHz linear array ultrasound probe
- Sterile ultrasound gel
- Sterile ultrasound probe cover

If a syringe that has not been designed specifically for ABG sampling is used, and it has not been pretreated with heparin or does not contain a lyophilized heparin pellet, it is necessary to prepare the syringe using heparin solution. Draw up 1 to 2 mL of heparin solution into the syringe and then expel the heparin, leaving only the heparin remaining in the dead space of the syringe and the needle. This amount of heparin is sufficient to prevent clotting of the sample.[5] It is important to remove all but the necessary amount of heparin as excess heparin has been found to falsely lower the PCO_2 measurement and may elevate the PO_2 measurement.[37]

Commercially produced, prepackaged kits are available for arterial puncture and arterial cannulation. These kits are complete and contain all the required equipment. Also available are individually packaged heparinized ABG syringes and arterial line catheters in various sizes.

The catheter size used for the procedure will vary by patient age and the artery chosen to cannulate. In neonates and infants, use a 22 or 24 gauge catheter for the radial or dorsalis pedis arteries and an 18 or 20 gauge for the femoral artery. In children up to 8 to 10 years of age, use a 22 gauge catheter for the radial or dorsalis pedis arteries and a 16 to 20 gauge for the femoral artery. In a larger child, adolescent, or adult, use a 20 or 22 gauge catheter for the radial or dorsalis pedis arteries and a 14 to 20 gauge for the femoral artery.

PATIENT PREPARATION

Explain the procedure, its risks, and benefits to the patient and/or their representative. Obtain an informed consent unless the procedure is being performed emergently or the patient is unable to give consent. Identify by palpation the arterial pulse at the intended skin puncture site. Clean the skin of any dirt and debris. Cleanse the skin with chlorhexidine or povidone iodine solution and allow it to dry.

Studies that examined the use of topical anesthetic agents have not shown a benefit that outweighs the delay required to perform the procedure.[12] The use of an injectable local anesthetic agent, however, may greatly aid in the process of arterial puncture or cannulation and significantly reduces patient discomfort.[13] Infiltrate 1 mL of local anesthetic solution subcutaneously over the brachial, dorsalis pedis, or radial arteries. Infiltrate 2 to 5 mL of local anesthetic solution subcutaneously and into the subcutaneous tissues over the femoral artery. **Aspirate before infiltrating the local anesthetic solution to prevent inadvertent intravascular injection.**

Descriptions of the anatomy for arterial puncture or cannulation sites are described in detail earlier in this chapter. The preferred site for the initial attempt at arterial puncture or cannulation is the radial artery.[1] Begin distally where the pulse is most palpable near the proximal wrist flexor crease. If the first attempt at needle or catheter introduction is unsuccessful, and the pulse is still palpable,

reattempt the procedure more proximally along this same artery. The radial artery on the contralateral wrist is also a satisfactory second site for attempted access. Other acceptable second-attempt sites of access include the femoral, dorsalis pedis, and brachial arteries. **An attempt at ipsilateral ulnar artery catheterization is not advisable as both limbs of the hand's circulation may be compromised.** The discussion below focuses on puncture or cannulation of the radial and femoral arteries as over 90% of arterial punctures or cannulations occur at these sites.[1] The use of other sites generally follows the techniques described below for the radial artery with the exception of the regional anatomic differences. Other useable sites include the dorsalis pedis, brachial, posterior tibial, and superficial temporal arteries.

TECHNIQUES

ARTERIAL PUNCTURE FOR A SINGLE SAMPLE

Position the patient to maximize exposure of the skin surface overlying the chosen artery. For the radial artery, this is best accomplished by dorsiflexing the wrist and supporting this position with a small towel rolled up under the dorsal wrist surface (**Figure 57-5**). For brachial and femoral artery puncture, ensure that the elbow or hip is extended fully. These positions provide maximum exposure and working area for the procedure. Locate the chosen artery, prep the overlying skin, and infiltrate local anesthetic solution subcutaneously.

Reidentify the pulse by palpation with the nondominant hand (**Figure 57-6A**). Grasp the heparinized syringe with the dominant hand. Withdraw the plunger of the syringe so that 1 to 3 mL of air space is available in the syringe. This will allow for easier assessment of arterial blood return. Insert the needle at a 30° to 45° angle to the skin and just above the arterial pulse (**Figure 57-5**). Advance the needle through the skin until blood enters the syringe (**Figure 57-6B**). The blood flow will generally fill the syringe without necessitating the withdrawal of the plunger in a patient with a brisk pulse. If no blood return occurs, slowly withdraw the needle and watch for blood flow into the syringe. **If it is necessary to redirect the needle, it is imperative to first withdraw the needle until the tip is just below the skin surface before changing the angle in order to avoid lacerating the artery or adjacent structures.** To minimize the possibility of error due to the presence of heparin, it is necessary to collect at least 1 mL of blood in a prepackaged syringe or 3 mL of blood if preparing your own syringe with heparin.[5]

Withdraw the needle after the arterial sample has been collected. Apply pressure to the puncture site for 3 to 5 minutes followed by a bandage or gauze dressing. Carefully remove the needle from the syringe if not using a safety needle. Evacuate any air from the syringe and apply a cap on the syringe. Place the syringe on ice for immediate transportation to the laboratory. Recheck the skin puncture site in 5 to 10 minutes to assess for the formation of a hematoma and/or vascular compromise to the distal extremity.

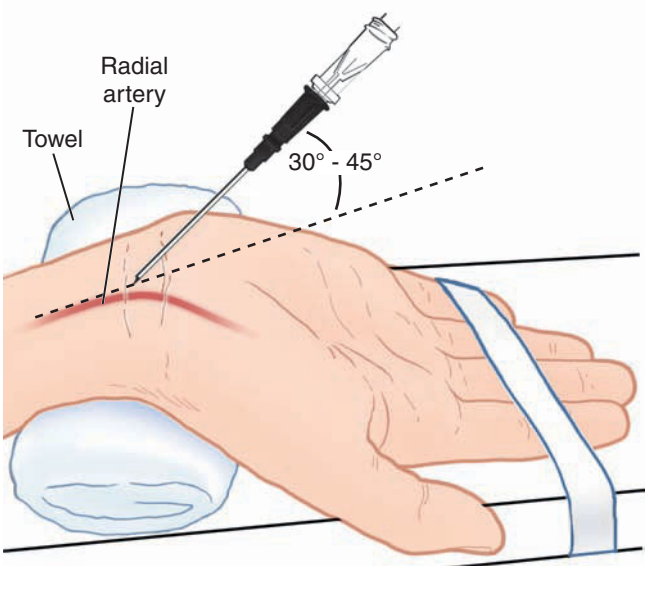

FIGURE 57-5. Correct positioning for radial artery puncture and cannulation. Dorsiflexing the wrist and supporting it with a small towel facilitates palpation of the artery and provides maximum working space. The needle or catheter-over-the-needle is aimed toward the oncoming blood flow at a 30° to 45° angle to the skin.

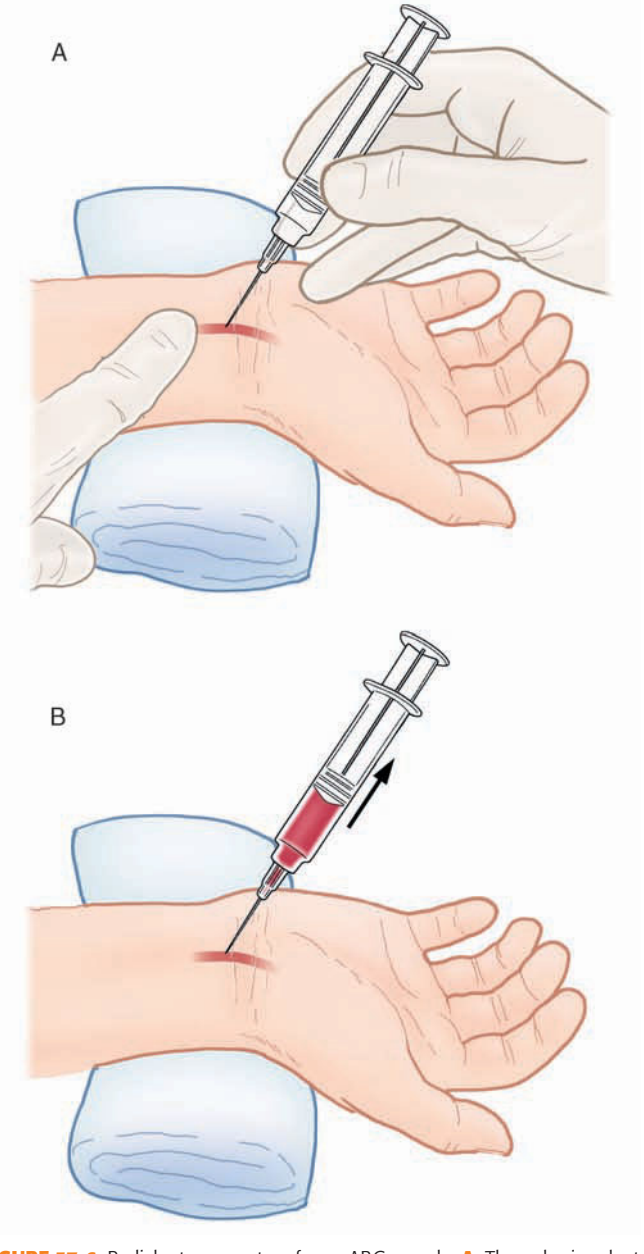

FIGURE 57-6. Radial artery puncture for an ABG sample. **A.** The pulse is palpated with the nondominant hand. The heparinized syringe is inserted at a 30° to 45° angle to the skin surface. **B.** Arterial blood fills the syringe.

RADIAL ARTERY CANNULATION: CATHETER-OVER-THE-NEEDLE-TECHNIQUE

The most basic method is direct introduction of the catheter-over-the-needle in a manner similar to that of inserting an intravenous catheter (**Figures 57-5 & 57-7**). This method is as effective as the more specialized wire-guided-catheter technique, except in situations where the pulse is weak, the pulse is absent, or in the hands of more experienced operators.[14,15] Clean, prep, and identify the radial artery as described previously. Insert the catheter-over-the-needle at a 30° to 45° angle to the skin and directly over the arterial pulse (**Figures 57-5 & 57-7A**). Advance the catheter-over-the-needle into the artery (**Figure 57-7A**). Bright red blood in the hub of the needle indicates that the tip of the needle is within the artery. Advance the catheter-over-the-needle another 1 to 2 mm to ensure that the catheter tip is completely within the arterial lumen. Securely hold the hub of the needle. Advance the catheter over the needle until its hub is against the skin (**Figure 57-7B**). Remove the needle and confirm pulsatile arterial flow from the hub of the catheter. **Free-flowing, pulsatile blood confirms proper catheter placement within the artery.** Apply a stopcock or intravenous extension tubing to the hub of the catheter. Secure the catheter to the skin. Apply a dressing to the skin puncture site.

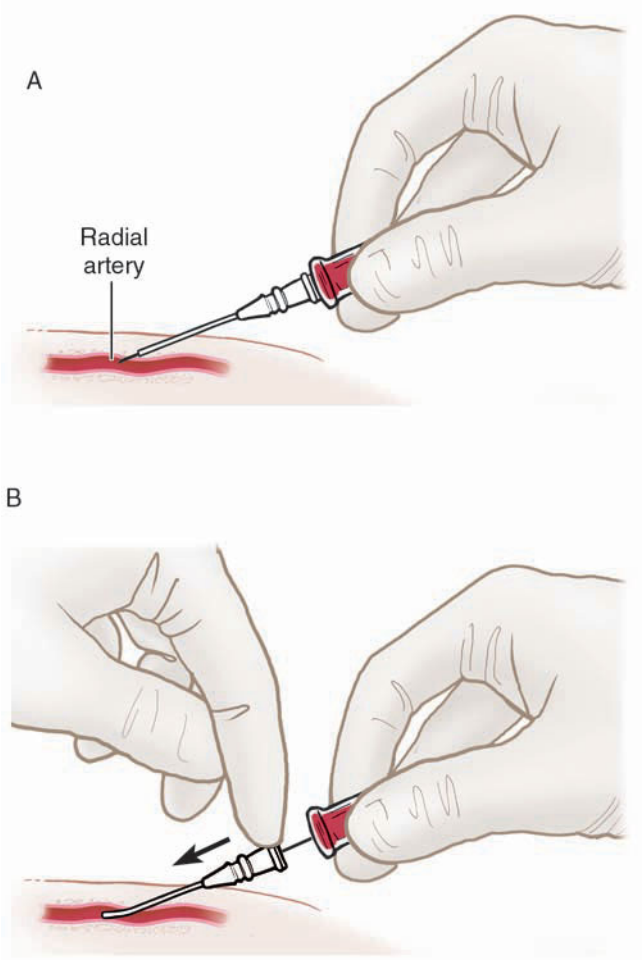

FIGURE 57-7. The catheter-over-the-needle technique for arterial cannulation. **A.** The unit is held at a 30° to 45° angle to the skin and advanced into the artery. **B.** The catheter is advanced over the needle and into the artery.

RADIAL ARTERY CANNULATION: SELDINGER-TYPE, SINGLE ARTERIAL WALL PUNCTURE

The second technique for arterial cannulation is a Seldinger-type technique (catheter-over-the-wire) utilizing one of a number of prepackaged commercially available kits. A commercially available one-piece catheter-over-the-needle kit is very popular (**Figure 57-8**). As noted previously, these wire-guided catheters have not been shown to increase successful cannulation or reduce the number of attempts except in situations where a weak or absent pulse is present, or with more experienced Physicians.[14,15] One study noted that the guidewire can be useful in salvaging an arterial line when a catheter-over-the-needle cannot be effectively advanced.

Open the package, remove the unit, and remove the protective cover over the needle. Advance and retract the guidewire to confirm it moves smoothly and does not get caught on the needle. Retract the guidewire as far back as possible. Identify the arterial pulse with the nondominant hand. Insert the catheter-over-the-needle through the skin and into the artery using a slow and continuous forward motion (**Figure 57-8A**). A flash of blood in the hub of the needle confirms successful entry through the arterial wall and into the vessel lumen. Stabilize the catheter-over-the-needle.

Advance the guidewire through the needle by pushing the actuating lever as far as possible toward the needle (**Figure 57-8B**). **Immediately stop if resistance is encountered while advancing the guidewire. The guidewire may be within the artery wall or through the artery wall and into the perivascular tissue. Do not try to force the guidewire into the vessel. Do not retract the guidewire. Withdraw the entire unit and apply pressure to the puncture site to prevent a hematoma.** Obtain a new kit and repeat the procedure.

Once advanced, the guidewire is successfully within the arterial lumen. Firmly grasp the clear hub of the needle and advance the catheter over the guidewire and into the artery (**Figure 57-8C**). **A rotating motion of the catheter is often helpful to advance it if difficulty is encountered.** Securely hold the catheter at the level of the skin. While firmly holding the catheter hub, remove the guidewire, needle, and feed tube assembly as a unit. Free-flowing, pulsatile blood confirms proper catheter placement within the artery. Apply a stopcock or intravenous extension tubing to the hub of the catheter. Secure the catheter by suturing it to the skin or by using commercially available devices that do not require suturing. Apply a dressing to the skin puncture site.

A commercially available Seldinger-type catheter-over-the-needle kit is an alternative to the one-piece unit (**Figure 57-9**). Open the package and review the equipment it contains. Place the finder needle on the syringe. Withdraw the plunger 1 cm to break the bead of the syringe. Identify the arterial pulse by palpation with the nondominant hand. Insert the needle through the skin and into the artery using a slow and continuous forward motion (**Figure 57-9A**). A flash of blood in the syringe confirms the successful entry through the arterial wall and into the vessel lumen. Firmly hold and stabilize the needle. Remove the syringe. Advance the guidewire through the needle (**Figure 57-9B**). **The guidewire should advance without resistance. Immediately stop if resistance is encountered while advancing the guidewire. The guidewire may be within the artery wall or through the artery wall and into the perivascular tissue. Do not try to force the guidewire into the vessel. Do not retract the guidewire. Withdraw the entire unit and apply pressure to the puncture site to prevent a hematoma.** Obtain a new kit and repeat the procedure.

After the guidewire is inserted, withdraw the needle while leaving the guidewire in place (**Figure 57-9C**). **Do not re-advance the needle as it can shear off the guidewire.** Make a 3 mm puncture wound

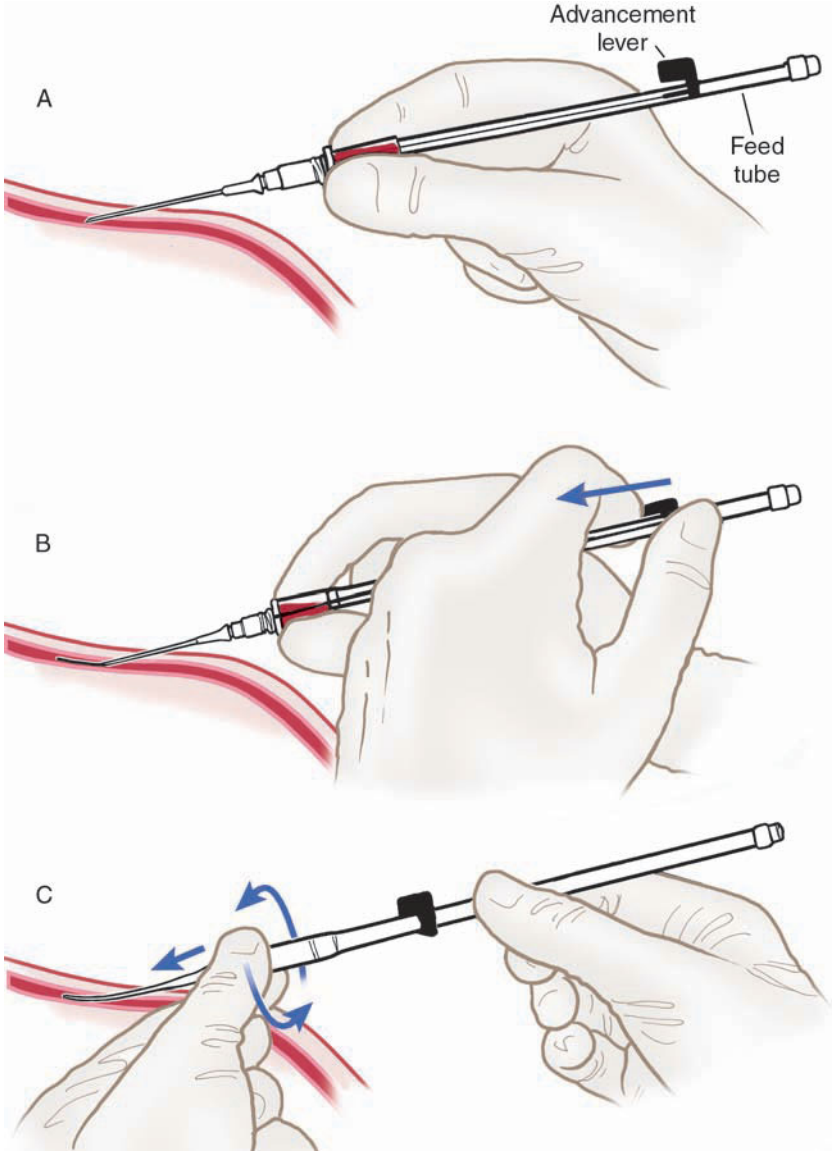

FIGURE 57-8. Catheter-over-the-needle technique using a commercially available one-piece unit. **A.** The catheter-over-the-needle is inserted into the artery. **B.** The guidewire is advanced through the needle and into the artery. **C.** The catheter is advanced over the guidewire into the artery with a twisting motion.

next to the skin puncture site of the guidewire using a #11 scalpel blade to facilitate inserting the catheter (**Figure 57-9D**). Thread the catheter over the guidewire. Advance the catheter over the guidewire until the hub of the catheter is against the skin (**Figure 57-9E**). **A rotating motion of the catheter is often helpful to advance it if difficulty is encountered.** Securely hold the catheter at the level of the skin. Remove the guidewire while firmly holding the catheter hub against the skin. Free-flowing, pulsatile blood confirms proper catheter placement within the artery. Apply a stopcock or intravenous extension tubing to the hub of the catheter. Secure the catheter by suturing it to the skin. Apply a dressing to the site.

RADIAL ARTERY CANNULATION: SELDINGER-TYPE, DOUBLE ARTERIAL WALL PUNCTURE

While localization and needle puncture of the artery are identical in all three techniques, commonly encountered difficulties include threading of the catheter with the first technique and threading of the guidewire into the vessel lumen with the second technique.[16] If the needle orifice is merely at the vessel edge, blood may enter and rise up through the needle. However, when trying to advance the catheter, it may get hung up outside the lumen with the catheter-over-the-needle technique.[17] The guidewire may not easily pass or may dissect into the vessel wall creating a false lumen when using the Seldinger-type single arterial wall puncture technique. Since pulsatile flow is more easily confirmed prior to the passage of the guidewire, this third technique in which both walls of the radial artery are punctured may offer an advantage in passing the guidewire and catheter into the arterial lumen.

It is imperative that the Emergency Physician assumes a position out of the trajectory line of the catheter to avoid being sprayed with blood when using this technique. This method is also a Seldinger-type technique that utilizes a guidewire separate from the catheter-over-the-needle. Locate the arterial pulse and insert the catheter-over-the-needle into the artery. Immediately advance the catheter-over-the-needle through the posterior wall as confirmed by no blood exiting the needle hub. Withdraw the needle while leaving the catheter in place through the artery. Flatten the angle of the catheter to the skin to less than 30°. Hold the tip of the guidewire poised at the hub of the catheter. Slowly

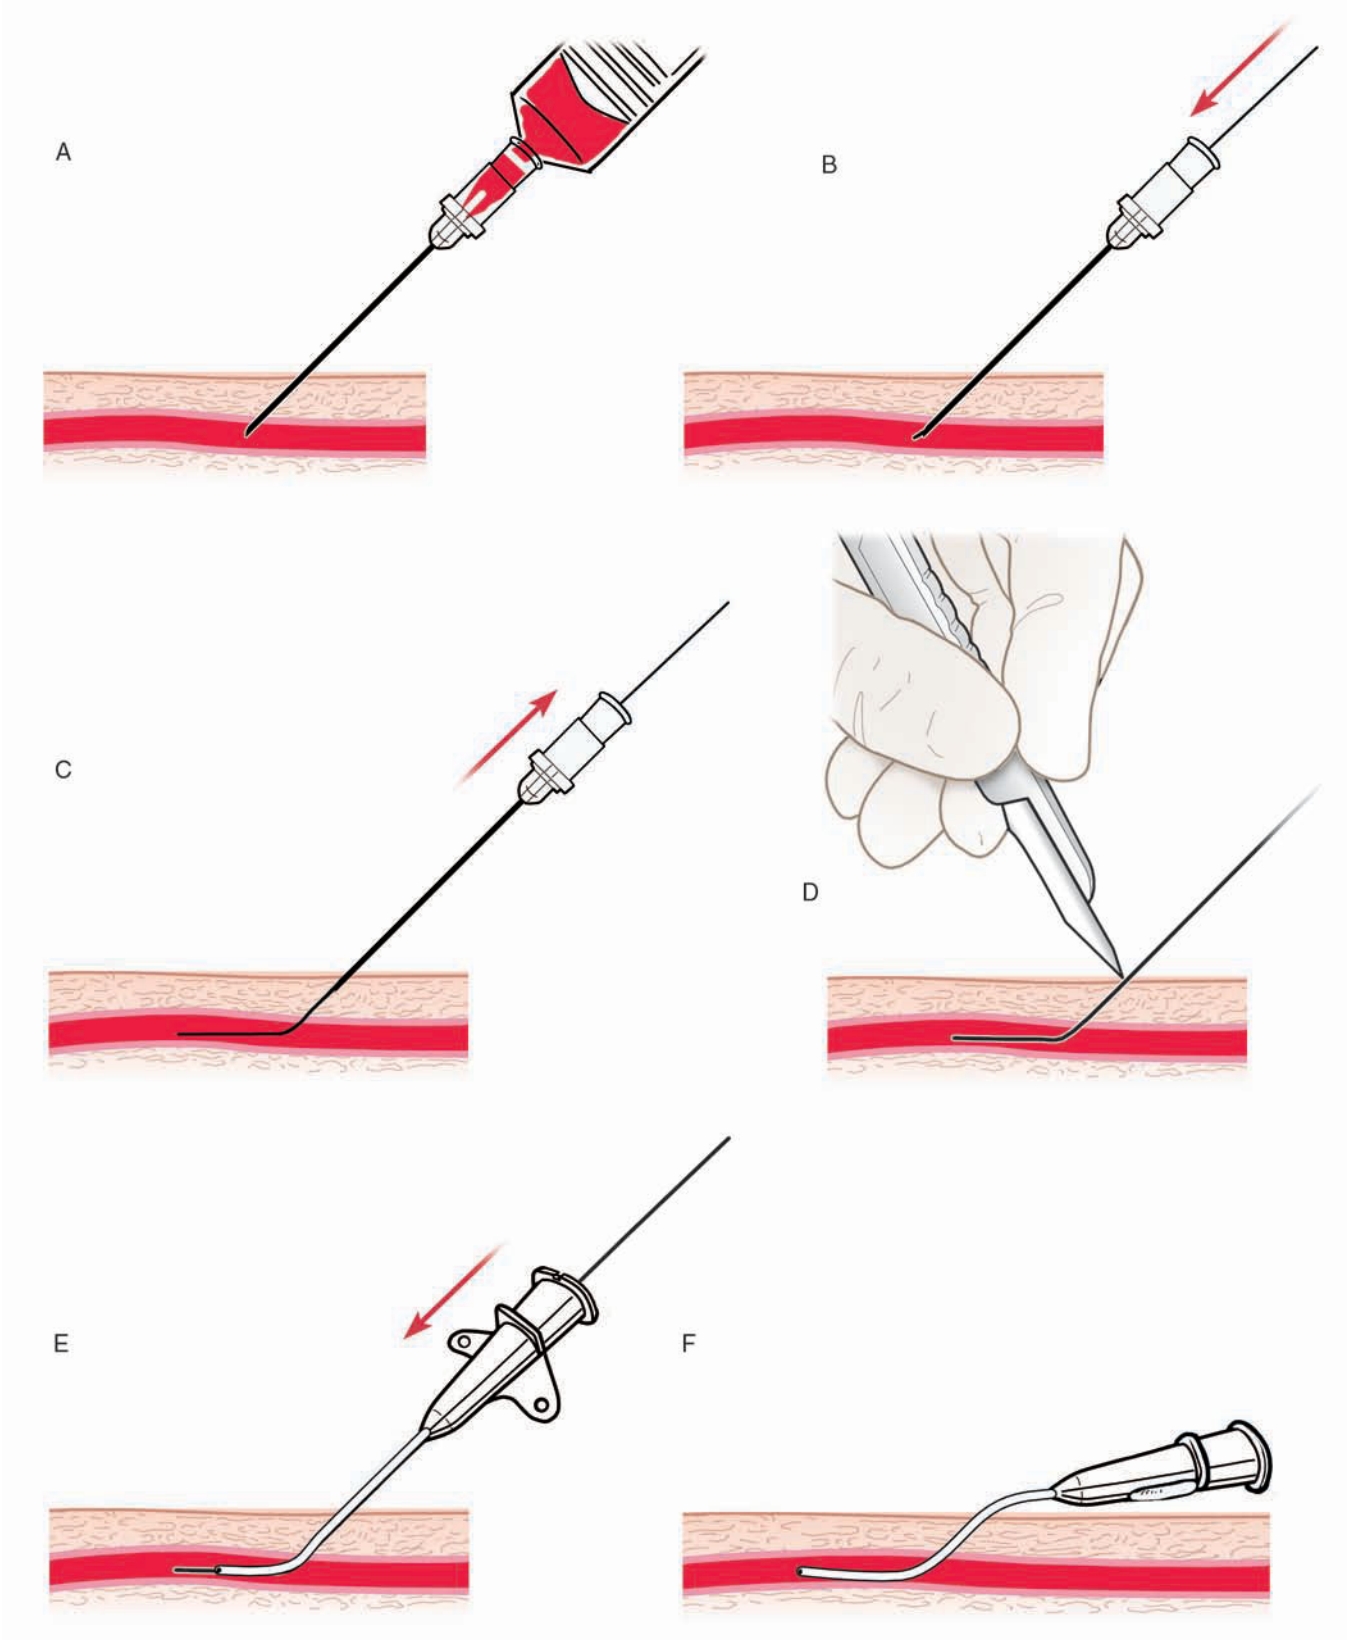

FIGURE 57-9. The Seldinger technique for arterial catheterization. **A.** The needle is inserted into the artery. **B.** The syringe has been removed from the needle. The guidewire is advanced through the needle and into the artery. **C.** The needle is removed while leaving the guidewire in place. **D.** The skin is punctured with a #11 scalpel blade to allow easy insertion of the catheter. **E.** The catheter is advanced over the guidewire and into the artery. **F.** The guidewire has been removed.

withdraw the catheter with the nondominant hand. Promptly insert the guidewire through the catheter and into the artery when pulsatile blood flow is noted from the hub of the catheter. Advance the catheter over the guidewire and into the lumen of the artery. Withdraw the guidewire and apply a stopcock or intravenous extension tubing. Secure the catheter and apply a bandage or dressing.

This double-puncture technique for cannulation theoretically may be associated with greater vascular damage. The technique should be reserved for instances in which the prior two arterial cannulation techniques have been unsuccessful. However, in an analysis of the complications associated with various techniques of peripheral artery cannulation, investigators found no difference in complications when using this technique.[18]

FEMORAL ARTERY CANNULATION

The femoral artery may be cannulated if the radial artery is inaccessible or attempts at cannulation are unsuccessful. A longer catheter, catheter-over-the-needle, and needle is required as the femoral artery is not superficial. Slightly abduct the patient's leg and identify the femoral artery pulse. Prep, drape, and anesthetize the skin and subcutaneous tissues. Maintain the fingers of the nondominant hand on the arterial pulse. Insert the needle or the catheter-over-the-needle at a 45° angle to the skin with the needle bevel pointing superiorly. The remainder of the technique is as described previously.

DORSALIS PEDIS ARTERY CANNULATION

The procedure for cannulation of the dorsalis pedis artery is the same as that described for the radial artery. Clean, prep, and plantar flex the foot. Do not plantar flex the foot more than 45° as this can stretch and occlude the artery. The needle angle of entry should be less than that used for the radial artery due to the superficial location of the artery. Insert it at 20° to 30° to the skin rather than 30° to 45°.

ULTRASOUND-GUIDED ARTERIAL CANNULATION

Ultrasound can be used to guide arterial puncture or cannulation. It can be a rescue method if the palpation technique fails. It can also be used initially to decrease the number of puncture attempts, to decrease the amount of time spent gaining access, and to potentially decrease complications such as hematomas and arterial laceration.[19,20] Most studies have focused on radial artery cannulation, but the technique for alternative sites is the same.

Clean and prep the skin over the artery. Apply a sterile probe cover or a sterile glove over the linear array ultrasound probe. Orient the probe marker on the side of the probe so it matches that on the screen. Identify the artery. It will appear as a round, thick-walled, and pulsatile vessel that is not easily compressible (**Figure 57-10A**). Move the probe proximally and distally over the artery to approximate its course, which is sometimes not perfectly parallel to the long axis of the extremity. Once the vessel has been identified, center it on the screen. The center of the probe is now directly over the vessel and can act as a guide to skin puncture. Hold the probe with the nondominant hand or have an assistant hold the probe. Insert the catheter 1 to 2 cm distal to the probe. When the needle is into the subcutaneous tissue, rock it in and out very slightly to create movement that is apparent on the screen. This will help to identify the location of the needle in relation to the artery. Slowly advance the needle. The needle itself may or may not be apparent, but motion through the tissue can be used to infer the site of the needle tip.

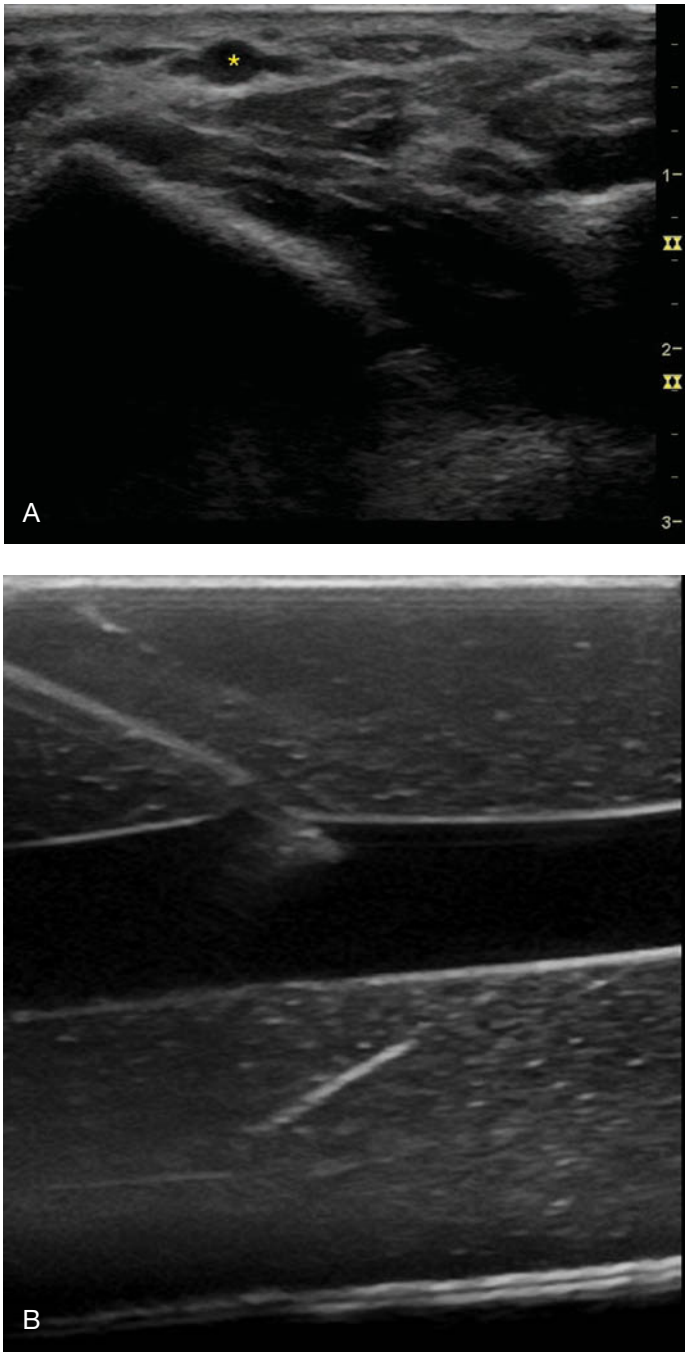

FIGURE 57-10. Ultrasound-guided arterial puncture. **A.** The artery is seen at the top of the image (*asterisk*). **B.** The longitudinal view demonstrating the needle entering the artery.

When the needle reaches the artery, it will dimple the wall of the artery. Advance the needle slowly while watching for the flash of blood in the needle hub. Once the flash is seen, ultrasound can be used to confirm placement of the needle and/or catheter within the artery (**Figure 57-10B**). Proceed from this point with either the catheter-over-the-needle or the Seldinger-type technique to complete the procedure.

ALTERNATIVE TECHNIQUE

A cutdown technique may be performed to cannulate an artery. It is primarily used for the brachial or radial arteries but may be used to access other peripheral arteries. This technique is rarely required

with the availability of ultrasound to locate an artery The technique is briefly described here. Please refer to Chapter 54 for more complete details.

Clean, prep, anesthetize, and drape the skin overlying the chosen artery. Make a 1.5 to 2.0 cm transverse skin incision centered over the artery. **Do not cut into the subcutaneous tissue so that blood vessels, nerves, and tendons are not transected.** Spread the subcutaneous tissues parallel to the artery with a mosquito hemostat. Expose 1.0 cm of the length of the artery. Pass a silk suture under the proximal end of the exposed artery. Insert a catheter-over-the-needle through the skin just distal to the incision and advance it into the incision. Elevate the suture to control the artery and occlude distal blood flow. Advance the catheter-over-the-needle into the artery. Release the suture and advance the catheter into the artery. The remainder of the procedure is as described previously. Apply pressure over the incision site for 5 to 10 minutes to prevent the formation of a hematoma or seroma.

AFTERCARE

Apply direct pressure for 3 to 5 minutes to the skin puncture site after an arterial puncture or removal of an arterial catheter. Apply direct pressure for 10 minutes or more if the patient has a bleeding diathesis or has received thrombolytic therapy. Apply a bandage or gauze dressing to the skin puncture site. Reassess the skin puncture site in 15 minutes for continued bleeding or hematoma formation.

An arterial catheter must be secured to the skin to prevent inadvertent dislodgement, hematoma formation, and exsanguination. Sew the hub of the catheter to the skin using 3-0 or 4-0 nylon sutures. Apply a protective dressing over the site. A splinting device should be used to secure the limb in the desired position for optimal monitoring if the catheter is in the wrist, arm, or foot. Monitor the site regularly to assess for signs of bleeding, infection, hematoma, arterial thrombosis, or catheter dislodgement. It is also important to assess the extremity distal to the catheter for evidence of ischemia. Replace the dressing regularly in accordance with your institutional guidelines.

Flush the arterial catheter with sterile saline solution. In the past, heparinized saline was the standard arterial line flush solution. The use of heparinized saline has not been shown to improve functionality, prevent thrombotic complications, or increase the duration of catheter patency when compared to saline.[40] The use of heparin risks an adverse reaction or heparin-induced thrombocytopenia.

COMPLICATIONS

Arterial puncture and catheterization are generally safe procedures with an incidence of clinically significant complications under 5%.[1] The primary complications of arterial catheterization are infection, bleeding, arterial injury, and thrombosis.[2,21–30] While secondary bacteremia and septic emboli may occur, infection is usually limited to the site of catheterization. The risk of catheter site infection is linearly related to the length of time the catheter is in place.[2] The infection rate is similar for both femoral and radial artery sites.[2,23,31–33] Nerve injury from direct puncture of the nerve has been reported in connection with arterial puncture or cannulation.[34] Multiple cases of neuropathy have occurred as a result of a hematoma formation and subsequent nerve compression.[35] In order to minimize hematoma formation after arterial puncture or arterial catheter removal, apply at least 3 minutes of direct pressure to radial, brachial, and dorsalis pedis puncture sites and 5 to 10 minutes of pressure to the femoral site.[34,36] Although small hematomas are common after arterial puncture, major bleeding is unusual and generally occurs only in the concealed retroperitoneum after femoral artery puncture or cannulation. Angiographically demonstrable thrombosis is common (25% to 40%) after prolonged arterial catheterization.[2] This rarely results in clinically significant morbidity. Secondary limb ischemia and necrosis requiring amputation occur in less than 1:2000 arterial catheterizations.[2] Other rare complications include the formation of a pseudoaneurysm or arteriovenous fistula.

The complications associated with an arterial catheter can be limited. Only insert an arterial catheter if it is truly needed. Always insert it using strict aseptic technique. Remove the catheter as soon as it is determined it is no longer required to assist in the management of the patient. Frequently check the skin puncture site for signs of bleeding, a hematoma, and infection. Frequently assess the distal extremity for signs of perfusion. Remove the catheter at the first sign of a complication. Place the catheter in the patients' nondominant hand, if known, to limit the impact of any complications.

SUMMARY

Arterial puncture and cannulation are quick, safe, and simple to perform. Arterial blood sampling may aid in determining the ventilator and acid–base status of critically ill patients. An arterial catheter is appropriate in patients who need continuous monitoring of arterial blood pressure or frequent ABGs. Arterial puncture and cannulation should be avoided in skin areas with evidence of burn, trauma, infection, severe dermatitis, or severe peripheral vascular disease. Palpation of the arterial pulse and correct anatomical positioning are necessary before these procedures are attempted. It is necessary to monitor the cannulated site for signs of bleeding, hematoma, thrombosis, or infection. After an arterial puncture or removal of an arterial catheter, it is necessary to apply direct pressure to the skin puncture site to prevent the formation of a hematoma.

SECTION 5

Gastrointestinal Procedures

58 Nasogastric Intubation

Lisa Freeman Grossheim

INTRODUCTION

Nasogastric (NG) intubation is one of the commonly performed procedures in the Emergency Department.[1] Its use as a conduit into the stomach was first popularized in the early twentieth century mainly through the efforts of Dr. Levin. Clinicians have since studied its use, have proposed methods to improve the ease with which the NG tube is inserted, and determined ways to diminish the incidence of potentially lethal complications. A NG tube is often placed in patients who have a bowel obstruction, intractable nausea and vomiting, intoxication, significant trauma, upper gastrointestinal bleeding, or who are endotracheally intubated. The procedure is rapid, simple, and straightforward.

ANATOMY AND PATHOPHYSIOLOGY

The nasal cavity is lined by the very vascular nasal mucosa. The medial wall of the nasal cavity is composed of the septum. The lateral wall of the nasal cavity is covered by the turbinates. The posterior nasal cavities are continuous with the nasopharynx that develops into the posterior oropharynx as you move caudally (**Figure 58-1**). The oropharynx continues inferiorly as the esophagus that enters the stomach below the diaphragm.[2]

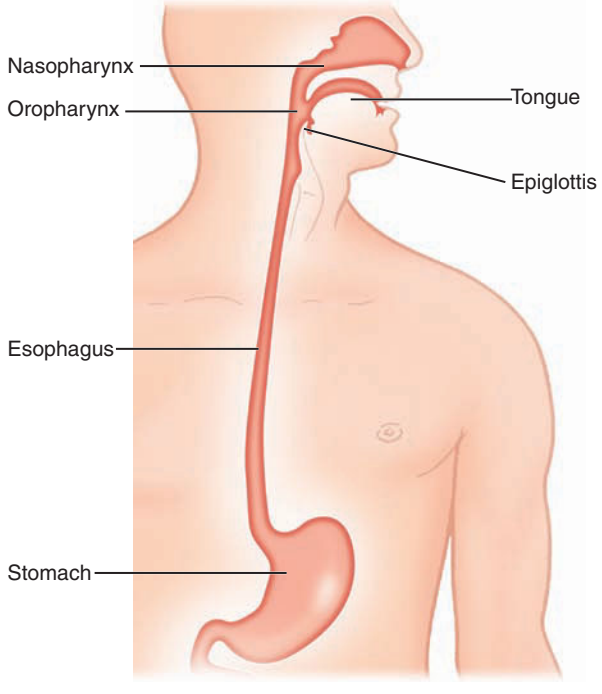

FIGURE 58-1. Basic anatomy of the path of the NG tube.

The placement of a NG tube in children is often difficult. Their large tonsils and adenoids may hinder the passage. These tissues are soft, easily injured, and may bleed as the NG tube is passed. The tongue, large by comparison with adults, may push into the oropharynx and impede passage of the NG tube. Their nostrils and nasal passage are quite small and limit the size of NG tube that may be passed.

INDICATIONS

Nasogastric intubation may be performed for diagnostic or therapeutic indications.[15] The primary indication for NG intubation is to aspirate stomach contents. It is used to evaluate the presence, rapidity, and volume of an upper gastrointestinal hemorrhage. However, unless the aspirate is grossly bloody, detection of blood may be unreliable. The fecal Hemoccult card should not be used to test for occult blood in gastric aspirates, as it may be accurate. The Gastroccult card uses a developer that neutralizes gastric acid, rendering it able to detect hemoglobin.[11] A NG tube may be inserted to instill air into the stomach to assess for an intraperitoneal perforation. Gastric fluid and contents may be aspirated for laboratory analysis. It may also be placed to visualize the stomach on chest radiography to assess for a diaphragmatic hernia. A NG tube is placed in patients for medication administration, relief of a bowel obstruction, treatment of recurrent vomiting, administration of oral contrast for diagnostic imaging, and to perform gastric lavage. They are placed to decompress the stomach preoperatively, postintubation, prior to a diagnostic peritoneal lavage, or prior to a pericardiocentesis.

CONTRAINDICATIONS

Absolute contraindications do not exist for NG tube placement. The relative contraindications are geared toward predicting which patients are more likely to experience complications and which patients are likely to have misplaced tubes. Insertion of a NG tube should be avoided, unless necessary, in the patient with midface trauma. Intubation through the nasal cavity can result in the NG tube being misdirected blindly into the respiratory tract or through the rare perforation of the thin cribriform plate of the ethmoid bone and into the brain. Patients with facial trauma are best served with orogastric intubation.[3] Patients with esophageal varices pose potential problems. Placement of a semi-rigid tube into the esophagus or stomach has the potential to cause rupture of the varices and uncontrollable hemorrhage. However, NG placement is generally considered safe in these patients if done carefully.[12,13] Other relative contraindications include patients with coagulopathies, esophageal strictures, ingestions of alkaline substances, nasal obstruction, or recent nasal surgery.

EQUIPMENT

- Topical anesthetic (benzocaine spray, cocaine, or viscous lidocaine)
- Topical vasoconstrictor (phenylephrine, oxymetazoline, or cocaine)
- 4% lidocaine

- Glass of water with straw
- Emesis basin
- Water-based lubricant
- NG tube, various sizes
- 60 mL syringe
- Wall suction, set to low intermittent suction
- Suction tubing
- Benzoin spray
- 1 in. adhesive tape
- Tongue depressor

NG tubes are usually made of clear polypropylene. They are somewhat rigid and single patient use devices. Typically used are the Levin tube and the Salem Sump tube. They both have multiple distal sideports. The Levin tube is a single-lumen tube that is easy to insert. It is simple to use for the aspiration of gastric contents, the instillation of fluids and/or medications, and the application of low intermittent suction. The tube is nonradiopaque. Unfortunately, the amount of suction is difficult to control with the Levin tube. The distal sideports often become occluded with the gastric mucosa, and damage this tissue, when the tube is attached to suction. The Salem Sump tube is a double-lumen, radiopaque tube. It has a smaller suction lumen than the Levin tube. The second lumen allows a constant inward airflow to prevent the sideports from becoming occluded by the gastric mucosa.

PATIENT PREPARATION

The most beneficial factor in the successful placement of a NG tube is a patient who is informed of the procedure and can cooperate with the instructions. Explain the risks, benefits, and complications associated with the procedure to the patient and/or their representative. Take the patient through each step prior to the start of the procedure to ensure maximal cooperation. Drape the patient to protect them and the bedding from soilage if there is emesis. A glass of water and a straw should be within reach, if not contraindicated, as should an emesis basin.

Place the patient seated upright in the Fowler's or semi-Fowler's position. Examine the patient for nasal septal deviation or other anatomic abnormalities that may hinder the passage of the NG tube. Ask the patient to breathe through one nostril while the other nostril is occluded to determine which nostril is the most patent.[4]

While often underused, consider using some form of anesthesia to make the procedure more tolerable.[20] A recent study suggests that the application of topical lidocaine and phenylephrine to the nose and benzocaine spray to the throat resulted in significantly less pain and discomfort than the use of lubricant alone.[5] The patient should be screened for allergies and contraindications, such as hypertension, if these adjuncts are to be used. A sample protocol would include the instillation of 0.5% phenylephrine nasal spray followed by viscous lidocaine. Cetacaine spray can be used to anesthetize the nose and the throat.[4] Nebulized 4% lidocaine (2.5 mL containing 100 mg of lidocaine) via a face mask can be used in adolescents and adults. It has been shown to be superior to lidocaine spray as an anesthetic to reduce gagging and vomiting and can increase the success of NG tube placement.[14,16] The dose used in children has been 4 mg/kg of lidocaine.[17] Either 2% or 4% lidocaine solutions can be used. **Be cautious when calculating the proper weight-based doses and volume of solution for children.** Lidocaine can also be administered in the nasal cavity, nasopharynx, and oropharynx using a mucosal atomizer device (MAD, Wolfe Tory Medical Inc., Salt Lake City, UT). Allow 3 to 5 minutes for these medications to take full effect before inserting the NG tube.

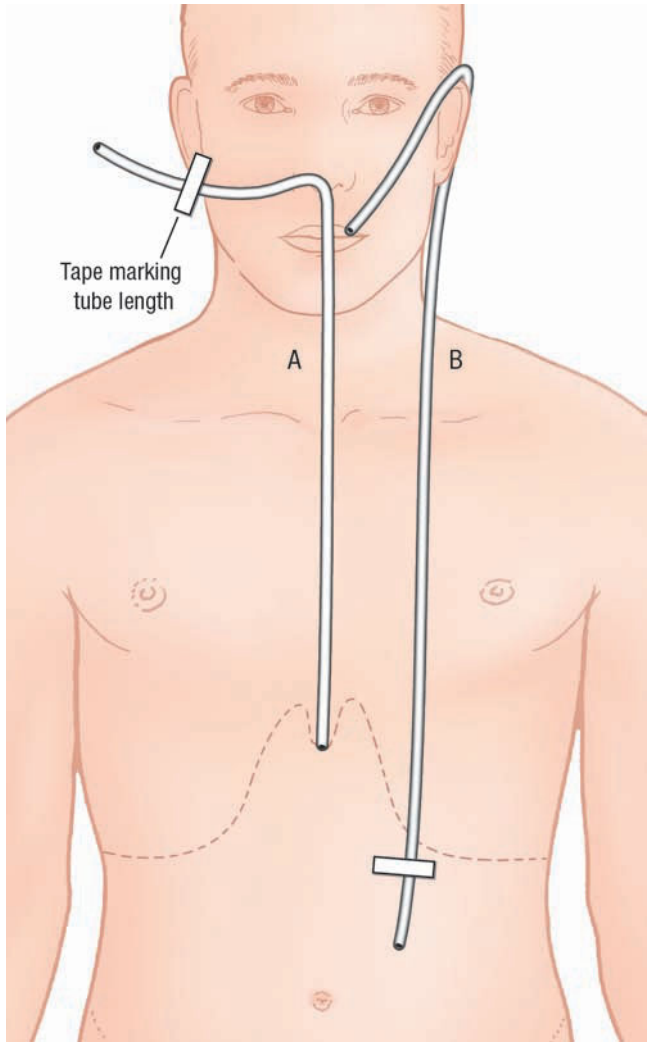

FIGURE 58-2. Determining the proper length of the NG tube to insert. **A.** The length is determined by the distance from the xiphoid process to the tip of the nose to the earlobe. **B.** The length is determined by the distance from the tip of the nose or lip to around the left ear and to just below the left costal margin. A piece of tape should be used to mark the distance on the NG tube.

Choose a size of NG tube that is appropriate for the patient. A size 16 to 18 French is typically used for an adolescent or adult patient. A formula ([age in years + 16] ÷ 2) may be used to choose the proper size NG tube for children. Other less commonly used methods are also available to determine the proper size NG tube in children.[21] Typical sizes include 8 French for infants, 10 to 12 French for small children, and 12 to 14 French for older children.

Estimate the length of the NG tube to be inserted (**Figure 58-2**). Place the tip of the NG tube on the patient's xiphoid process and extend it to the tip of the nose and over the earlobe (**Figure 58-2A**). Mark this distance with a piece of tape.[4] Alternatively, place the tip of the NG tube on the tip of the nose or lip and extend it over the left ear and to just below the left costal margin (**Figure 58-2B**). Mark this distance with a piece of tape.[4]

TECHNIQUE

Lubricate the first 4 in. (10 cm) of the NG tube with a water-soluble lubricant. Position the patient. Place their neck in slight flexion. Gently introduce the NG tube along the floor of the nostril (**Figure 58-3A**). Advance the NG tube parallel to the nasal

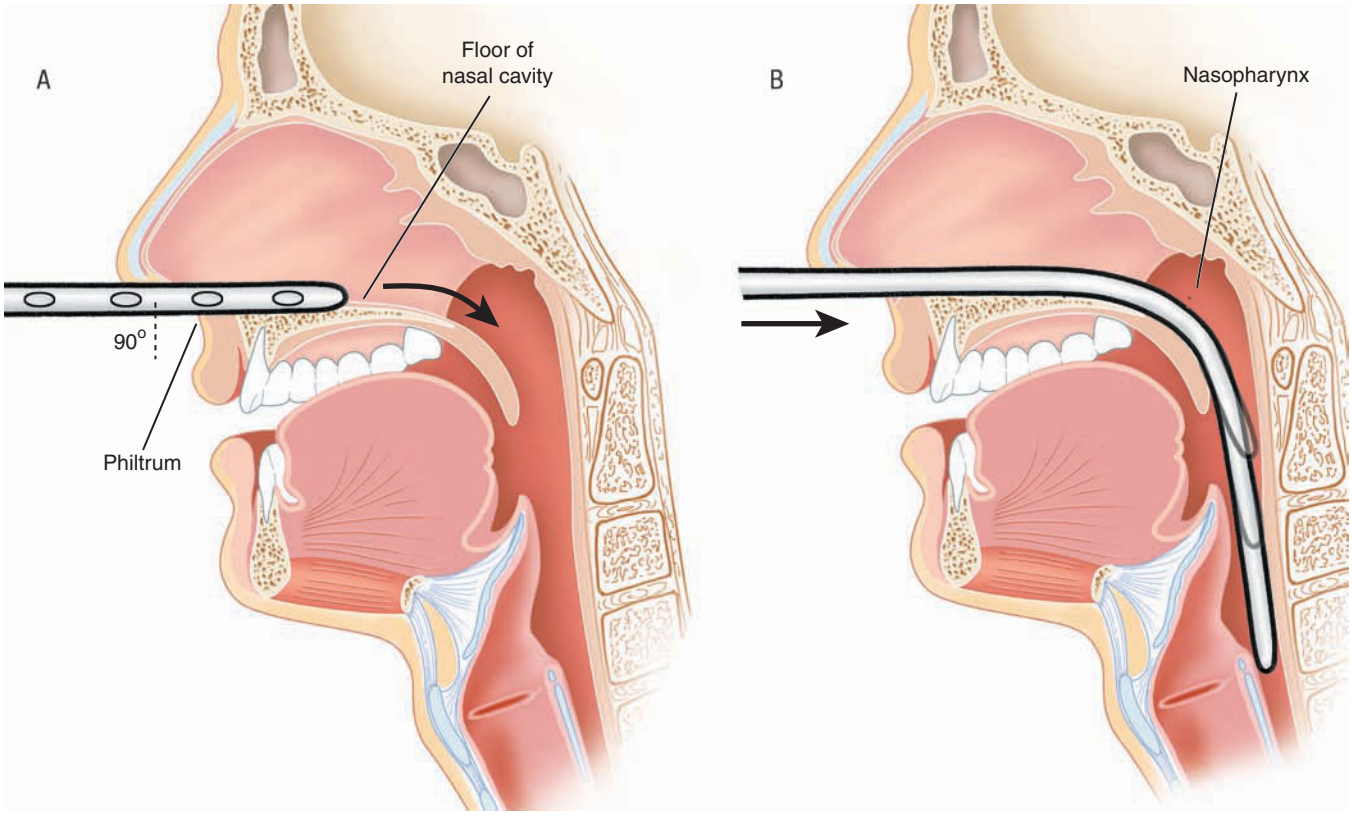

FIGURE 58-3. Insertion of the NG tube. **A.** The NG tube is inserted parallel to the floor of the nasal cavity and at a 90° angle to the philtrum. **B.** The NG tube is advanced along the floor of the nasal cavity, through the nasopharynx and oropharynx, and into the esophagus. It is further advanced until the tape mark is at the philtrum.

floor until it reaches the nasopharynx as indicated by mild resistance (**Figure 58-3A**). Do not insert and advance the NG tube in an upward or lateral direction to prevent impingement and damage to the turbinates. Instruct the patient to swallow. This may be assisted by having the patient sip water through a straw if not contraindicated. Continue to advance the NG tube (**Figure 58-3B**). Advancement may be aided by rotating the NG tube medially. **Withdraw the NG tube if at any time significant resistance to advancement, respiratory distress, the inability to speak, or significant nasal hemorrhage occurs.**[5]

Advance the NG tube until the distance previously measured with the tape is at the nostril (**Figure 58-4**). Verify proper placement by aspirating stomach contents, by auscultating a rush of air over the stomach while 60 mL of air is insufflated through the NG tube, or by radiographically demonstrating the tip of the NG tube in the stomach and below the diaphragm. The latter is the most reliable and should be strongly considered when the NG tube is to be used for medication administration or alimentation.[6] **Infusion of substances through a misplaced NG tube could be disastrous.** Apply benzoin to the patient's nose. Apply tape to the nose and around the NG tube to secure it in place (**Figure 58-5**). Attach the NG tube to wall suction.

ALTERNATIVE TECHNIQUES AND HELPFUL HINTS

One study attempted to improve the success rate of NG tube placement by providing external and medially directed pressure on the ipsilateral neck at the level of the thyrohyoid membrane.[7] This maneuver will collapse the piriform sinus and eliminate it as a potential site for impaction. This maneuver was successful for difficult NG intubation in 85% of patients.

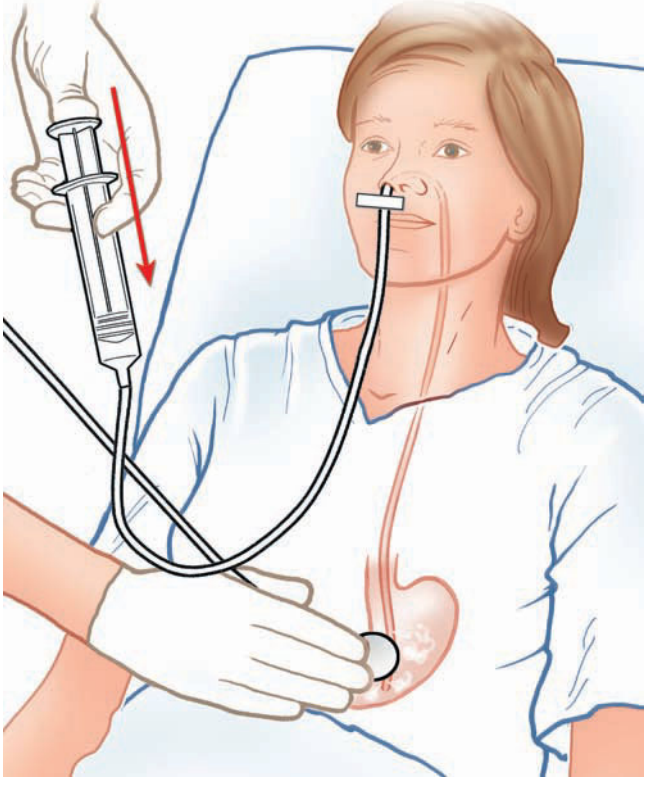

FIGURE 58-4. Proper placement of the NG tube. The tip of the tube resides within the stomach. To confirm proper placement, inject air through the NG tube while simultaneously auscultating over the stomach.

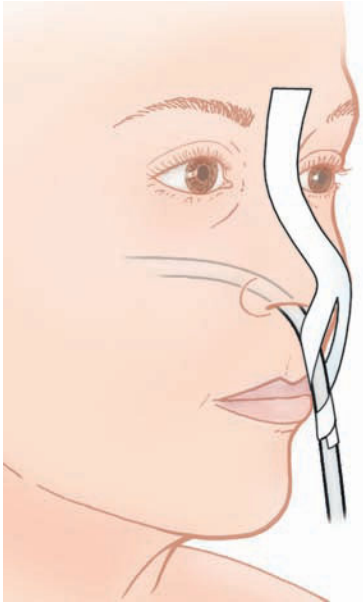

FIGURE 58-5. Securing the NG tube. Apply tincture of benzoin to the bridge of the nose. A piece of tape is attached to the nose with the distal end split into two and intertwined around the NG tube.

The NG tube may coil in the oropharynx, mouth, or hypopharynx. A larger-bore NG tube may be used and may not coil. Cool the NG tube in cold tap water or ice water for 5 minutes to make the tube stiffer and then reinsert it. An alternative is to place the distal end of a NG tube into an oropharyngeal airway then chill it in ice water (**Figure 58-6**). The oropharyngeal airway will place a curve in the chilled NG tube, which may allow it to pass easier. The chilled NG tube will retain this curve for 30 to 60 seconds until it rewarms (**Figure 58-6**).

A final option is to place several fingers through the patient's mouth and into the oropharynx. The fingers can be used to guide the NG tube against the posterior oropharyngeal wall and into the hypopharynx without it coiling. A tongue depressor may be used to move the tongue to the floor of the mouth and make manipulation of the NG tube easier by creating more space in the mouth to maneuver. **This finger technique should be reserved for intubated patients in whom the gag reflex is not a concern. Do not attempt this unless the patient is unconscious or paralyzed to prevent them from biting and injuring the fingers.**

FIGURE 58-6. A NG tube is inserted into an oropharyngeal airway before being chilled in ice water. The chilled NG tube will retain its curve for 30 to 60 seconds.

The NG tube may easily pass the hypopharynx but not be able to be passed completely through the esophagus and into the stomach. The tip of the tube may be caught at the level of the cricopharyngeus muscle, behind the left mainstem bronchus, or at the lower esophageal sphincter. Attempt to pass a NG tube that has been cooled for 3 to 5 minutes in cold tap water or ice water. Grasp the thyroid cartilage and lift it anterior and upward to open the esophagus and allow passage of the NG tube through the upper esophagus.

An orotracheally intubated patient requires a NG tube to decompress the stomach. Unfortunately, one cannot always be passed into the stomach. Remove the respiratory adapter from the proximal end of a second endotracheal tube. Liberally lubricate the endotracheal tube and insert it through the patient's mouth and into the esophagus. Insert a well-lubricated NG tube through the endotracheal tube and into the stomach. Confirm the proper position of the NG tube. Carefully withdraw the endotracheal tube over the NG tube. Reconfirm that the distal end of the NG tube still remains within the stomach.

The risk for tube misplacement is greater in the intubated patient who is unable to assist with NG intubation. Observe that the NG tube does not come out of the patient's mouth and that there are no changes in the patient's oxygen saturation when inserting the NG tube. It is very easy for the NG tube to pass by the cuff of an endotracheal tube without much resistance.[7] **It is paramount that correct placement of the NG tube is verified both clinically and radiographically before it is used to instill any fluid or medication.**

A final technique to help pass a NG tube involves direct visualization using a laryngoscope and Magill forceps. Insert the NG tube through the nose and advance it into the oropharynx or hypopharynx. Insert the laryngoscope blade and visualize the distal tip of the NG tube and the esophageal opening. Grasp the tip of the NG tube with the Magill forceps and advance it into the esophagus. Continue to advance the NG tube until the tip is within the stomach. The technique can be used on the unconscious and intubated patient in which a NG tube will not pass into the esophagus.

ASSESSMENT

The patient should be able to speak without respiratory distress immediately after placement of the NG tube. Observe the patient for complaints of neck pain, substernal chest pain, dysphagia, drooling, trismus, fever, or subcutaneous and mediastinal air. These would be signs of esophageal perforation or errant placement of the NG tube.[6] Although auscultation of air in the stomach has been classically used to determine correct placement, air insufflated into the pleural space or the esophagus after misplacement of the NG tube can be just as easily heard over the upper abdomen.[6] Gastric contents should be able to be aspirated through the NG tube. Testing the pH of the gastric contents can help predict the placement of the NG tube. The pH of the aspirated fluid will be ≥7 in 99% of patients if the NG tube is in the respiratory tree.[8] The pH of the aspirated fluid will be ≤5 in 70% of the patients if the NG tube was correctly placed in the stomach. The use of H_2 blockers makes the assessment of gastric pH difficult. Radiographic demonstration of the tube in the antral or fundal portion of the stomach is the preferred method of confirmation.[9]

NASOGASTIC TUBE REMOVAL

Explain to the patient the procedure and what they will experience as the NG tube is removed. It is recommended for the Emergency Physician to wear gloves, a mask with an eye shield, and a gown to prevent being contaminated during the removal. Place the patient in the Fowler's or semi-Fowler's position. Place towels or pads over the

patient's neck and chest. Have an emesis basin, tissues, and Yankauer suction immediately available. Disconnect the NG tube from suction. Fold over the proximal end of the NG tube and hold it tightly. Ask the patient to slightly flex their neck, breath in, and hold it. Place a drape or towel around the NG tube as it is exiting the patient's nose. Firmly squeeze the drape around the NG tube. Briskly withdraw the NG tube through the drape. The drape will contain all the secretions and bodily fluids and prevent them from splashing on the patient or the Emergency Physician. Discard the NG tube and the drape.

COMPLICATIONS

The most common complication of NG intubation is discomfort in the nasopharynx and oropharynx. Placement in the nares can result in epistaxis if the nasal mucosa is irritated, abraded, or ulcerated. These complications can be reduced or avoided with generous lubrication of the NG tube and the instillation of topical anesthetics and vasoconstrictors prior to inserting the NG tube. Sinusitis may occur from the NG tube obstructing the sinus ostia. These complications are usually of no clinical significance.

A more serious consequence of NG intubation is misplacement into the respiratory tree. This is estimated to occur in up to 15% of cases.[10] The incidence increases in frequency with the patient who has a diminished gag reflex or a decreased level of consciousness. **The presence of a cuffed endotracheal tube does not preclude passage into the respiratory tree.** The NG tube will pass the cuff of the endotracheal tube without significant resistance. Advancing the NG tube into the airway can result in perforation of a bronchus or the lung and result in a pneumothorax, hydropneumothorax, pulmonary hemorrhage, empyema, or bronchopulmonary fistula.[10] These complications are increased if medication or alimentation is infused into the respiratory tree.

The most serious complication of NG tube placement is esophageal perforation. This most often occurs in the posterior wall of the cervical portion of the esophagus and through the cricopharyngeus muscle. Risk factors for esophageal perforation include a preexisting esophageal abnormality, altered mental status, cervical osteophytes, cardiomegaly, tracheal intubation, a stiff NG tube, and multiple attempts.[6] Other risk factors for esophageal perforation include esophageal cancer or the ingestion of alkaline substances. Perforation often results in mediastinitis with a subsequent mortality rate of up to 30%.[6] Prompt recognition, surgical repair, and parenteral antibiotics can reduce the mortality rate to less than 10%. The use of softer and smaller NG tubes with generous lubrication can reduce the risk of esophageal perforation.

Use caution when inserting a NG tube in patients who have suffered trauma to the face, neck, and/or skull, or if they have medical conditions affecting these areas.[18,19] Fractures of the base of the skull, cribriform plate, maxilla, nasal walls, orbital floors, and palate may allow a nasally inserted tube to exit the nasal cavity and cause further injury. The NG tube may exit traumatic or medical wounds and penetrate neighboring vascular structures.[19]

SUMMARY

NG intubation is a widely used procedure in the Emergency Department. It is primarily used to evacuate air and stomach contents in the poisoned, intubated, or bowel obstructed patient. Placement is generally considered easy, although it can be uncomfortable. Recent studies suggest that topical anesthetics and vasoconstrictors, along with generous lubrication, can diminish the discomfort and reduce the chance of misplacement.

Placement of the NG tube into the airway or coiled in the esophagus can result in serious complications. Although auscultation of air has been classically used to determine correct placement, radiographic confirmation of gastric placement is considered the gold standard. Postintubation patients should be carefully observed for signs of esophageal perforation.

59 Activated Charcoal Administration

Jenny J. Lu

INTRODUCTION

The adsorptive capacity of charcoal has been documented since the time of Hippocrates and has been known for centuries. Two independent researchers were responsible for its wide acceptance in the early nineteenth century when each of them performed a demonstration of its effectiveness by ingesting lethal doses of strychnine and arsenic, respectively, followed by charcoal. Both of them survived. The twentieth century has seen charcoal come into wide medical use as further investigation showed its effectiveness at adsorbing a wide variety of compounds.[1] Activated charcoal is currently the most commonly used mode of decontamination in the Emergency Department for poisoned patients.[2]

ANATOMY AND PATHOPHYSIOLOGY

Charcoal is produced by the distillation of the pyrolysis products of vegetable matter or wood. It works by directly adsorbing toxicants via a variety of chemical binding properties, and thus preventing substances in the gastrointestinal tract from being absorbed into the circulation. Enhancement of the adsorptive capability of charcoal is achieved by heating it to a temperature of 900°C and then subjecting it to a stream of oxidizing gas such as carbon dioxide gas or steam. This process is termed "activation" and creates an internal pore structure, which increases the surface area from 2 to 4 square meters per gram to greater than 2000 square meters per gram.[2] A typical dose of 50 g of activated charcoal has the surface area of 10 football fields. Charcoal is not absorbed from the intestinal lumen nor is it modified by the numerous enzymes that aid in the digestion of food. It passes through the intestinal tract unchanged and is expelled as a sticky black substance.

Some charcoal preparations contain sorbitol. Sorbitol is typically used as a flavoring agent to make food, drinks, and medications more palatable. It is also used as a hyperosmotic laxative agent. It is poorly absorbed from the gastrointestinal tract and converted into fructose by the liver. Its limited absorption results in an increased volume of water being secreted into the intestine causing an increased intraluminal pressure that stimulates a catharsis.

Charcoal can help enhance the elimination of certain compounds by disrupting the enteroenteric or enterohepatic circulation. A diffusion gradient is created in the intestine due to the enormous adsorptive ability of charcoal to bind free toxicants. The intestinal mucosa essentially functions as a semipermeable membrane allowing absorbed drug or toxin to diffuse from the capillaries back into the lumen of the intestine. Charcoal can adsorb and "trap" it within the intestinal lumen to be subsequently eliminated.[3,4] This mechanism essentially dialyzes the blood in the capillaries of the intestinal circulation, hence the term "gastrointestinal dialysis." Similarly, drugs and drug metabolites secreted into the bile may be absorbed and trapped by charcoal within the intestinal lumen. By adsorbing these substances, activated charcoal may shorten the half-life, although evidence for clinical benefit of doing so remains limited. Substances that may benefit from multiple dosing of charcoal for

enhanced elimination include phenobarbital, theophylline, dapsone, diazepam, amitriptyline, carbamazepine, phenytoin, quinine, salicylates, piroxicam, digoxin, doxepin, quinine, tricyclic antidepressants, and meprobamate.[3,4]

INDICATIONS

Activated charcoal binds to most commonly ingested substances and is currently considered the modality of choice for gastrointestinal decontamination.[5] It is generally indicated for an ingestion of toxic materials that are adsorbable to charcoal. Charcoal may be used to enhance the elimination of toxicants that are metabolized by the liver and secreted into the bile.

Charcoal has an excellent safety profile. It can be used in pregnancy, in lactation, and in the pediatric population. Its use is widely accepted even though no good randomized controlled clinical studies have been performed.[4] Animal and volunteer studies have repeatedly shown activated charcoal's efficacy. Activated charcoal has been found in clinical studies to be as efficacious and safer when compared with emetics or gastric lavage as a single modality for decontamination purposes. A large randomized controlled trial examined gastric emptying procedures, comparing ipecac-induced emesis, gastric lavage and activated charcoal, and activated charcoal alone in patients with drug overdoses.[6] No significant differences in clinical severity, length of hospital stay, morbidity, or mortality among the treatment groups were found. These findings are similar to those found in other studies.[7,8]

Ipecac-induced emesis, activated charcoal, and gastric lavage were compared in volunteers 1 hour after the ingestion of ampicillin.[9] Activated charcoal was found to be superior in decreasing the absorption of blood ampicillin levels by 57%. Gastric lavage decreased absorption by 32% and emesis decreased it by 38%. The authors concluded that activated charcoal without a gastric emptying procedure may be the preferred method of gastrointestinal decontamination. Limitations of the study included using subtoxic doses of ampicillin on volunteers and the small sample size.

The optimal timing for administration of charcoal remains controversial. None of the studies demonstrating efficacy of activated charcoal administered it more than 1 hour after the ingestion.[10] The American Academy of Clinical Toxicology has noted that there is insufficient evidence to support or exclude the use of activated charcoal more than 1 hour after a toxic ingestion.[11] Additionally, there is no evidence that the use of activated charcoal decreases mortality or improves clinical outcome.[11] This does not mean that activated charcoal should not be given if the patient presents later than 1 hour after ingestion. It simply means that this has not been studied and not enough evidence exists to make a firm decision.

CONTRAINDICATIONS

One absolute contraindication to the use of activated charcoal is in the patient with an unprotected airway. The patient must be able to maintain an intact gag reflex or should be endotracheally intubated to protect against aspiration, although it is not recommended that patients be intubated solely for the purpose of decontamination. Patients with depressed levels of consciousness and those at risk for seizures from their toxic ingestions should not be given activated charcoal. Patients with absent bowel sounds, evidence of gastrointestinal obstruction, or recent gastrointestinal surgery should not be given charcoal secondary to the risk of bezoar formation or perforation and leakage of charcoal into the abdominal cavity.

Activated charcoal is not effective against xenobiotics such as acids and alkalis, alcohols, fluoride, heavy metals, inorganic salts, iron, lithium, or potassium. Its use is limited in liquid ingestions where absorption is rapid. It is unlikely to be helpful in hydrocarbon and pesticide ingestions. Besides being minimally effective in preventing the absorption of caustics, administration of charcoal can render endoscopic visualization technically difficult. However, for most other ingestions, including mixed ingestions, a dose of activated charcoal can be given, if no contraindications exist. **Charcoal combined with cathartics is contraindicated in young children due to the risk of severe electrolyte imbalances and it should be used with caution in renally impaired patients.[12]**

EQUIPMENT

Several charcoal preparations are available.[13] These include capsules, tablets, powder, oral suspensions, and suspensions containing sorbitol. Powder, premixed oral suspensions, and suspensions with sorbitol are the only preparations indicated for use in an acute poisoning. Powder is available in doses from 15 to 500 g that must be mixed with water to make a slurry. The premixed suspension is available in strengths of 12.5 g/60 mL to 50 g/240 mL. Charcoal suspensions with sorbitol are available containing 25 to 50 g of activated charcoal and 25 to 96 g of sorbitol in a volume of 120 to 150 mL.

PATIENT PREPARATION

A cuffed endotracheal tube should be placed prior to the administration of activated charcoal in patients who are comatose, drowsy, obtunded, unconscious, or have an absent or impaired gag reflex. Endotracheal intubation should be strongly considered in any patient who has ingested a central nervous system depressant, tricyclic antidepressants, a sympathomimetic or other agent that may result in seizures, or any substances that can cause an altered mental status. A patient may become nauseous and vomit due to the ingested substances, the nasogastric tube, or the activated charcoal slurry. This can be controlled with the intravenous administration of an antiemetic medication.

Thoroughly mix the charcoal slurry prior to opening the container. Some preparations settle with the charcoal in the bottom of the container. Activated charcoal suspensions are gritty and unpleasant to swallow but have no taste. Some newer charcoal preparations dissolve completely when added to water to form a solution that is not gritty (Paddock Laboratories, Minneapolis, MN). The addition of sorbitol causes the suspension to be less gritty and have a sweet taste. This may enhance the palatability of the charcoal. Some manufacturers supply cherry or other flavorings to make the charcoal more palatable.

TECHNIQUE

Charcoal should be administered as early as possible after the ingestion and optimally within the first hour after an ingestion as its efficacy is reduced with the passage of time. An aqueous slurry should be used rather than tablets or powder. A single dose is typically administered. Multiple doses may be considered if the xenobiotic is expected to be absorbed slowly (e.g., massive ingestions or sustained release preparations) or if enhanced elimination of amenable substances is the objective. The recommended dose for the single or initial dose is five to 10 times the amount (in grams) of toxicant ingested, although standard practice is to give 1 g/kg (50 to 100 g to an adult or 10 to 25 g child <5 years).[13] An alert patient typically tolerates drinking the slurry well. Repeated doses may range from 15 to 30 g every 2 to 4 hours, although optimal dosing is not known.[13] A cathartic may be used in special circumstances with alternating doses as long as hydration and electrolyte levels are vigorously monitored.[13]

Sorbitol may be premixed with the charcoal. The sorbitol will decrease gastrointestinal transit time and may prevent bezoar formation. However, it may also increase nausea and vomiting and the

risk of aspiration. **Sorbitol-containing charcoal should be given only to adults and only with the first dose.** Attention should be paid to verify whether or not the charcoal preparation contains sorbitol, especially where multiple doses are given.

A nasogastric tube can be placed in the cooperative or uncooperative patient to facilitate administration of the charcoal. **Correct placement of the nasogastric tube in the gastrointestinal tract is absolutely essential prior to charcoal administration.** Confirmation of gastric placement can be done by auscultation of insufflated air into the stomach over the epigastrium, by the aspiration of stomach contents through the nasogastric tube, or radiographically by demonstrating the tube below the level of the diaphragm. Please refer to Chapter 58 for the details regarding the placement of a nasogastric tube. Attempts should be made to minimize gastric pressures by the overly aggressive administration, which can increase the risk of aspiration.[14]

COMPLICATIONS

The most feared complication of activated charcoal use is pulmonary aspiration. Activated charcoal can cause severe pneumonitis that can lead to respiratory failure, prolonged ventilatory support, and death. In addition to pneumonitis, an empyema and bronchiolitis obliterans can occur. **Avoiding aspiration is paramount when giving charcoal.** The patient must be awake and have an intact gag reflex in order to protect against aspiration. Errant placement of a nasogastric tube into the trachea or bronchi, and even past the inflated cuff of a properly placed endotracheal tube, can result in aspiration.[12] **The proper placement of nasogastric tubes must be confirmed prior to instilling activated charcoal.** Reports of life-threatening pulmonary complications as a result of aspiration have also been reported with the removal of the nasogastric tube subsequent to charcoal administration.[15] Aspiration of activated charcoal can occur in the intubated patient with an inflated endotracheal cuff and a properly placed nasogastric tube.[16]

Charcoal containing or administered with sorbitol or magnesium decreases the risk of intestinal obstruction and constipation. Yet, this can induce its own set of problems. Electrolyte disturbances can result despite the benefits of decreasing transit time through the gut and the concomitant decrease in toxicant absorption. Cathartic-induced hypernatremia, typically a complication seen in the very young, can lead to serious central nervous system damage, brain swelling, long-term morbidity, and death. Sorbitol dosing in children is not clearly established, and the typical premixed preparations are not appropriate in the pediatric population. Hypermagnesemia is seen in the adult population when a magnesium-containing cathartic is given in a patient with gastrointestinal abnormalities or renal compromise. Dehydration is a problem encountered in the elderly and young. Osmotic volume loss from the gastrointestinal tract can cause these fragile populations to decompensate.[12]

Intestinal obstruction is a rare complication but carries significant morbidity. Case reports of obstruction and perforation requiring laparotomy have been documented. Charcoal bezoars are the usual culprits. Bezoars can form when intestinal motility is compromised allowing continued absorption of water from the intestinal contents. Once sufficient water has been absorbed, bonds form between charcoal particles and the mass continues to harden. Ingestions of anticholinergic substances, antiperistaltic coingestions, or medications administered during the hospital course have also been implicated. Caution should therefore be used when giving these patients narcotic or anticholinergic medications. Typically, patients receiving multiple-dose activated charcoal therapy or activated charcoal without cathartics are at the greater risk. Constipation is a milder form of this complication and is uncommon and rarely of clinical significance.[12]

SUMMARY

Activated charcoal is currently the most commonly used modality of gastrointestinal decontamination in the acutely poisoned patient. This is despite limited evidence demonstrating improved clinical outcomes or decreased mortality rates. Administration of charcoal is relatively straightforward and is generally well tolerated orally. The usual dose of activated charcoal is 50 to 100 g in an adult and 1 g/kg in a child. Preparations containing a cathartic such as sorbitol can be used with the first dose in the adult unless contraindicated. Cathartics and charcoal preparations containing sorbitol should not be used in children or those with renal impairment due to the risk of electrolyte disturbances. The most significant complications occur as a result of aspiration and can be minimized by paying close attention to the patients at risk (i.e., those with a decreased level of consciousness or a weakened gag reflex) and by checking placement of the nasogastric tube prior to administration of charcoal. The risks and benefits of multiple dosing must be carefully weighed when considering to prevent the absorption or to enhance the elimination of the toxicants. Activated charcoal may be judiciously administered in appropriately selected acutely poisoned patients as long as there are no contraindications.

Should the use of activated charcoal continue because there may be some benefit despite the potential complications?[17–19] Should activated charcoal not be used until it is proven to be beneficial compared to the potential complications? This continuing controversy in toxicology will persist until more evidence becomes available. The decision to use activated charcoal should be determined on a case-by-case basis by the treating Emergency Physician, with possible consultation from a poison control center.

60 Gastric Lavage

Jenny J. Lu

INTRODUCTION

Gastric lavage is a method of gastrointestinal decontamination, performed in the setting of an acute poisoning by ingestion, to decrease the absorption of substances in the stomach. This technique was first described in 1812 and has been used for nearly 200 years.[1] It was repopularized in the 1950s and 1960s and thrived during the heyday of the "tricyclic era" of the 1970s and 1980s. The use of gastric lavage in the Emergency Department has decreased greatly in modern toxicology for several reasons. Most notable is the trend toward evidence-based medicine and the growing body of experimental and clinical data pointing to the limited efficacy of gastric lavage. Gastric lavage was performed in approximately 10.3% of all ED-treated poisoning cases between 1998 and 2003, a decrease from 18.7% during the period of 1993 through 1997.[2] The increasing use of other modalities for gut decontamination, especially activated charcoal, has further limited the role of gastric lavage.[1,3]

ANATOMY AND PATHOPHYSIOLOGY

With the widespread administration of activated charcoal as the current decontamination measure of choice, there remain very few indications for performing gastric lavage for decontamination, if any. These rare indications would include a highly toxic or potentially lethal ingestion presenting acutely where no antidote exists or where other usual therapies are ineffective, unavailable, or nonexistent.

The optimal timing of gastric lavage is also controversial. Any benefit of gastric lavage would likely be gained if performed promptly and within 1 hour of an oral ingestion.[3] Authors agree that the sooner it is instituted, the better. The range of recovered ingestant is highly variable at each time point following an ingestion in volunteer and overdose studies. The trend for mean removal of ingestants is 90% recovery at 5 minutes postingestion, 45% recovery at 10 minutes, 30% recovery at 19 minutes, and as little as 8% recovery at 60 minutes.[3]

Undoubtedly, the efficacy of gastric lavage diminishes rapidly over time. Some toxicants or coingestants may cause delayed gastric emptying, while others may form masses or concretions in the stomach. Removal of only a small percentage of the ingested dose may theoretically lessen the severity of the poisoning in some cases, but these benefits remain unproven. Gastric lavage has never been demonstrated to decrease mortality. **A reasonable approach when considering gastric lavage is in the acutely poisoned patient who presents within 1 hour of a life-threatening ingestion.** The decision should be made with consideration to the specifics of the ingestion. Delayed gastric lavage should be considered only in a severely toxic poisoning or where delayed gastric emptying is suspected (e.g., anticholinergic or opioid coingestant). It would be prudent to consult a poison control center or a Medical Toxicologist when considering gastric lavage in any poisoned patient.

Nasogastric placement of a gastric lavage tube is not advised. The orogastric route should be used to avoid traumatic injury to the nasal mucosa, nasal turbinates, and nasal septum. The use of a small-bore nasogastric tube is discouraged if the objective is gastric emptying. If an appropriately sized nasogastric tube is placed for other reasons and if the ingestant is in liquid form, aspiration of gastric contents can be attempted through a nasogastric tube. Lavage fluid can be instilled through a nasogastric tube with the expectation that the return of gastric contents may be inadequate. Lavage fluid that does not return through the nasogastric tube will pass through the pyloric sphincter and could potentially allow increased absorption of the toxicant.[4] Sustained-release tablets or capsules are particularly large in size and unlikely to be removed through a nasogastric tube or through the fenestrae of a 40 French orogastric lavage tube (**Figure 60-1**).

Placement of gastric lavage tubes in the pediatric population is precarious and may result in complications (**Figure 60-2**).[5] A formula for the depth of insertion has been prospectively evaluated to ensure adequate placement in this population and is depicted graphically in **Figure 60-3**.[5,6] Moreover, the size of the oropharyngeal aperture and esophagus are proportional to the size of the individual. **Appropriate tube diameter is essential to minimizing complications.**

A 40 French tube with a 450 mg sustained-release theophylline tablet in the side port (*middle*). A generic 250 mg ampicillin tablet (*bottom*) (Courtesy of F.P. Paloucek, PharmD).

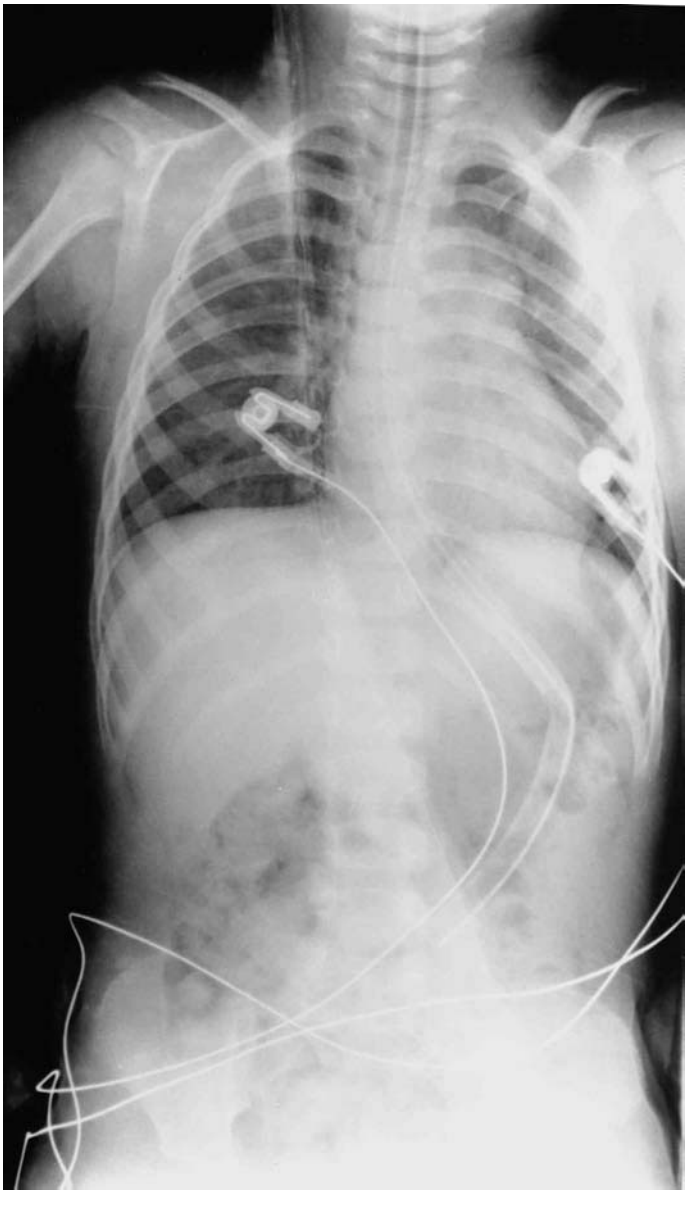

FIGURE 60-2. Malposition of an orogastric tube placed for gastric lavage in a pediatric patient (Courtesy of Ann E. Klasner, MD, MPH).

INDICATIONS

Gastric lavage is indicated for immediate stomach emptying within 1 hour after an orally ingested overdose or poisoning and when not contraindicated. Consideration should first be given to other less invasive modalities of gastrointestinal decontamination such as activated charcoal or whole bowel irrigation. Consideration should be given to the specific characteristics of the toxicant, the ingested dose, and the risks versus benefits of performing the procedure. **Gastric lavage should be considered only where there is risk of significant toxicity or imminent fatality and where antidotal or other supportive modalities are inadequate (Table 60-1).** It may be considered beyond 1 hour in patients with known or suspected delayed gastric motility (e.g., in the setting of anticholinergic or opioid ingestion) or where the evidence of a durable mass (concretion) of pill fragments is a concern.

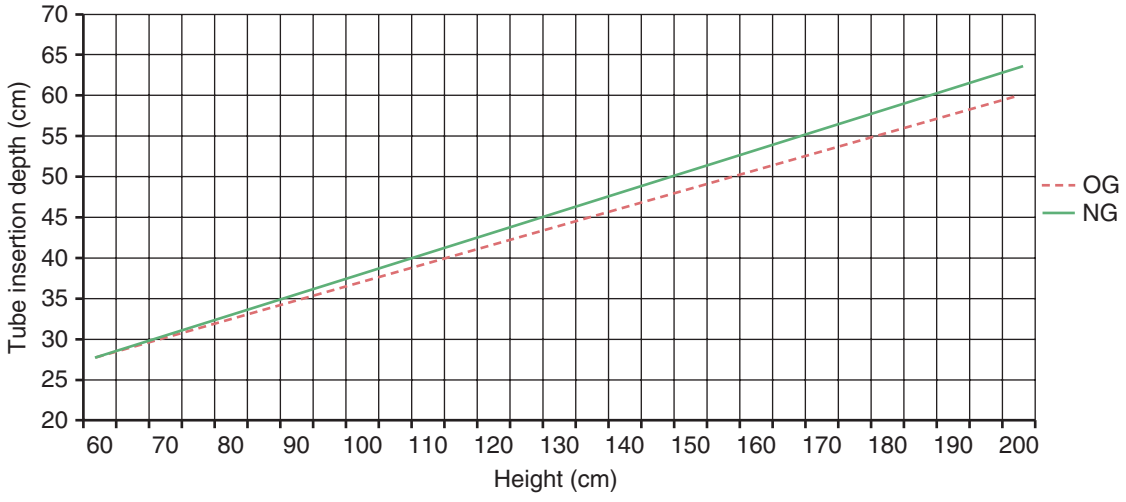

FIGURE 60-3. Estimated lavage tube insertion depth in children based on their height. The lengths for both nasogastric (NG) and orogastric (OG) tubes are represented on the graph (Reprinted from Scalzo et al.,[5] with permission from Elsevier Science).

CONTRAINDICATIONS

The contraindications to performing a gastric lavage are summarized in **Table 60-2**. **An absolute contraindication to gastric lavage is in a patient with a depressed level of consciousness who is at risk of losing protective airway reflexes.** Gastric lavage should also not be performed in combative patients, patients at high risk of seizures, and in those who may be expected to deteriorate rapidly. Gastric lavage can be performed, as indicated, if the airway is protected, but intubating a patient solely for the purpose of gastric lavage is not recommended. Gastric lavage is contraindicated in caustic ingestions. Local mucosal damage amplifies the risk for traumatic perforation. Gastric lavage should not be performed to retrieve large pills, large foreign bodies, or sharp foreign bodies. It is relatively contraindicated in hydrocarbon ingestions, especially where there is high pulmonary aspiration potential. Significantly abnormal upper airway or upper gastrointestinal anatomy (i.e., anomalies, strictures, or a fresh interposition graft) may restrict the use of gastric lavage in rare circumstances.

Vomiting is common after many overdoses and may serve as a "natural" decontamination measure. Multiple episodes of emesis may clear the majority of a toxicant from the stomach and obviate the need for gastric lavage. Vomiting in the setting of caustic ingestions, however, can cause further harm by re-exposing the gastrointestinal mucosa to the caustic substance. Attempts at gastric intubation in the setting of an actively vomiting patient are likely to be met with minimal success and may cause injury.[7] Gastric lavage is thus contraindicated in the vomiting patient due to the risk of aspiration and perforation in a setting where it is unlikely to be beneficial.

Gastric lavage is unlikely to change the outcome of a nontoxic or minimally toxic ingestion. It must be ascertained that significant toxicity or death may result if the patient is not lavaged. Otherwise, the risk–benefit ratio is unacceptably high. The determination of whether or not to perform a gastric lavage must be individualized and rests upon the evaluating Emergency Physician. Consult a Medical Toxicologist or a poison control center in questionable cases.

EQUIPMENT

- Pulse oximeter
- Cardiac monitor
- Noninvasive blood pressure monitor
- Protective clothing
- Bite block
- Oral airway

TABLE 60-1 Indications for Performing a Gastric Lavage

Acute presentation (within 1 h) and:

1. *Evident or high risk of morbidity or mortality*
   - Beta-blockers
   - Calcium channel blockers
   - Chloroquine
   - Colchicine
   - Cyanide
   - Heavy metals
   - Heterocyclic antidepressants
   - Iron
   - Paraquat
   - Salicylates
   - Selenious acid
2. *Poor absorption by activated charcoal*
   - Heavy metals
   - Iron
   - Lithium
   - Toxic alcohols
3. *Evidence of formed concretion*
   - Enteric-coated preparations
   - Iron
   - Phenothiazines
   - Salicylates
4. *Ineffective or no antidotal therapy available*
   - Cellular poisons (e.g., colchicine)
   - Paraquat
   - Selenious acid

TABLE 60-2 Contraindications to Performing a Gastric Lavage

- Abnormal or absent pharyngeal or upper gastrointestinal anatomy
- Active or substantial antecedent vomiting
- Caustic ingestion
- Coagulopathy
- Combative or uncooperative patient
- Decreased level of consciousness
- Diminished or absent airway reflexes
- Large pills
- Large or sharp foreign body
- Nontoxic or minimally toxic ingestion
- Significant aspiration risk (e.g., hydrocarbon ingestion)
- Seizures or high risk of seizures

- Emesis basin
- Suction source
- Yankauer suction catheter
- Suction tubing
- Funnel or large (50 to 100 mL) syringe
- Tap water or normal saline
- Bulb suction device or large syringe
- Water-soluble lubricant
- Orogastric lavage tube
- Resuscitative equipment readily available

All required instrumentation should be gathered at the bedside prior to initiating the procedure. A variety of orogastric lavage tubes are available. Most have a distal port and at least one sideport. A semirigid tube is preferable to soft rubber or polyvinyl chloride collapsible tubes. Several additional ports should be cut in the sides of the tube near the tip to maximize the return of pill fragments if the tube has only a single sideport. Examples of rigid tubing are shown in **Figures 60-1 & 60-4**. A larger tube diameter provides less flexibility, so that the tube is less likely to kink, collapse, or curl back on itself. Larger-diameter tubes are more likely to facilitate retrieval of larger pill fragments. A 30 to 50 French lavage tube is preferred in an adult. A 30 to 34 French tube is adequate for an adolescent. Small children can generally accommodate 24 French tubes. Gastric lavage is generally contraindicated in neonates and infants.

There are numerous types of gastric lavage systems. Open systems are less expensive, messy, and time-consuming to use. A passive open system uses gravity to instill and drain the lavage fluid. An active open system uses a large syringe to inject and aspirate lavage fluid through the orogastric tube. The syringe must be removed from the orogastric tube to be filled with fresh lavage fluid, and used lavage fluid must be discarded after each lavage cycle. Closed systems are commercially available, single-patient use devices, self-contained, easy to use, and do not cause a mess (**Figure 60-4**). The Emergency Physician should be familiar with the type of system available at their institution.

FIGURE 60-4. Example of a closed lavage pump system (Courtesy of Kimberly-Clark Corporation).

Gastric lavage solution typically consists of tap water or normal saline. **Do not use tap water in small children, as this can result in electrolyte abnormalities.** Specialized lavage solutions may be indicated if the ingested substance is fluoride, formaldehyde, iodine, iron, or oxalic acid. Fluoride ingestions may be lavaged with 15 to 30 g/L of calcium gluconate to produce an insoluble calcium fluoride. Formaldehyde ingestions may be lavaged with 10 mg/L of ammonium acetate to produce the nontoxic substance methenamine. Iodine ingestions may be lavaged with 75 g of cornstarch in 1 L of water. Iron ingestions may be lavaged with 2% sodium bicarbonate (50 mEq in 150 mL of normal saline) to produce the insoluble ferrous carbonate. Oxalic acid ingestions may be lavaged with 15 to 30 g/L of calcium gluconate to form the insoluble calcium oxalate. **These specialized lavage solutions should be used only in consultation with a Medical Toxicologist or a poison control center.**

PATIENT PREPARATION

Explain the indications, details of the procedure, risks and benefits, and alternative modalities with the patient and/or their representative when possible. Informed consent should be obtained or may be presumed in the setting of a suicidal overdose.

Place the patient in the left lateral decubitus position and in 15° to 20° of Trendelenburg. This position is intended to maximize gastric emptying.[7,8] However, the removal of ingestants by gastric lavage in the overdose setting is modest, and other circumstances may intervene, such as an uncooperative patient or technical factors.[3] The supine and lateral decubitus positions are associated with a higher risk of pulmonary aspiration in comatose and mechanically ventilated patients.[9–12] It is assumed that this positioning risk is similarly increased in patients who are not mechanically ventilated and undergoing gastric lavage. Most gastric lavages can be performed safely and effectively with the conscious patient placed in the semi-upright position. The use of a topical anesthetic spray into the oropharynx may decrease the patient's gag reflex and allow easier passage of the orogastric tube. Unfortunately, this can also increase the risk of aspiration.

It is recommended that a cardiac monitor, noninvasive blood pressure cuff, and pulse oximeter be placed on the patient prior to performing gastric lavage. This equipment may also be required based upon the patient's physiologic status, the nature of the ingestant or toxicant, and/or other underlying problems.

TECHNIQUE

Measure the length of the orogastric lavage tube to be inserted (**Figure 60-5**). The length should be marked with a permanent marker or a piece of surgical tape. Liberally lubricate the tip of the lavage tube. Place a bite block into the patient's mouth if they are conscious. A bite block or oral airway may preclude biting of the tube by an uncooperative or stuporous patient.[13]

Gently insert the lavage tube into the patient's mouth and direct it into the hypopharynx. Flexion of the patient's neck may facilitate passage of the tube into the esophagus and avoid endotracheal insertion. Conscious and cooperative patients may be asked to swallow water through a straw or their saliva to facilitate passage of the tube. Stridor, cough, or cyanosis indicates that the lavage tube is in the airway and should prompt removal of the tube. If significant resistance

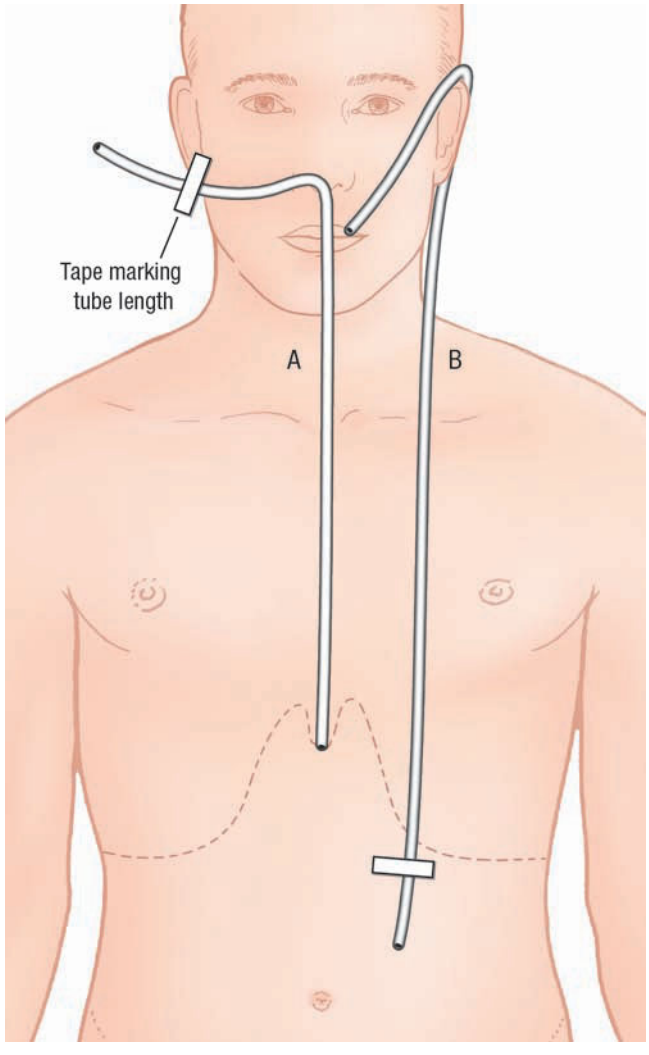

FIGURE 60-5. Determining the proper length of an orogastric tube to insert. **A.** The length is determined by the distance from the xiphoid process to the tip of the nose to the earlobe. **B.** The length is determined by the distance from the tip of the nose or lip, around the left ear, and to just below the left costal margin. A piece of tape is used to mark the distance on the orogastric tube.

is met in the hypopharynx, applying gentle pressure to the tube while instructing the patient to swallow should allow passage through the upper esophageal sphincter. **The tube should not be forced, as misplacement may damage the larynx or perforate the pyriform sinus.** Slowly advance the tube to the premeasured depth.

Confirmation of intragastric tube placement must precede instillation of any fluid through the tube. Proper placement should be confirmed by aspiration of gastric contents, auscultation of insufflated air over the epigastrium (from a 50 mL Toomey syringe), and/or by radiography. Gastric irrigation should be preceded by aspiration of available gastric contents. The initial aspirate may be sent for toxicologic assay.

Perform the gastric lavage. Instill normal saline or tap water through the lavage tube. The lavage fluid should ideally be warmed to body temperature. This is often not practical, and room temperature lavage fluid is satisfactory. Instill aliquots of 10 to 15 mL/kg to a maximum of 300 mL of the irrigant solution. Instillation of larger volumes may result in vomiting, with pulmonary aspiration and the passage of gastric contents past the pyloric sphincter where subsequent absorption may occur.[2] Lavage aliquots may be instilled by placing a funnel in the free end of the lavage tube and allowing gravity instillation or they may be infused with a Toomey syringe. Remove the lavage fluid after a brief (i.e., 1 to 2 minutes) equilibration period by either gravity drainage into an emesis basin or aspiration with a syringe or suction bulb. Repeat the lavage process until 2 to 3 L of irrigant has been used in the adult or the lavage fluid is free of particulate matter and pill fragments. Some authors have suggested that agitation of the stomach by manual massage of the epigastrium during the equilibration period will ensure mixing of the gastric contents.[13] No substantive data support this approach. Alternatively, closed systems are available for both instilling and suctioning lavage fluids through a common tube (**Figure 60-4**).

Activated charcoal may be administered, if indicated, through the lavage tube before it is removed. A dose of 1 g/kg of body weight is typically recommended, either in a premixed slurry or diluted in normal saline or tap water (30 g charcoal per 240 mL of diluent). Refer to Chapter 59 regarding the details of administering activated charcoal.

Remove the lavage tube. It is recommended for the Emergency Physician to wear gloves, a mask with an eye shield, and a gown to prevent being contaminated during the removal. Place towels or pads over the patient's neck and chest. Have an emesis basin, tissues, and Yankauer suction immediately available. Disconnect the lavage tube from its proximal attachment. Fold over the proximal end of the lavage tube and hold it tightly. Ask the patient to slightly flex their neck, breath in, and hold it. Place a drape or towel around the lavage tube as it is exiting the patient's mouth. Firmly squeeze the drape around the lavage tube. Briskly withdraw the lavage tube through the drape. The drape will contain all the secretions and bodily fluids and prevent them from splashing on the patient or the Emergency Physician. Discard the lavage tube and the drape.

Further gastric access, when needed, should be provided by the subsequent placement of a smaller-bore nasogastric tube.

ALTERNATIVE TECHNIQUES

Because of concern over toxicants passing or being pushed through the pyloric valve during the gastric lavage procedure, an alternative sequence could be considered. Administer activated charcoal after the initial aspiration of gastric contents through the lavage tube. Perform the gastric lavage anticipating that a significant amount of activated charcoal will be removed along with the ingestant. Infuse a second dose of activated charcoal through the lavage tube before it is removed. The rationale here is an attempt to make charcoal available to adsorb toxicant from any gastric contents pushed into the small bowel during the lavage procedure.[1] While no human data support this technique, it is reasonable to consider.

ASSESSMENT

The patient should be continuously monitored and reassessed throughout the procedure so as to avoid complications. Strict adherence to the procedures noted will help minimize the risk of complications. Prompt removal of the lavage tube at the end of the procedure will help decrease the risk of delayed complications.

AFTERCARE

Most patients who require gastric lavage for an overdose or poisoning will require inpatient monitoring for complications of the ingestion. A situation wherein a patient requires gastric lavage and is then sent home immediately is conceivable though unlikely. An observation period of 6 to 8 hours for the immediate complications of gastric lavage and the effects of the ingested substance is probably appropriate. Delayed complications related to the perforation of the upper gastrointestinal tract may occur.[14]

TABLE 60-3 Complications Associated with Gastric Lavage

Cardiac dysrhythmias
Electrolyte abnormalities
Empyema
Esophageal tear or perforation
Gastric perforation
Hypothermia
Laryngospasm
Nasal, oral, or pharyngeal injury
Pneumothorax
Pulmonary aspiration
Pyriform sinus perforation
Tracheal placement
Tube impaction

COMPLICATIONS

The complications associated with gastric lavage can be minimized by careful patient selection and technique[7] (**Table 60-3**). Placement of the lavage tube can result in mucosal injury, bleeding, esophageal perforation, gastric perforation, or endotracheal placement. The patient should be monitored, as the procedure may result in cardiac arrhythmias, hypoxemia, and tachycardia.[1,7] No more than 15 mL/kg or 300 mL aliquots of lavage fluid should be used to prevent vomiting, aspiration, or pushing of gastric contents into the small bowel. The impaction of a lavage tube may prevent its removal.[1,7,14] **Do not use force to remove the lavage tube, as this may injure or rupture the stomach or esophagus.** Evaluate the tube using fluoroscopy or plain radiographs. A lavage tube that is kinked or knotted will require endoscopically aided or surgical removal.

Gastric lavage with large volumes of cold fluid can result in hypothermia. Warmed lavage fluid should be used if available, although this is somewhat controversial. Warm lavage fluid may dissolve more of the intoxicant and allow rapid access of gastric contents past the pylorus, to be absorbed into the systemic circulation. Electrolyte abnormalities may result, especially in children, if the lavage fluid is hypotonic (i.e., tap water). The use of normal saline for lavage is recommended.

There are definite risks and complications associated with gastric lavage. It is usually unknown if pills and/or pill fragments remain within the patients stomach when they present to the Emergency Department. Two recent case reports used CT scans to determine that pills and/or pill fragments remained in the stomach and subsequently performed gastric lavage.[15,16] The use of CT scans to identify pills and/or pill fragments in the stomach cannot be recommended. There is no evidence that the expense and radiation exposure prevent any morbidity or mortality nor provides any benefit to the patient.

SUMMARY

Gastric lavage is an invasive procedure to decontaminate the stomach of patients following an ingested overdose or poisoning. While its use has significantly decreased as a mode of decontamination, there are a few specific indications in an acute poisoning or overdose in which it should be considered. Complications can be minimized if the procedure is performed cautiously. Maximal efficacy can be expected if it is performed within 1 hour of an acute ingestion. Gastric lavage is not indicated in the setting of a nontoxic or minimally toxic ingestion or where specific and less invasive antidotes exist and are readily available. Consultation with a Medical Toxicologist or a poison control center is prudent and can provide valuable information regarding the indications, contraindications, complications, and techniques associated with gastric lavage.

61 Whole Bowel Irrigation

Steven E. Aks and David D. Gummin

INTRODUCTION

Whole bowel irrigation is the infusion of polyethylene glycol electrolyte lavage solution into the stomach at flow rates higher than are otherwise commonly used. This technique can be used to decontaminate the gastrointestinal tract after an acute toxic ingestion or overdose. Most of the literature supporting its use is in the form of case reports or case series.[1] While available reports are compelling, the indications for whole bowel irrigation are mostly theoretical and will be refined as more extensive data become available. The role of whole bowel irrigation currently remains limited.

ANATOMY AND PATHOPHYSIOLOGY

Current methods of gastrointestinal decontamination (i.e., emesis, gastric lavage, and activated charcoal administration) focus primarily on decontaminating the stomach. Absorption of most toxicants occurs principally in the proximal small bowel. Sustained- or delayed-release preparations continue to liberate drug during intestinal transit that is then available for absorption throughout the bowel. Infusion of polyethylene glycol electrolyte lavage solution decreases the enteric transit time, attenuating the contact time of a toxicant with the gastrointestinal mucosa.[2] This reduces absorption of the drug or toxin throughout the gastrointestinal tract. The 3500 Da molecular weight polyethylene glycol solution is specifically designed to prevent electrolyte and fluid shifts.

INDICATIONS

Whole bowel irrigation may be indicated for acute ingestions where severe or potentially fatal toxicity is anticipated (Table 61-1). Other decontamination methods, such as activated charcoal, should be employed if they are known to be effective rather than whole bowel irrigation. Whole bowel irrigation may be indicated in situations where activated charcoal is known to be ineffective. Whole bowel irrigation has been safely utilized to decrease bioavailability of ingested iron, lithium, and heavy metals.[3–7] Whole bowel irrigation has been proposed to be effective in flushing the gastrointestinal tract free of toxicant before absorption can be affected by sustained-release preparations.[8] Whole bowel irrigation may speed gastrointestinal transit of ingested packets or vials of illicit drugs ingested by a "body packer."[9] Recently, the role of whole bowel irrigation in the "body stuffing syndrome" has recently been questioned.[10] While the indications are limited, additional settings may be envisioned where whole bowel irrigation might be useful. Unfortunately, there is not yet data to support broader indications.

TABLE 61-1 Conditions in Which Whole Bowel Irrigation Can Be Considered

1. Acute, life-threatening, or serious ingestion and hemodynamically stable
2. Any of the following:
Delayed or enteric-coated preparation
Heavy metals
Ingested packets of illicit drug
Iron
Lithium
Toxin or toxicant poorly adsorbed by activated charcoal

TABLE 61-2 Contraindications to Performing Whole Bowel Irrigation

Bowel obstruction or perforation
Hypotension or hemodynamic instability
Ileus
Intractable vomiting
Nontoxic ingestion
Potentially compromised or unprotected airway
Significant gastrointestinal bleeding

CONTRAINDICATIONS

There are few contraindications to performing whole bowel irrigation (**Table 61-2**). **It should not be used in the setting of a patient with a potentially compromised or unprotected airway.** Whole bowel irrigation could result in pulmonary aspiration.[11,12] Significant vomiting will hinder the ability to perform whole bowel irrigation. It should not be performed in the hypotensive or hemodynamically unstable patient.[11] Other contraindications include abnormal upper airway or upper gastrointestinal anatomy (e.g., anomalies, strictures, or fresh interposition graft). Ingestion of toxic substances that markedly slow gastrointestinal motility (e.g., anticholinergics or opioids) may cause an ileus, diminishing the ability to perform whole bowel irrigation effectively. The administration of polyethylene glycol in a patient with a bowel obstruction will result in vomiting with the potential for aspiration. This solution should not be used in patients with an actual or suspected perforated bowel. The risk of whole bowel irrigation is quite small but the procedure is not without effort, expense, and risk of complications. In this light, the risk–benefit ratio would be high if whole bowel irrigation were used to treat a nontoxic ingestion.

EQUIPMENT

- Nasogastric or enteral feeding tube, size 10 to 12 French
- Water-soluble lubricant
- Nasal decongestant and anesthetic
- Enteral feeding reservoir and tubing
- Polyethylene glycol electrolyte lavage solution (packets or reconstituted)
- Emesis basin
- Stethoscope
- Toomey syringe
- Intravenous extension tubing

The equipment required for whole bowel irrigation is readily available in most Emergency Departments. A small-bore, 10 to 12 French, nasogastric tube is sufficient for an adult or adolescent. An enteral feeding tube can be substituted if a sufficient flow rate can be ensured. A smaller tube is required in infants or very small children. Infants will tolerate an 8 French tube and a 10 to 12 French tube is adequate beyond the first year.[13,14]

Standard enteral feeding reservoirs and tubing are typically available as packaged kits. An enteral feeding or an enema bag with enteral feed tubing may be substituted. Enteral feeding pumps, however, are not useful, as the flow rate through the pump is typically inadequate to perform whole bowel irrigation effectively. Alternatively, an empty 1 L intravenous fluid bag with intravenous extension tubing can be used for the procedure.

PATIENT PREPARATION

Explain the procedure, its risks, its benefits, and alternatives to the patient and/or their representative. Informed consent should be obtained. Informed consent can be assumed in the case of suicidal ingestions. Inspect the nasal passages and oropharynx to rule out any anatomic abnormalities or obstruction that would preclude the passage of a nasogastric tube.

Place the patient in the upright or semi-upright position (**Figure 61-1**).[14] The supine and lateral decubitus positions are associated with a higher risk of pulmonary aspiration in comatose and mechanically ventilated patients.[15–18] It can be assumed that this positioning risk is similarly increased in patients undergoing whole bowel irrigation.

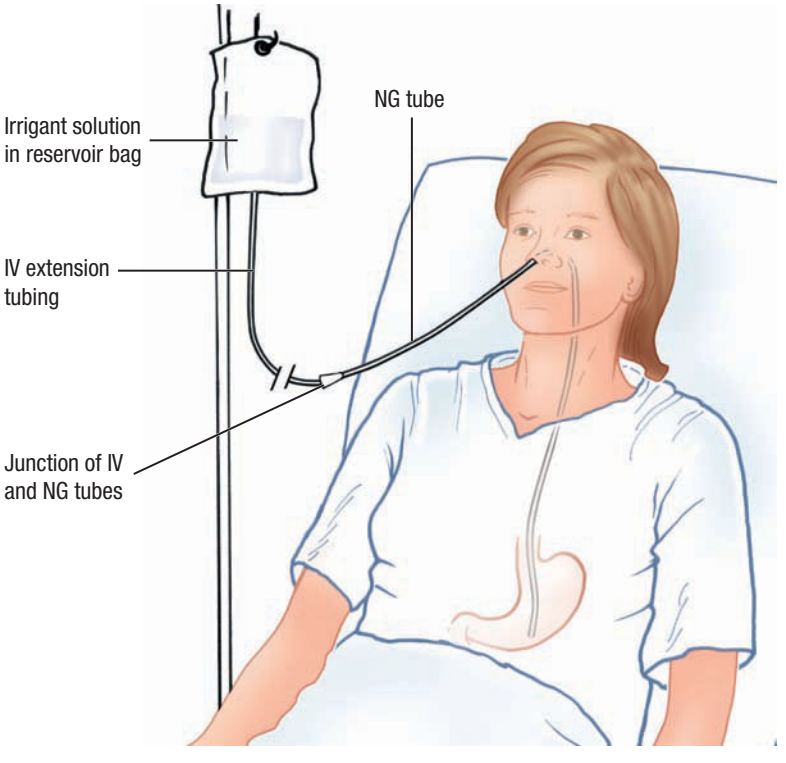

FIGURE 61-1. Setup required to perform whole bowel irrigation.

It is recommended that a cardiac monitor, noninvasive blood pressure cuff, and pulse oximeter be placed on the patient prior to performing gastric lavage. This equipment may also be required based upon the patient's physiologic status, the nature of the ingestant or toxicant, and/or other underlying problems.

Choose the smallest diameter nasogastric or feeding tube that will allow adequate flow of polyethylene glycol electrolyte lavage solution into the stomach. All necessary equipment should be placed at the bedside and assembled prior to beginning the procedure.

A cuffed endotracheal tube should be placed prior to performing whole bowel irrigation in patients who are comatose, drowsy, obtunded, unconscious, or have an absent or impaired gag reflex. Endotracheal intubation should be strongly considered in any patient who has ingested a central nervous system depressant, tricyclic antidepressants, a sympathomimetic or other agent that may result in seizures, or any substances that can cause an altered mental status.

TECHNIQUE

Insert a nasogastric tube. Refer to Chapter 58 for the complete details regarding nasogastric tube placement. Measure the length of the nasogastric tube to be inserted. Place the tip of the nasogastric tube over the xiphoid process. Extend the tube over the anterior chest, lateral neck, behind the angle of the mandible, and to the tip of the nose. Mark this length with a permanent marker or a piece of surgical tape. Liberally lubricate the tip of the nasogastric tube. The application of a nasal anesthetic and decongestant is optional but can facilitate the passage of the nasogastric tube.

Gently insert the nasogastric tube into the naris. Advance it posteriorly along the nasal floor into the nasopharynx and through to the hypopharynx. Flexion of the neck may facilitate passage of the tube into the esophagus and avoid endotracheal insertion. The conscious and cooperative patient may be asked to swallow water through a straw or to swallow their saliva to facilitate passage of the tube. Stridor, cough, or cyanosis may indicate endotracheal passage and should prompt removal of the tube. Gentle pressure and patient swallowing should allow passage through the upper esophageal sphincter if significant resistance is met in the hypopharynx. **Do not force the nasogastric tube as misplacement may damage the larynx or perforate the pyriform sinus.** Advance the nasogastric tube to the marked level. Confirm proper placement by the aspiration of gastric contents, by auscultation of insufflated air over the epigastrium (from a 50 mL syringe), and/or by radiography. **Confirmation of intragastric placement must precede administration of any fluids through the nasogastric tube. A radiograph must be obtained prior to using the nasogastric tube if any question exists regarding its position.**

Instill the polyethylene glycol electrolyte lavage solution through a setup such as that shown in **Figure 61-1**. Flow rates are dependent upon the size of the patient. Begin instillation at an initial rate of 25 to 30 mL of polyethylene glycol electrolyte lavage solution per kilogram per hour. Adults may tolerate more than 3 L of solution per hour. The rate may be adjusted somewhat to accommodate patient tolerance (e.g., vomiting, abdominal distension). Irrigation should be continued until the patient passes the ingestant in the stool or until clear liquid rectal effluent is passed. Liquid stools will continue to be passed after discontinuing whole bowel irrigation. **Stop the irrigation if the patient vomits, develops an ileus, or if gastrointestinal perforation is suspected.**

ALTERNATIVE TECHNIQUES

Some Emergency Physicians may attempt whole bowel irrigation by offering the patient polyethylene glycol electrolyte lavage solution to drink. This is rarely successful. Experience shows that whole bowel irrigation is ineffectively performed if a nasogastric tube is not placed. Even the most cooperative patient is unlikely to drink the solution at the required administration rate.

ASSESSMENT

Patient assessment must be continuous throughout the process of whole bowel irrigation. Mild abdominal distention, gassiness, and mild abdominal discomfort are common side effects and do not require the discontinuation of the infusion. Providers must be vigilant in monitoring the patient's bowel sounds. If bowel sounds cease or significant abdominal distension is noted, the irrigation should be held for 30 to 90 minutes and the patient reassessed. Resume the irrigation at a reduced rate if bowel sounds return, if the clinical status improves, and if the patient then tolerates the infusion. Significant electrolyte or osmotic shifts do not occur solely from whole bowel irrigation. Electrolytes may be monitored if otherwise indicated for the type of ingestion or for overall patient status. Of greater concern is vomiting with the risk of aspiration. The patient's posture should be maintained in the upright sitting or the semi-upright position to facilitate passage of irrigant solution into the small bowel and to protect against aspiration. Discontinue whole bowel irrigation if the patent develops an altered mental status or hemodynamic instability.

AFTERCARE

Patients who undergo whole bowel irrigation must all be admitted to the hospital for ongoing assessment of the intervention and the underlying ingestion or overdose. In most cases, intensive care or step-down monitoring will be required to ensure adequacy of the intervention and to monitor for complications of the ingestion or overdose. Delayed complications from whole bowel irrigation are unlikely once the procedure is completed.

COMPLICATIONS

Documented complications from whole bowel irrigation include pulmonary aspiration of the irrigant solution and/or ingestant.[11,12] This would be especially concerning in the patient with an unprotected and potentially compromised airway. An ileus and intestinal distension has been documented in a hypotensive patient receiving whole bowel irrigation.[12]

Osmotic and electrolyte abnormalities will not occur with the standard preparations of high molecular weight (c. 3500 Da) polyethylene glycol electrolyte lavage solutions (e.g., Colyte, GoLYTELY, NuLYTELY). Complications of nasogastric tube placement are well described and can occur. Refer to Chapter 58 for the complications associated with nasogastric intubation. These are unlikely if proper technique is employed and can be minimized by use of the smallest effective diameter nasogastric tube.

SUMMARY

Whole bowel irrigation is a technique performed to speed gastrointestinal transit and decontaminate the gut after an acute toxic ingestion. Available reports suggest that whole bowel irrigation can decrease bioavailability of toxicants by two-thirds in volunteers.[4,14] It may be useful where activated charcoal is not expected to adequately bind ingestants (e.g., iron, lithium). Efficacy is still undefined in the setting of sustained- or delayed-release preparations. Whole bowel irrigation is not the method of choice, however, when more effective methods of gastrointestinal decontamination are possible (e.g., repetitive-dose activated charcoal for sustained-release theophylline). Until further data emerge, whole bowel irrigation's role in managing the toxic ingestion remains limited.

62 Esophageal Foreign Body Removal

Bashar M. Attar

INTRODUCTION

Most foreign bodies (90%) that are ingested enter the gastrointestinal tract while 10% enter the tracheobronchial tree.[1] Approximately 1500 people die annually in the United States from ingested foreign bodies in the upper gastrointestinal tract.[2] Most objects (80% to 90%) usually pass spontaneously but about 10% to 20% must be removed endoscopically. Approximately 1% require surgical removal.[3] Most (80%) esophageal foreign bodies occur in children followed by edentulous adults, prisoners, and psychiatric patients.[4] Recurrent episodes of foreign body ingestion occur in 5% to 10% of patients, especially prisoners and psychiatric patients.[1]

The presentations are best divided according to accidental and deliberate ingestors.[1–5] The accidental ingestion patient is usually cooperative and has a single foreign body. Conversely, the deliberate ingestion patient is often uncooperative and the foreign bodies are multiple and often unusual. It is important to identify such individuals at their initial presentation since foreign body removal is usually performed under procedural sedation or general anesthesia.

The patient's history is the most important part of the diagnostic evaluation.[3] The identity of the object ingested is usually known to the patient. **Persistent odynophagia, dysphagia, or foreign body sensation may indicate the presence of an esophageal foreign body despite negative radiographic results.** A high index of suspicion must be maintained in younger children and mentally retarded adults. Patients with a history of eosinophilic esophagitis have a higher incidence of food impaction and higher risk of perforation associated with interventions.[6]

The physical examination is most likely negative unless complications are present. Stridor, wheezing, signs of consolidation, and the absence of breath sounds should be sought. Subcutaneous emphysema in the neck or chest indicates perforation of the esophagus or the stomach. The most common sites for a foreign body to get trapped are where the esophagus is narrow: at the cricopharyngeus muscle, where the aortic arch crosses the esophagus, and at the gastroesophageal junction.

Radiographic evaluation is often helpful in the evaluation of an esophageal foreign body.[3–5,7] Obtain plain radiographs of the neck and chest in the posteroanterior and lateral positions. Evaluate the radiographs for the presence of a foreign body in all planes. Air in the subcutaneous tissues, mediastinum, and/or beneath the diaphragm is indicative of a perforation. Barium studies are undesirable in patients with a food bolus impaction and obscure endoscopic visualization. Esophagrams performed using a minimal amount of thin barium may be necessary in situations where the foreign body is made of wood, thin metals, aluminum can tops, and plastics. **Meglumine diatrizoate (Gastrografin) is contraindicated in food bolus impactions because it is highly hypertonic and can lead to severe chemical pneumonitis if aspirated into the lungs.**[5] Toothpicks, wood, and fishbones may not be seen on radiographs. Food or meat bolus impaction may not be evident radiographically unless it contains bony tissue. **Failure to locate an object on radiologic examination should not rule out its presence.** Computerized tomography may be useful, especially in cases where the foreign body could not be detected as it may have become embedded in or penetrated the esophageal wall.[7]

Endoscopy is important for both the diagnosis and possible removal of an esophageal foreign body. Extraction with the flexible endoscope is successful in 84% to 98% of cases and with no associated complications.[8,9] Success is more likely and complications are minimized with proper patient preparation.

INDICATIONS

Esophageal foreign body extraction is required in a minority of patients, as most foreign bodies will pass spontaneously into the stomach. The indications for removal depend upon the type of foreign body and whether it impacts in the esophagus. Sharp objects impacted above the cricopharyngeus should be removed under direct vision using a laryngoscope to elevate the soft tissues and a Magill forcep to grasp it.

Meat boluses are commonly impacted in the esophagus. Patients will swallow large pieces that may or may not be well chewed. **Impaction of a meat bolus, or another foreign body, at or just below the cricopharyngeus muscle with tracheal compression and resultant respiratory obstruction is a true emergency.** The Heimlich maneuver may be lifesaving in this situation.[10] The patient should be immediately orotracheally intubated or a cricothyroidotomy performed if the Heimlich maneuver is unsuccessful. Early removal of a meat bolus impaction is recommended, even when the bolus is located in the distal third of the esophagus. Delays in extraction allow the food to soften, making extraction more difficult. The administration of glucagon intravenously may lead to esophageal relaxation and facilitate spontaneous passage of the food bolus to the stomach. If this fails, it must be endoscopically removed.

Blunt and round objects may become impacted in the esophagus. Earlier removal is necessary if a blunt object is impacted higher in the esophagus with associated sialorrhea and the potential for pulmonary aspiration. Esophageal obstruction at lower levels requires prompt, but not emergent, treatment. Most rounded objects in the lower third of the esophagus will pass spontaneously into the stomach. Therefore, a 12-hour period of observation is permissible in this situation.[11] It is common for sharp, pointed, and elongated objects to become impacted in the esophagus. Toothpicks, open safety pins, nails, and chicken bones are associated with up to a 35% incidence of esophageal perforation and should be removed.[12,13] Toothpicks should be removed promptly from the esophagus or stomach even if they are not impacted because they are particularly prone to penetration of the gastrointestinal wall. Toothpicks may migrate into surrounding structures, leading to vascular and other serious complications.[12]

Numerous other objects can also become impacted in the esophagus. Elongated, narrow foreign bodies such as stiff wires are prone to penetration and perforation of the esophageal wall. They should be removed even if they passed through the esophagus and into the stomach. These objects may become trapped by the retroperitoneally fixed angles of the duodenum and eventually result in perforation. Plastic bag clips, although not sharp and pointed, should be removed before they pass from the esophagus into the stomach and through the pylorus. They have claws that can attach to the small bowel mucosa leading to ulceration, stricture formation, and bleeding.[14] Toxic foreign bodies such as button batteries that become impacted in the esophagus should be removed promptly to prevent perforation and systemic toxicity.

CONTRAINDICATIONS

There are no absolute contraindications to the removal of an esophageal foreign body. Serious, life- and limb-threatening injuries should be treated prior to esophageal foreign body removal. The patient's airway, breathing, and circulation should be evaluated and supported as necessary prior to removing the foreign body.

EQUIPMENT

- Flexible upper gastrointestinal endoscope
- Rigid gastroscope
- Through-the-scope-balloon
- Stiegmann-Goff friction-fit adaptor of the esophageal variceal rubber banding ligating kit
- Glucagon
- 44 French Maloney rubber dilator
- Lubricant gel
- Endoscopic overtube, for use with sharp or pointed foreign bodies
- Soft latex protector hood for the flexible scope
- Rat-tooth or alligator forceps
- Retrieval nets or Dormia baskets
- Polypectomy snares
- Laryngoscope
- Laryngoscope blades, Miller and Macintosh of various sizes
- Curved clamp
- Medications for providing procedural sedation (Chapter 129)
- Cardiac monitoring
- Pulse oximetry
- Supplemental oxygen
- Foley catheters, 14 to 16 French
- Topical anesthetic spray
- Water-soluble contrast material
- 5 mL syringe
- Fluoroscopy machine, optional

PATIENT PREPARATION

If possible, obtain a duplicate sample of the ingested foreign body. Manipulate the duplicate object with available foreign body forceps and snares. Determine which instrument is best suited to grasping the foreign body. Instruments that are most useful include alligator and rat-toothed forceps, polypectomy snares, and Dormia baskets.

Explain the risks, benefits, and aftercare of the procedure to the patient and/or their representative. Obtain an informed consent for the procedure. Place the patient supine. Obtain intravenous access. Apply the cardiac monitor, pulse oximeter, and supplemental oxygen to the patient. Administer intravenous sedation or procedural sedation (Chapter 129) as necessary.

TECHNIQUES

GENERAL PRINCIPLES

The flexible upper gastrointestinal endoscope should be inserted under direct visualization to avoid inadvertently striking an object and further impacting it or causing it to penetrate the esophageal wall. Blunt foreign bodies such as coins can be securely grasped with a forceps or a snare. **A firm grasp on the foreign body is required before withdrawal is attempted.** Otherwise, the foreign body may become dislodged as it is withdrawn through points of anatomic narrowing. This can result in aspiration of the foreign body. An overtube should be used if multiple insertions and withdrawals of the endoscope are needed. Pointed foreign bodies should be withdrawn with the point trailing to avoid perforating any structures. Objects with sharp edges, such as razor blades, should be extracted through an overtube to prevent secondary injury. Elongated foreign bodies such as wires or pens should be grasped with a snare close to the cephalad end of the object so it can align itself with the long axis of the esophagus during withdrawal. Foreign bodies that penetrate the mucosa can be safely extracted with the endoscope if frank perforation or vascular penetration has not occurred.

FOOD IMPACTIONS

ENDOSCOPY

Food impactions are more likely to occur in the distal esophagus. If the patient is symptomatic, there is no need for barium studies because it will obscure visualization during endoscopy. **Endoscopic intervention should be carried out immediately to prevent aspiration if the patient is salivating and unable to handle oral secretions. The impacted food bolus should not remain in the esophagus for more than 12 hours. Thereafter, the risk of complications increases significantly.**

Underlying esophageal disease is found in 65% to 97% of adults presenting with an esophageal food impaction.[8,15] **Endoscopic removal is the procedure of choice if a meat bolus does not pass spontaneously or after an unsuccessful trial of gas-forming agents, glucagon, nifedipine, or nitroglycerine.** The entire bolus could be removed slowly with a polypectomy snare or Dormia basket under direct visualization. When the endoscope is just below the cricopharyngeus muscle, snugly pull the snare with the food bolus against the tip of the endoscope. Extend the patient's head and quickly remove the endoscope.[16]

If the food bolus is soft, a piecemeal approach can be accomplished with several passages of the endoscope through an overtube.[17] The overtube will facilitate reinsertion of the endoscope. Insert a Maloney rubber dilator (44 French) into the esophagus and proximal to the foreign body. Pass the overtube, lubricated internally and externally, over the Maloney dilator. Remove the Maloney dilator. Introduce the flexible endoscope through the overtube.

Another method, the push technique, has been useful in dealing with an impacted food bolus.[9] A small-caliber flexible endoscope may be used to bypass the food bolus and evaluate the area distal to the obstruction. If the endoscope is able to pass into the stomach successfully, pull it back until it is just proximal to the food bolus. Use the endoscope to gently push the food bolus into the stomach. It is preferable to push from the right side of the food bolus rather than straight, especially in patients with a hiatal hernia, since the gastroesophageal junction usually takes a left turn as it enters the hernia. The presence of a bone spicule should always be considered, whether the meat bolus is being extracted or pushed into the stomach.

A newer technique is accomplished by attaching the Stiegmann-Goff friction-fit adaptor of the esophageal variceal rubber banding ligating kit to the tip of the endoscope.[18] The tip of the endoscope is replaced with a screw-on drum from the variceal ligation kit. After placing an esophageal overtube proximal to the food bolus, the endoscope is passed through the overtube.[19–22] To avoid the risk of dropping the food in the trachea, a Roth retrieval net may be passed through the endoscope to retrieve food from the esophagus.[23,24]

A last resort approach is the use of Nd:YAG laser to burn an opening in the center of an impacted meat bolus. This method is expensive and carries a high risk of complications.[25] Finally, if a food impaction of the esophagus cannot successfully be removed using the flexible endoscope, rigid endoscopy under general anesthesia should be considered.[26]

GAS-FORMING AGENTS

Gas-forming agents can be used to relieve a distal esophageal food impaction. They are occasionally used in an attempt to relieve a

food impaction in the proximal and middle thirds of the esophagus. These agents produce carbon dioxide gas that distends the esophagus, relaxes the lower esophageal sphincter, and "pushes" the food bolus through the gastroesophageal junction with the aid of esophageal peristalsis. Gas-forming agents may be used in conjunction with glucagon, nifedipine, or nitroglycerine to help relieve the impacted food bolus. Complications associated with gas-forming agents include aspiration, vomiting, forceful vomiting, and esophageal perforation due to distention and/or vomiting. Many physicians do not use these agents due to the risk of perforation.

Three classes of gas-forming agents have been used. Commonly used are commercially available agents that are used by Radiologists for upper gastrointestinal contrast studies. A mixture of tartaric acid (1.5 to 3.0 g in 15 mL H_2O) immediately followed by sodium bicarbonate (1.5 to 3.0 g in 15 mL H_2O) has been successfully used. A final agent is carbonated soda pop.

GLUCAGON

A trial of intravenous glucagon before endoscopic therapy is a reasonable approach. It may disimpact a food bolus in the distal esophagus and allow it to pass into the stomach. Glucagon relaxes the smooth muscle of the lower esophagus and decreases lower-esophageal sphincter tone. It relaxes the esophageal smooth muscle within 1 minute of intravenous injection, and its effects last approximately 20 to 25 minutes. Glucagon has no effect on the proximal third of the esophagus that is composed of skeletal muscle. It has a minimal effect on the middle third of the esophagus that is composed of both skeletal and smooth muscle. Glucagon has an overall success rate of ≤50%. Glucagon has been also combined with gas-forming agents to enhance esophageal clearance.

The dose of glucagon is 0.03 to 0.1 mg/kg intravenously with a maximum dose of 1 mg in children and 2 mg in adults. It should be administered over 1 to 2 minutes. **It is recommended to give a test dose (1/10 of the full dose) and observe the patient for 5 minutes for signs of hypersensitivity or hypotension before giving the full dose.** Have the patient take one to two sips of water after the administration of glucagon to stimulate lower esophageal peristalsis. Administer a second dose of glucagon if the food bolus impaction is not relieved within 10 to 20 minutes.

Glucagon is a relatively safe medication. It should not be administered to patients with known hypersensitivity to glucagon, esophageal fibrosis, esophageal rings, esophageal strictures, insulinomas, pheochromocytomas, sharp or irregular foreign bodies, or Zollinger–Ellison syndrome. Exogenous glucagon stimulates the release of catecholamines. It can stimulate a pheochromocytoma to release catecholamines resulting in marked hypertension and tachycardia. The hypertension can be controlled using 5 to 10 mg of intravenous phentolamine. Glucagon's hyperglycemic effect can cause an insulinoma to release insulin and cause subsequent hypoglycemia. Common complications associated with glucagon include nausea, vomiting, transient hyperglycemia, allergic reactions, tachycardia, and hypertension. Glucagon is a polypeptide hormone synthesized in nonpathogenic *Escherichia coli* that have been genetically altered. This is the basis of the allergic/hypersensitivity reactions. A transient rise in blood pressure and heart rate is often seen after administration of glucagon. Patients taking β-blockers may be more susceptible to transient hypertension and tachycardia. These side effects are short-lived as the half-life of glucagon is 8 to 18 minutes.

NIFEDIPINE

Nifedipine is a calcium channel blocker that decreases lower esophageal sphincter tone. It has been administered to allow an impacted food bolus to pass into the stomach. It should not be administered if the patient has an allergy to calcium channel blockers, has hypotension, or ingested a sharp or irregular shaped foreign body. With a single dose, nifedipine has few side effects. These are usually minimal (i.e., dizziness, flushing, headache, hypotension, lightheadedness, muscle cramps, nausea, nervousness, and palpitations) and do not preclude its use. **The most significant effect of nifedipine is hypotension that may last 6 to 8 hours.** Some patients will have a significant hypotensive response to nifedipine and there is no way to predict which patients will be affected. For these reasons, many physicians will not use nifedipine in the elderly or in patients with a history of cardiac disease, coronary artery disease, stroke, or who are concurrently taking antihypertensive medications. The typical dose is 10 mg of oral nifedipine. The medication may be chewed then held in the mouth and subsequently swallowed. Alternatively, open the capsule, place the medicine sublingually, and have the patient hold it in their mouth and then swallow the dissolved nifedipine. Attempt another technique if the food bolus does not pass with one dose of nifedipine.

NITROGLYCERINE

Sublingual nitroglycerine (0.3, 0.4, or 0.5 mg) relaxes vascular smooth muscle and the smooth muscle contained within the middle and distal thirds of the esophagus. The use of sublingual nitroglycerine may allow the esophagus to dilate enough so that a food bolus can pass into the stomach. **Nitroglycerine should not be administered if the patient is hypotensive or has ingested a sharp or irregular shaped foreign body. It should also not be administered if the patient is taking prescription medications for erectile dysfunction (e.g., Levitra, Cialis, and Viagra). The combination of these medications with nitroglycerine can result in life-threatening hypotension.** The onset of action is within 1 to 3 minutes with a maximum effect by 4 to 5 minutes. The major side effect of nitroglycerine is hypotension, but that is short-lived. Administer one pill sublingually and allow 4 to 5 minutes for an effect. The dose may be repeated a second time. Attempt another technique if the food bolus does not pass after two doses of nitroglycerine.

PAPAIN

Papain is a proteolytic enzyme that has been used to dissolve an impacted food bolus. It is available in markets as meat tenderizer and in health food stores as a digestive supplement. It will dissolve the esophageal mucosa and continue to work its way through the esophageal wall and into the mediastinum if it does not first dissolve the food bolus. The use of papain to dissolve an impacted food bolus may be associated with a fatal esophageal perforation and, if aspirated, hemorrhagic pulmonary edema. **Papain should never be used to dissolve an impacted food bolus.**

SUMATRIPTAN

Sumatriptan is a 5-HT1 agonist that reduces fasting fundic tone, prolongs fundic relaxation, and delays gastric emptying.[27] It also increases the number of esophageal motor waves. This may be useful in cases of distal esophageal food boluses and coins, although no formal studies have been conducted.

SHARP AND POINTED FOREIGN BODIES

Removal of sharp and pointed objects requires extreme caution due to potential life-threatening complications, higher morbidity, and higher mortality. An experienced Endoscopist should manage these cases. It may be safer, in some cases, to consider surgical intervention. Toothpicks and bones are the most common foreign bodies requiring surgical removal.[28–30] Nails, needles, razor blades, safety pins, and dental prostheses may be removed endoscopically.[28–30] It is important to remember that "advancing points puncture while trailing points do not."[31] Objects longer than 5 cm and wider than

2 cm require removal as they will rarely pass through the pylorus.[32] Intravenous glucagon (0.4 to 0.6 mg in adults) may be used to facilitate extraction from the stomach and duodenum.

An alligator forceps or snares are needed to grasp the object over the feeding tube. A plastic overtube should be considered for the removal of any sharp object.[19,33] The overtube should be at least 60 cm long to remove a sharp object from the stomach. This will limit objects for endoscopic removal to those smaller than 11 to 15 mm in diameter that fit within the overtube.[34] A soft latex protector hood may be used for the removal of large objects.

Razor blade ingestions may be managed with the flexible esophagoscope in adults. An alligator forceps, a snare, and an overtube will be needed. A razor blade that has passed the pylorus will often traverse through the intestinal tract without difficulty.

Safety pins and toothpicks pose additional risks due to their sharp ends that may perforate the esophagus. An open safety pin in the esophagus, with the open end proximal, should be pushed into the stomach with the flexible endoscope. Once in the stomach, the object is turned and the hinged end is grasped and pulled out first. A closed safety pin in the stomach will often pass without difficulty. Grasp a toothpick with an alligator forceps or snare very close to the tip so that the longitudinal axis of the toothpick is parallel to the scope as it is withdrawn into the overtube.[16]

Numerous other sharp objects are often encountered in the esophagus. Pens, pencils, thermometers, and wires are extracted in a fashion similar to a toothpick with a snare grasping the end of the object.[15] Glass may be withdrawn similarly or by using an end-hood attachment.[33,35]

Attempts should be made to remove all sharp and pointed foreign bodies before they pass from the stomach. Approximately 15% to 35% of sharp or pointed foreign bodies will cause intestinal perforation, especially in the area of the ileocecal valve.[36,37]

BUTTON BATTERIES

Most button batteries ingested (96%) are small and 7.9 to 11.6 mm in diameter.[39] Batteries less than 15 mm in diameter almost never lodge in the esophagus. Only 3% of button batteries are larger than 20 mm but are responsible for the severe esophageal injuries.[39,50–53] Guidelines for the evaluation and treatment of button battery ingestions are available from the National Capital Poison Center.[54]

Button batteries cause injury by multiple methods. Their electrical discharge causes hydrolysis and the creation of hydroxide ions in tissue, which causes alkali burns. Leakage of the high pH contents can result in alkali burns. Their physical presence cause direct pressure necrosis. Some button batteries contain mercuric oxide. Mercury toxicity can result if the mercuric oxide leaks from the batteries.

The majority of these batteries contain manganese dioxide, silver oxide, mercuric oxide, zinc air, or lithium. Obtain anteroposterior and lateral abdominal and chest radiographs to distinguish between coins and button batteries. A double density shadow is suggestive of batteries. The coin has a much sharper edge.

A button battery lodged in the esophagus is a true emergency and immediate removal is indicated to avoid the rapid corrosive action of the alkaline substance on the mucosa and subsequent complications.[38,40] Endotracheal intubation is usually necessary to protect the airway prior to endoscopic removal. The battery is removed from the esophagus under direct viewing using a through-the-scope balloon. A biopsy forceps may be needed to free the edge of the battery prior to removal. Alternatively, the battery may be pushed to the stomach and then removed using a polypectomy snare or a Dormia basket. **Do not use a Foley catheter or a magnet to remove a button battery without the aid of endotracheal intubation and general anesthesia due to the possibility of the button battery falling into the airway.** The patient should be admitted to the intensive care unit and monitored for signs of perforation and sepsis if they suffered severe esophageal injury when evaluated by endoscopy after removal of the button battery. If the injury is localized to the anterior wall of the esophagus, bronchoscopy may be performed to evaluate the extent of injury.

Generally, a button battery in the stomach need not be removed unless the patient is symptomatic with abdominal pain, tenderness, or gastrointestinal bleeding. Asymptomatic patients with button batteries less than 15 mm in diameter in their stomachs need follow-up abdominal radiographs every 24 hours to document forward progress until it is expelled. In a child less than 6 years old, the battery should be endoscopically removed if it is larger in size and has not passed within 48 hours.[38,41] Patients may be placed on H_2 blockers and/or proton pump inhibitors to decrease the acid in the stomach and therefore decrease the battery reaction. If mercury poisoning is expected, serum and urine mercury levels should be obtained and monitored.

MAGNETS

Magnets are commonly found in homes and are easily accessible to children. They are contained in appliances, jewelry, and toys. The ingestion of a single magnet is usually not problematic. The ingestion of multiple magnets should be considered an emergency requiring removal. The magnets can move separately through the gastrointestinal tract. They then have the potential to attract each other and trap bowel between them. This can result in pressure necrosis, fistula formation, and perforation.

Perform plain radiographs to determine the number and the location of the magnets. A single magnet should be treated as any other small, nonsharp, foreign body ingestion. Multiple magnets require removal. Remove them endoscopically if they are located within the esophagus and/or stomach. If they have passed the pylorus, consult a Surgeon for urgent removal versus careful inpatient monitoring by the Surgeon and frequent radiographs to localize the magnets.

FOLEY CATHETER TECHNIQUE

A Foley catheter has been successfully used to remove recently ingested, radiographically opaque, smooth and blunt foreign bodies from the esophagus. This technique is inexpensive, has a high success rate, does not require hospitalization, and avoids the complications associated with endotracheal intubation and general anesthesia. Coins are the foreign bodies primarily removed with a Foley catheter. The technique has also been used to remove button batteries, food boluses, and other smooth foreign bodies.

This technique cannot be used on all patients with an esophageal foreign body. This technique should not be attempted in patients who are confused or uncooperative. Patients with an altered mental status, airway compromise, or potential airway compromise should be endotracheally intubated prior to Foley catheter removal of the foreign body. Sharp or irregular shaped objects can lacerate or perforate the esophagus upon removal. Known or suspected esophageal perforation is a contraindication to this technique. Patients with complete esophageal obstruction, as demonstrated by an esophageal air-fluid level on radiographs, are not candidates. Esophageal fibrosis, esophageal tumors, anatomic anomalies, or a history of prior esophageal surgery is also a contraindication.

The equipment required for the technique is minimal. This includes topical anesthetic spray, a bite block, and a size 12 to 16 Foley catheter with a 5 to 10 mL balloon. The technique may be performed ideally in a fluoroscopy suite or blindly in the Emergency Department. A water-soluble contrast agent is required if using

fluoroscopy. **The most dangerous and immediate complication of this technique is airway obstruction. Airway and emergency equipment must be available if this technique is to be performed.**

Explain the procedure to the patient, including the sensations they will experience. The use of a topical anesthetic spray for the oropharynx is beneficial but optional. Its use may increase the risk of aspiration. The use of physical restraints, procedural sedation, and/or intubation may be required as needed on a case-by-case basis. Preinflate the Foley catheter balloon with 5 to 10 mL of water-soluble contrast material. Inspect the integrity of the balloon. Withdraw the contrast material back into the syringe to deflate the balloon. The small amount of contrast material left in the balloon will facilitate identification under fluoroscopy. Place the patient prone in 10° to 20° of Trendelenburg or in the left lateral decubitus position in 10° to 20° of Trendelenburg. The fluoroscopy technique and then the blind technique are described in the following paragraphs.

Insert the Foley catheter. Some physicians insert a bite block and place the Foley catheter through the mouth (**Figure 62-1**). Others use the nasal route. The oral route avoids the potential problem of lodging the foreign body in the nasopharynx with subsequent aspiration. Advance the Foley catheter under fluoroscopy until the balloon is just distal to the foreign body (**Figure 62-1A**). Slowly inflate the balloon with 5 mL of contrast material (**Figure 62-1B**). Stop inflating the balloon if the patient complains of pain; deflate the balloon, then reposition the catheter before reinflating. Withdraw the catheter with moderate and steady traction until it exits the mouth (**Figures 62-1C & D**). **Stop withdrawing the catheter if resistance is met to prevent an esophageal tear or perforation.** The balloon may occasionally slide past the foreign body as the catheter is being withdrawn. Reinsert the catheter and inflate the balloon with 7 to 8 mL of contrast material and then withdraw the catheter. **Do not overinflate the balloon as it can rupture the esophagus.**

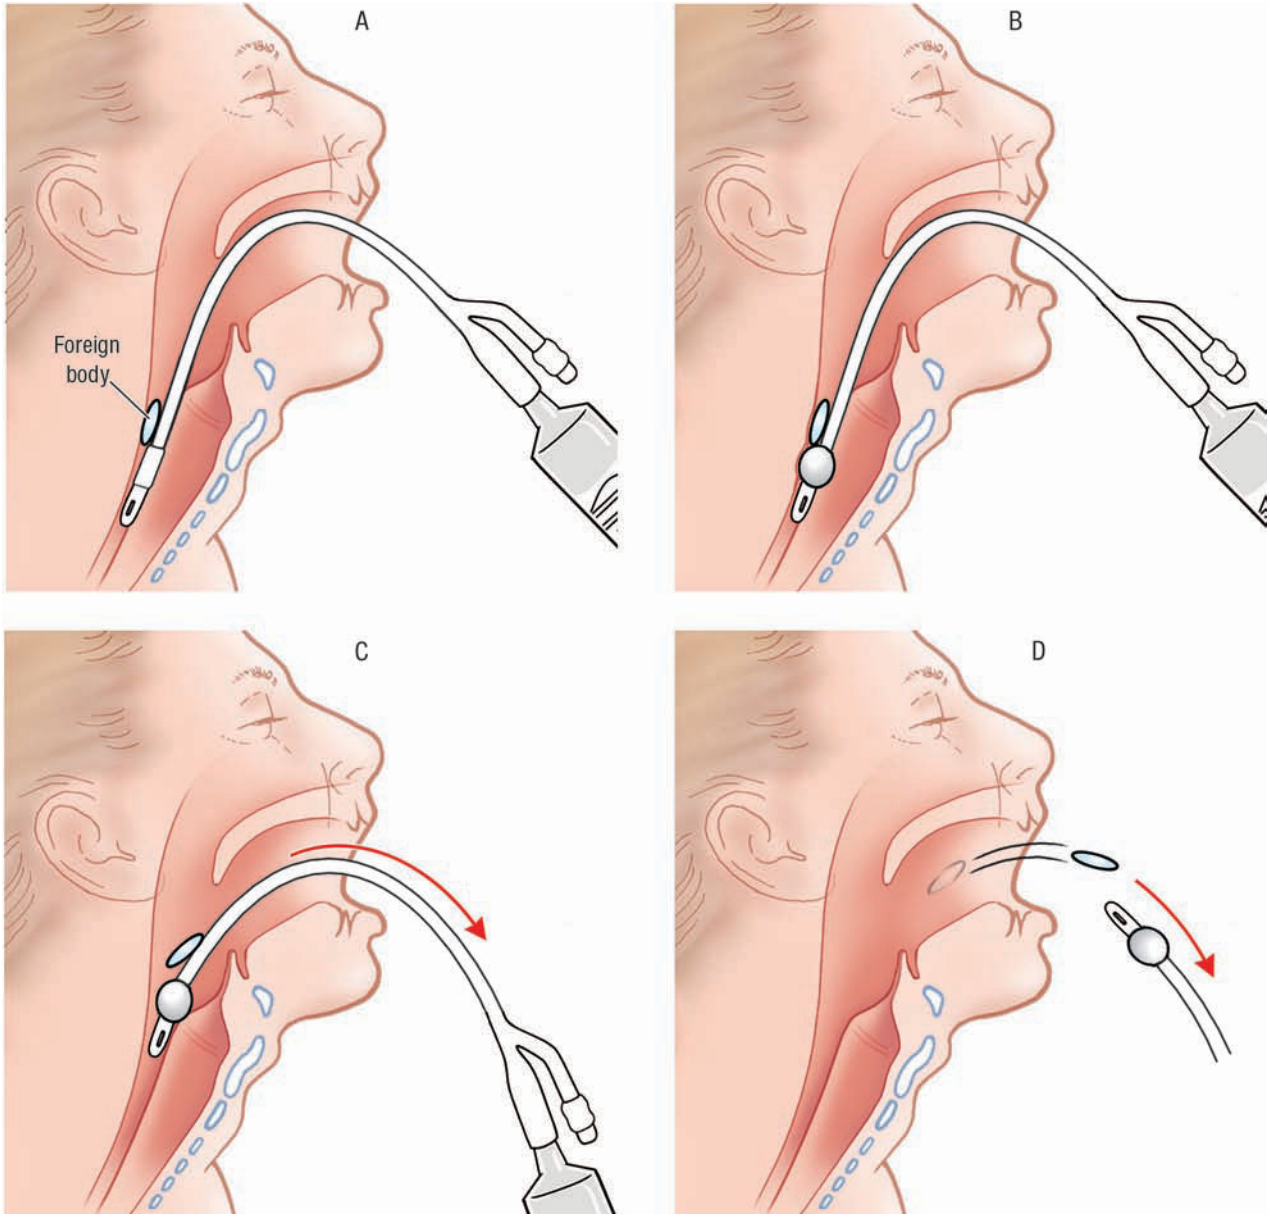

FIGURE 62-1. The Foley catheter technique to remove an esophageal foreign body. This illustration demonstrates the oral route for catheter insertion. The nasal route may also be utilized. **A.** The catheter is inserted and advanced until the balloon is just distal to the foreign body. **B.** The balloon is inflated. **C.** The catheter is withdrawn and pulls the foreign body into the hypopharynx. **D.** Completely withdrawing the catheter will pull the foreign body into and out the mouth. Steps (**C**) and (**D**) are performed in one smooth motion.

Do not attempt this technique more than twice. The balloon will pull the foreign body ahead of it into the hypopharynx and then the mouth. Tell the patient to spit out the foreign body; or you can grasp it with fingers, forceps, or a hemostat.

This technique may also be used "blindly" if fluoroscopy is not available. Estimate the distance, on the radiographs, from the mouth or nose to the foreign body. Place the Foley catheter over the radiograph with the balloon just distal to the foreign body. Mark the distance with tape on the catheter as it exits the mouth or nose. The catheter will then be inserted into the patient until the tape is positioned at their mouth or nose. Use saline rather than contrast material to inflate the balloon. Obtain repeat radiographs if the foreign body is not expelled with the catheter as it may have been pushed into the stomach. The remainder of the technique is the same as described for removal under fluoroscopy.

Complications with this technique are uncommon but do occur. This technique may not be able to remove the foreign body. Insertion of the catheter can cause laryngospasm or vomiting. The Foley catheter may enter the airway, resulting in coughing and laryngospasm. The esophagus may be lacerated or perforated if the foreign body is large, completely impacted, sharp, irregular, or has been in place for over 12 to 24 hours. Overinflation of the balloon can rupture the esophagus. Removal through the nose may result in epistaxis or impaction of the foreign body in the nasopharynx or nasal cavity. The most feared complication is complete or partial airway obstruction if the foreign body falls into the larynx.

BOUGIENAGE

The use of a Bougie dilator to push an esophageal foreign body into the stomach has been used in children.[42–44] The technique has been successfully used in asymptomatic children who have radiographs documenting a coin in the esophagus, no history of esophageal disease, and less than 24 hours has passed from the time of ingestion. The advantages of this technique are that it is quick, simple to perform, does not require sedation, does not require intravenous access, decreases length of stay, and saves money when compared to endoscopy.[55]

Apply a topical anesthetic spray to the child's oropharynx. Select an appropriate size Bougie dilator. Physically restrain the patient while they are sitting upright or standing on the bed. Place the tip of the Bougie dilator at the mouth and run the rest of the dilator to the earlobe and to just below the left costal margin. Place a piece of tape on the Bougie dilator 3 to 4 cm below the costal margin. Insert the Bougie dilator through the mouth and advance it in one smooth motion until the tape is at the mouth. Remove the Bougie dilator. Obtain a repeat radiograph to confirm that the coin is now in the stomach.

Complications can occur and are avoided with proper patient selection. Esophageal perforation may occur if the patient has known esophageal disease, prior esophageal surgery or manipulation, a sharp foreign body, or an irregular shaped foreign body. A foreign body present for more than 24 hours can cause pressure necrosis to the esophagus and increase the risk of perforation.

OROGASTRIC TUBE MAGNET

The orogastric tube magnet (OGTM) is an orogastric tube that has a magnet sealed within the distal end. It may be used to retrieve smooth, metallic foreign bodies from the esophagus and stomach under fluoroscopy. Place the patient in the lateral decubitus position. Apply a topical anesthetic spray to the oropharynx. Insert the OGTM through the mouth. Advance the OGTM under fluoroscopy into the esophagus and directed toward the foreign body until it makes contact. Withdraw the OGTM and the foreign body out the mouth. This is a rarely used technique.

ALTERNATIVE TECHNIQUES

Numerous other methods for the removal of esophageal foreign bodies have been tried and reported in the literature. Surgical removal is rarely indicated except when complications such as perforation or vascular penetration have occurred. **Do not blindly push food boluses into the stomach.** This is hazardous because many patients have underlying esophageal disease. **Blind maneuvers can result in esophageal perforation.**

PEDIATRIC CONSIDERATIONS

Children less than 4 years of age are predisposed to occasionally have an esophageal foreign body. They explore objects with their mouth, have a high curiosity level, lack molars to chew food, and have poor motor and sensory coordination. Common esophageal foreign bodies include balls, button batteries, buttons, candies, coins, gumballs, jacks, marbles, partially chewed food, and pen caps. **A high index of suspicion must be maintained as a history of an ingestion may not be obtained.**

Children may present asymptomatically or with cough, drooling, dysphagia, respiratory distress, unwillingness to eat, or vomiting. An asymptomatic child with an esophageal coin or round object, except button batteries, can be admitted to the hospital and watched for 24 hours to see if the object will spontaneously pass into the stomach. The object should be removed with a Bougie dilator, a Foley catheter, or an endoscope if the child is or becomes symptomatic, or if the object does not pass within 24 hours. Foreign bodies in a mainstem bronchus require removal by an Otolaryngologist in the operating room with a rigid bronchoscope. Turning the child upside down or performing the Heimlich maneuver may move the foreign body into the trachea or larynx and cause a complete airway obstruction.

Waltzman et al. reported that 25% to 30% of esophageal coins in children pass spontaneously without complications.[45] Treatment of these patients may reasonably include a period of observation (e.g., 8 to 16 hours), especially in older children with coins in the distal esophagus. A "combination" technique using fluoroscopy and endoscopic forceps, called the "penny-pincher," has been described to remove coins in children.[46] In this technique, grasping endoscopic forceps are covered by a soft rubber catheter and fluoroscopically guided into place. The forceps firmly hold the coin while the catheter protects the oropharynx and aligns the device with the coin. When the tip of the catheter is close to the upper edge of the coin, the retracted radiopaque prongs of the forceps are deployed. At this point, the coin edge is grasped, and the coin is extracted.

It is important not to attempt these techniques or bougienage with patients with known anomalies of the gastrointestinal tract. These anomalies may be anatomic, functional, or postsurgical. They can lead to the coin again becoming lodged, this time in a position that would require a more invasive intervention than endoscopy.[47]

ASSESSMENT

The patient should be observed until the effects of the sedation have resolved. This includes monitoring the vital signs as per protocol of the hospital. The patients should be given a trial of liquids to swallow prior to discharge. The patient may be safely discharged after they tolerate oral fluids, are awake and oriented, and are able to ambulate without difficulty. The patient should be driven home by another person if sedation was used to extract the foreign body.

Admission is required in a few instances. The inability to tolerate oral fluids is a contraindication to discharge. Foreign bodies that are

not retrievable must be removed. These patients should be admitted for observation, further endoscopy, or operative removal. Any patient with evidence of esophageal perforation should be admitted, observed, and evaluated by a Surgeon.

The esophagus should be endoscopically examined after removal of most foreign bodies. A Gastroenterologist should be consulted on anyone with an esophageal foreign body. All patients discharged from the Emergency Department should follow up with a Gastroenterologist in 24 to 48 hours. The presence of any lacerations, perforations, or erosions should be noted and may require repair. Any strictures will require dilation in the future. Some recommend a second endoscopic follow-up in 3 to 6 weeks for reevaluation of the esophagus. This is Endoscopist-specific.

AFTERCARE

Instruct the patient to only ingest liquids for the first 12 to 18 hours. A soft diet should begin after this trial period of liquid and advanced to a general diet over 24 hours. Instruct the patient to take small bites of food and completely chew it before swallowing. They should immediately return to the Emergency Department if they experience abdominal pain, chest pain, dysphagia, hematemesis, hemoptysis, melena, odynophagia, or if they have any concerns.

COMPLICATIONS

Esophageal perforation can occur due to the foreign body or the extraction procedure. The patient may present with fever, tachycardia, shortness of breath, chest pain, abdominal pain, and crepitation in the neck. An immediate chest radiograph and/or a radiographic contrast study should be performed if the extraction of the foreign body has been difficult.[1–3] An aortoesophageal fistula can form due to sharp foreign bodies in the esophagus that erode through the esophageal wall. This should be considered when the patient presents with dysphagia and significant hematemesis.[9,33] A latency period between the ingestion of the foreign body and hematemesis is usually 1 to 3 weeks, though it can occur years later.[15] Tracheoesophageal fistulas can occur more than a year after ingestion of the foreign body.[3]

Other life-threatening cardiopulmonary emergencies include mediastinitis, lung abscess, pericarditis, cardiac tamponade, pneumothorax, and pneumomediastinum. These complications mostly result from a delay in recognizing an esophageal perforation.[8,9,15] The remaining complications are discussed with each of the individual techniques of foreign body removal.

SUMMARY

Foreign body ingestion and food bolus impaction in the upper gastrointestinal tract are relatively common problems seen in the Emergency Department. Several studies have shown that 80% to 90% of foreign bodies in the gastrointestinal tract will pass spontaneously. Approximately 10% to 20% will require nonoperative intervention while 1% will require surgical removal.[3,48] The most common presenting symptoms are chest or pharyngeal pain, odynophagia, dysphagia, foreign body sensation, and sialorrhea.[48] Despite performing emergent upper endoscopy, no foreign body could be found in almost half of patients.[49] The urgency for the endoscopic examination depends upon the potential risk of aspiration or perforation, the type and size of the foreign body, the degree of obstruction, and the inability to manage secretions.[9] The presence of dysphagia and the immediate onset of symptoms would increase the probability of a positive foreign body finding on endoscopy.

Numerous techniques may be used to remove an esophageal foreign body. The technique of choice depends upon the level of patient cooperation, the type of foreign body, the time since ingestion, physician experience and comfort, Gastroenterology consultation, and presenting symptoms. Complications can be minimized by the proper selection of the removal technique and the appropriate patient for the technique.

63 Balloon Tamponade of Gastrointestinal Bleeding

Bashar M. Attar

INTRODUCTION

Gastroesophageal varices are among the most dangerous complications associated with cirrhosis. They are present in 50% to 60% of cirrhotic patients, and about 30% of them will experience an episode of variceal hemorrhage within 2 years of the diagnosis of varices.[1] The major factors that determine the risk of bleeding are variceal size and the degree of liver dysfunction.[1–3] While variceal bleeding stops spontaneously in 20% to 30% of cases, it recurs in 70% within 1 year of the initial episode.[1–4] Mortality is as high as 50% in the first year.[5] Variceal bleeding accounts for almost one-third of deaths in cirrhotic patients. Variceal hemorrhage has a poor prognosis if it is associated with coexisting or subsequent complications including rebleeding, infection, hepatic dysfunction, and portal pressure ≥12 mmHg.[6,7] Somatostatin and its analogs cause splanchnic vasoconstriction leading to reduced portal pressure and portal blood flow while venodilators reduce portal pressure by reducing resistance to portal flow.[7,8]

Doctors Sengstaken and Blakemore developed the concept of balloon tamponade to control bleeding esophageal and gastric varices in 1950. They developed a triple-lumen and double-balloon system that bears their names. The Sengstaken–Blakemore (SB) tube is used as a temporizing measure to stop variceal bleeding until more definitive means are available. A variant of the SB tube is the Minnesota tube. It is a quadruple-lumen, double-balloon system. These tubes are rarely used today due to the significant complications and the widespread availability of endoscopy and its therapeutic interventions. Removal of the balloon after its initial control of the bleeding results in a 50% rebleeding rate. It is also associated with serious complications such as esophageal ulceration and perforation.[9] Emergency Physicians should become familiar with the SB and Minnesota tubes, as they can be potentially lifesaving in an emergent setting, especially when endoscopy is not available or contraindicated.

ANATOMY AND PATHOPHYSIOLOGY

Cirrhosis results in portal venous hypertension and a decrease in blood flow through the portal system. Collateral circulation develops, so that the blood in the portal vein can find an alternative route to the inferior vena cava. Large collateral systems include the esophageal, gastric, paraumbilical, and rectal veins. The left gastric and esophageal veins form one of the larger collateral circulation channels due to the pressure generated from the portal venous system and the large volume of blood flow through them. The collateral veins distend from the pressure and large volume of blood flow, resulting in weakening of the walls of the vein. Ulceration and rupture of these veins can result in large amounts of blood entering

the esophagus and stomach. Patients may present with bright red blood per rectum, hematemesis, hemorrhagic shock, hypotension, or complications associated with hypotension and hemorrhage (e.g., cerebrovascular accidents and myocardial infarction).

The inflated balloons will control most bleeding. The esophageal balloon exerts lateral pressure to tamponade esophageal varices. The gastric balloon exerts pressure on the gastric cardia to tamponade varices. When both are inflated, they meet to compress the gastric cardia against the diaphragm and block the upward flow of collateral blood from feeding the esophageal varices.

INDICATIONS

Balloon tamponade should be considered in patients with acute bleeding from esophageal and/or gastric varices if medical therapy (e.g., somatostatin, octreotide, and vasopressin) or emergent endoscopic therapy (i.e., banding or sclerotherapy) is not available, contraindicated, or unsuccessful.

CONTRAINDICATIONS

Absolute contraindications to balloon tamponade of variceal bleeding include a history of esophageal stricture, a history of recent surgery involving the gastroesophageal junction, or if the hemorrhage has terminated based upon nasogastric lavage and aspiration.

There are numerous relative contraindications to balloon tamponade of variceal bleeding. The procedure should not be performed if the equipment required is defective or missing components. Untrained support staff make the procedure, as well as the aftercare, more difficult. Significant active medical problems (e.g., respiratory failure, congestive heart failure, and cardiac arrhythmias) preclude the use of balloon devices. Incomplete gastric lavage leaving particulates in the stomach can cause retching and elevated intraabdominal pressure. The balloons will not properly position and may perforate the esophagus if the patient has a hiatal hernia. Esophageal ulcerations preclude the use of the esophageal balloon (a gastric balloon may be used). The device is not helpful if a variceal source of bleeding cannot be demonstrated by examination, history, and/or nasogastric aspiration. Patients with altered mental status, confusion, diminished gag reflexes, hypoxemia, or who are uncooperative should have their airway secured by endotracheal intubation prior to this procedure. Recurrent bleeding after the initial successful tamponade should be followed by endoscopic or operative intervention.

EQUIPMENT

- SB tube (or Minnesota tube)
- Topical anesthetic spray
- Tongue blades
- Lidocaine or water-soluble jelly
- 60 mL syringe
- Catheter tips for the syringe
- Two wall-suction setups with plastic connectors and suction tubing
- Adhesive tape
- Rubber shod clamps, hemostats, or plugs
- Scissors
- Y-adapter or three-way stopcock
- Intravenous extension tubing
- Pressure bulb
- Mercury manometer or handheld manometer
- Bite block
- Nasogastric tube
- Football helmet, catcher's mask, or endotracheal tube holder

The SB tube is a triple-lumen and double-balloon system (**Figures 63-1 & 63-2**). It is available in a variety of sizes, including pediatric sizes. The proximal end contains three ports. A syringe attaches to the esophageal balloon inflation port to inflate the esophageal balloon. A syringe attaches to the gastric balloon inflation port to inflate the gastric balloon. The gastric aspiration port may be used to aspirate gastric contents, instill fluid into the stomach, or lavage the stomach. The ports may be opened and closed by the application of rubber shod clamps, hemostats, or plugs. The tube is made of a soft rubber and is extremely flexible. The proximal or esophageal balloon is elongated. The distal or gastric balloon is round. The maximum volume to inflate each balloon is manufacturer- and size-specific. Numerous perforations in the distal end of the tube allow for gastric aspiration and lavage.

The Minnesota tube is a quadruple-lumen and double-balloon system (**Figure 63-3**). It is similar to the SB tube with the exception of an additional port and lumen. The esophageal aspiration port allows saliva and esophageal secretions to be aspirated from a perforation just above the esophageal balloon. The only advantage of this tube over the SB tube is that the SB tube requires a nasogastric tube to be passed nasally or orally into the esophagus to aspirate secretions.

PATIENT PREPARATION

Explain the risks and benefits of the procedure to the patient and/or their representative. An informed consent should be obtained for the procedure. Thoroughly assess the patient's airway and breathing. Have a low threshold to protect the airway by endotracheal intubation. Endotracheal intubation is required before performing the

procedure if the patient has altered mental status, airway compromise, or the potential for airway compromise. Patients are often ill and require intubation anyway. The procedure and the tube are not well tolerated, and intubation makes it easier. Endotracheal intubation reduces the risk of aspiration.

The patient should have intravenous access established with at least two large-bore catheters. Cardiac monitoring, continuous pulse oximetry, and supplemental oxygen should be applied. The patient may require the judicious use of intravenous sedatives and soft restraints during the insertion and inflation of the tube. The patient should be resuscitated, including blood transfusion, to stabilize them hemodynamically.

Place the patient sitting upright to semi-upright by elevating the head of the bed at least 45°. This is the ideal position. The procedure can be performed with the patient in the left lateral decubitus position if they cannot sit upright. The procedure can be performed with the patient supine if they are is endotracheally intubated.

Apply topical anesthetic spray to the nostrils and pharynx. Insert a nasogastric tube or an Ewald tube. Aspirate the stomach contents. Evacuate the stomach with tap-water lavage through the nasogastric tube (or Ewald tube), then remove the nasogastric tube.

Prepare the equipment. Flush the aspiration ports with air to ensure their patency. Inflate the balloons with the maximum recommended volume of air and check for leaks. It is advisable to inflate the balloons under water to look for small leaks. Connect the mercury manometer to the balloon ports and inflate the balloons to the recommended pressures and check for leaks. Completely

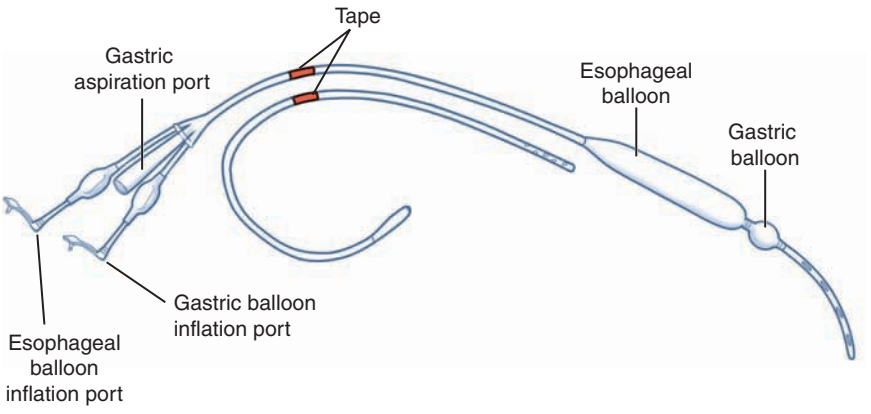

FIGURE 63-4. Preparing the nasogastric tube. Place the nasogastric tube alongside of the SB tube with the tip just above the esophageal balloon. Place tape on both tubes to mark a common point proximal to the 50 cm mark on the SB tube.

deflate the balloons. Record the manometric pressure of each balloon when it is deflated. Insert the plastic plugs in the balloon inflation ports or loosely clamp each port with a hemostat or rubber shod clamp.[10–12] Lubricate the SB tube with a water-soluble lubricant. Place the SB tube on a table. Position a nasogastric tube next to the SB tube so that the tip of the nasogastric tube is just above the esophageal balloon (**Figure 63-4**). Place a piece of tape on both tubes to mark a common point, proximal to the 50 cm mark of the SB tube, that will be outside of the patient. The nasogastric tube will be inserted after the SB tube is placed. Alternatively, position the tubes as above and tape both tubes together at two or three sites. This allows the nasogastric tube to be inserted simultaneously with the SB tube.

The SB tube may be inserted through the nose or through the mouth. The nasal route is more difficult to use and may be associated with a higher rate of complications. Despite this, many physicians recommend this route in the awake patient. The oral route is the preferred route of insertion by some physicians, especially if the patient is intubated. Apply topical anesthetic spray into the nasal cavity and oropharynx if the SB tube will be placed nasogastrically. Apply topical anesthetic spray into the oropharynx if the SB tube will be placed orally. Place a bite block in the patient's mouth if the SB tube will be placed orally to prevent the patient from biting the SB tube.

TECHNIQUE

Insert the lubricated SB tube until the 50 cm mark is located just outside the nares, or outside the teeth if inserted through the mouth. Flush the gastric aspiration port with air while auscultating over the epigastrium (**Figure 63-5**). A rush of air should be heard to ensure that the distal end of the SB tube is properly positioned within the stomach. If possible, confirm the position of the SB tube with portable plain radiographs or fluoroscopy. **It is imperative to know that the gastric balloon is within the stomach before it is inflated.** Apply suction to the gastric aspiration port.

Remove the rubber shod clamp and plastic plug from the gastric balloon inflation port. Connect the Y-adapter with a handheld or mercury manometer and a pressure bulb or a 50 mL syringe with a catheter tip to the gastric balloon inflation port (**Figure 63-6**). Measure the intragastric balloon pressure. **If the intragastric balloon pressure after intubation is 15 mmHg greater than that prior to the intubation, deflate the balloon, as it may be located within the esophagus.** Inflate the gastric balloon in increments with 50 to 100 mL boluses of air (**Figure 63-7**). **Deflate the balloon immediately if the patient experiences chest pain. This signifies that the gastric balloon is in the esophagus.** Clamp the gastric balloon inflation port when the gastric balloon is inflated initially with 200 to 250 mL of air. Gently pull the SB tube back until resistance is felt as the gastric balloon lodges against the gastroesophageal junction (**Figure 63-8**).

Apply slight tension to the SB tube to occlude the veins at the gastroesophageal junction. This tension must be maintained by one of several methods. Fix the upper end of the SB tube as it exits from the mouth or nose to the crossbar of a football helmet or a catcher's mask (**Figure 63-9**). Apply over-the-bed traction with a one pound weight. Alternatively, fix the upper end of the SB tube, if it emerges from the nostril, by a cuff of sponge rubber held in place by an adhesive tape band. Insert the nasogastric tube until the tape is at the level of the tape on the SB tube (**Figure 63-10**).

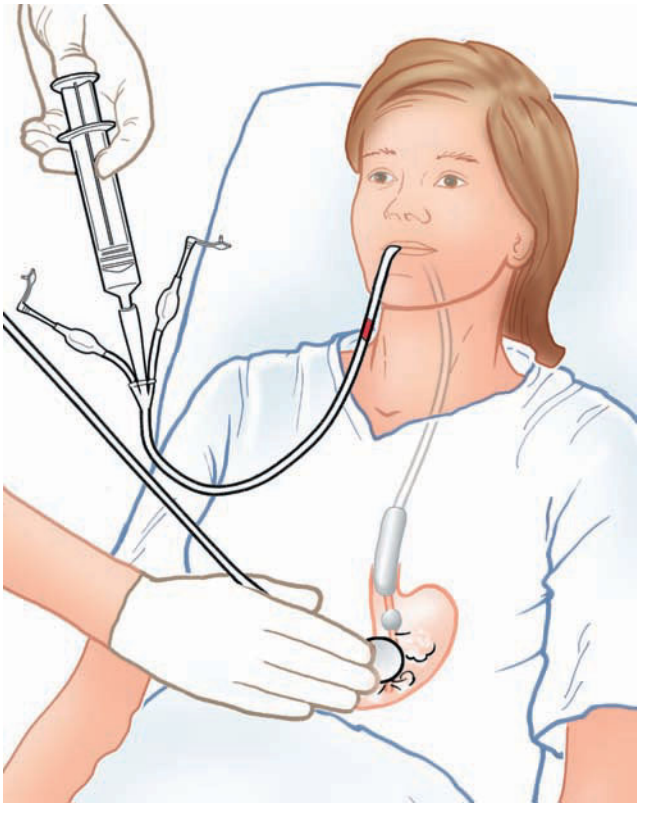

FIGURE 63-5. The SB tube has been inserted until the 50 cm mark is just outside the teeth. Inject 50 mL of air while auscultating over the epigastric area. A rush of air should be heard if the distal end of the SB tube is within the stomach.

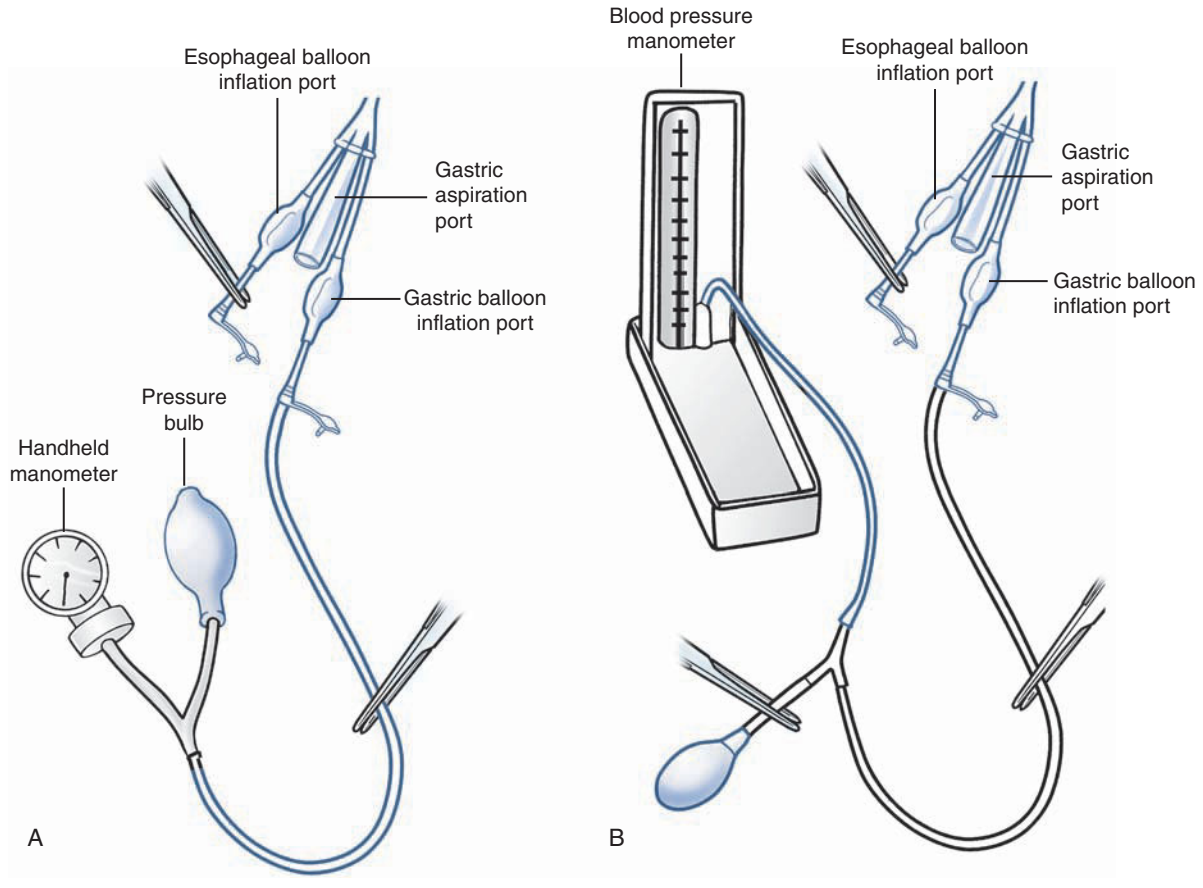

FIGURE 63-6. Connecting the handheld manometer (**A**) or mercury manometer (**B**) to the gastric aspiration port. A 50 mL syringe may be used if a handheld pressure bulb is not available.

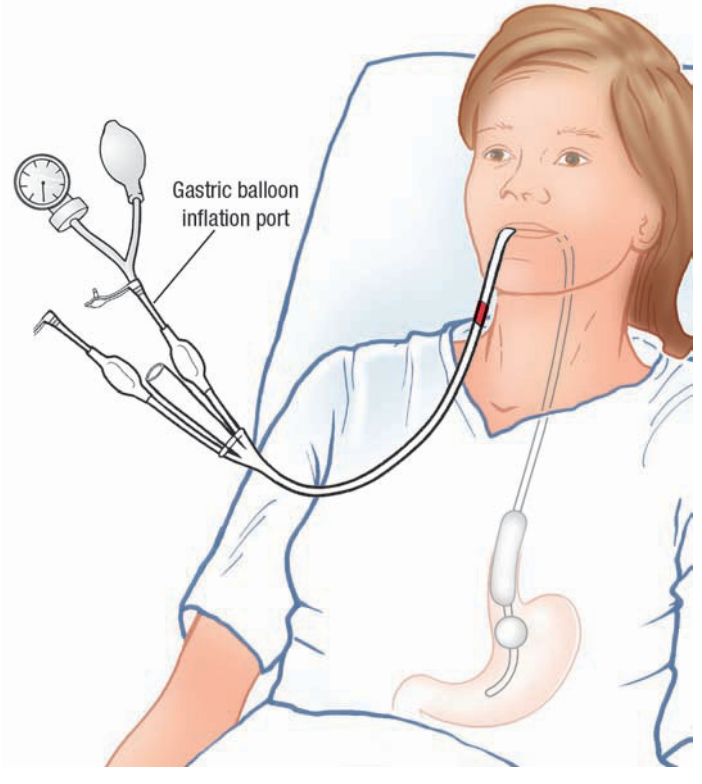

FIGURE 63-7. The gastric balloon is inflated with 50 to 100 mL increments of air to a volume of 250 to 300 mL.

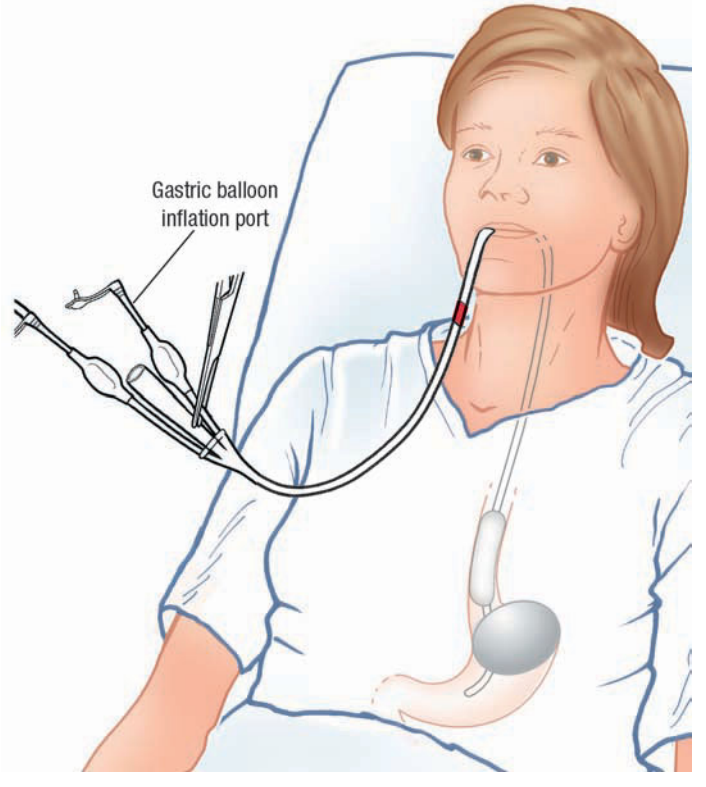

FIGURE 63-8. Tension is applied to the SB tube to lodge the gastric balloon against the gastroesophageal junction.

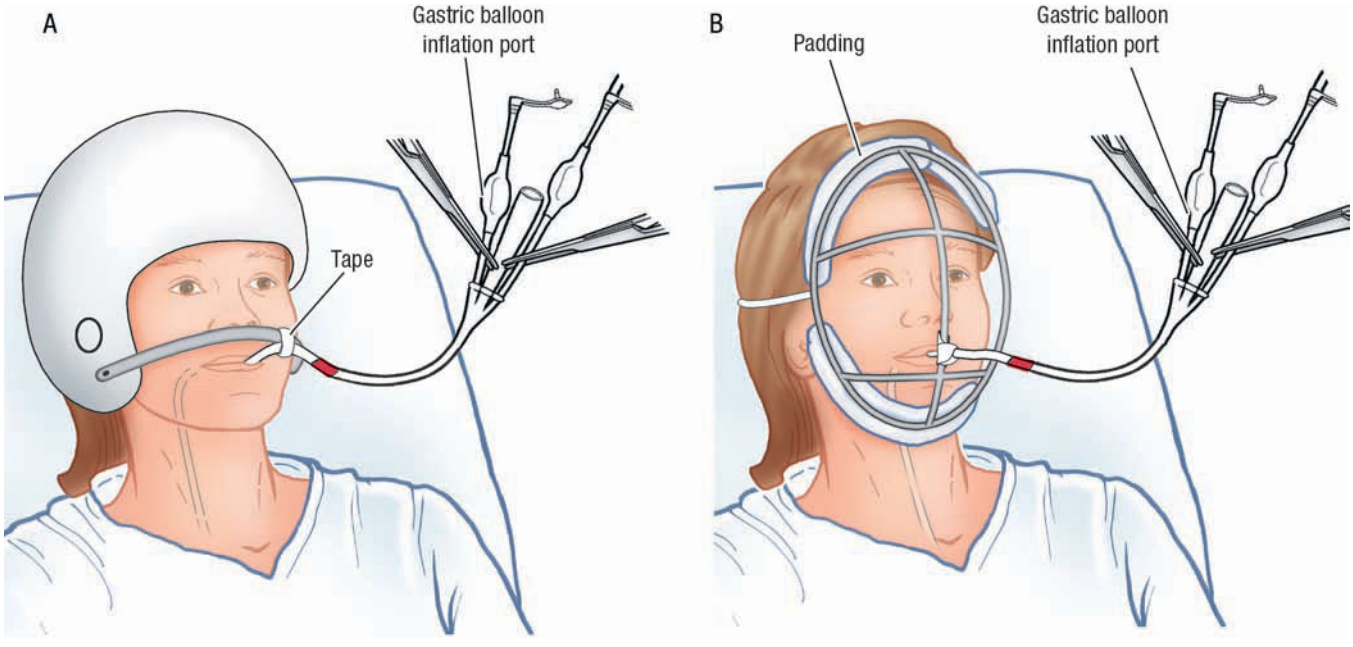

FIGURE 63-9. The SB tube is commonly secured to the faceguard of a football helmet (**A**) or to a catcher's mask (**B**).
